CITATION: In (Eds.) T. Fukawa-Connelly, N. Infante, M. Wawro, and S. Brown, Proceedings of the 19th Annual Conference on Research in Undergraduate Mathematics Education, Pittsburgh, Pennsylvania.

Foreword

As part of its on-going activities to foster research in undergraduate mathematics education and the dissemination of such research, the Special Interest Group of the Mathematical Association of America on Research in Undergraduate Mathematics Education (SIGMAA on RUME) held its nineteenth annual Conference on Research in Undergraduate Mathematics Education in Pittsburgh, Pennsylvania from February 25 - 27, 2016. The conference is a forum for researchers in collegiate mathematics education to share results of research addressing issues pertinent to the learning and teaching of undergraduate mathematics. The conference is organized around the following themes: results of current research, contemporary theoretical perspectives and research paradigms, and innovative methodologies and analytic approaches as they pertain to the study of undergraduate mathematics education. The program included plenary addresses by Dr. Sean Larsen, Dr. Peg Smith, and Dr. David Stinson and the presentation of over 160 contributed, preliminary, and theoretical research reports and posters.

The Proceedings of the 19th Annual Conference on Research in Undergraduate Mathematics Education are our record of the presentations given and it is our hope that they will serve both as a resource for future research, as our field continues to expand in its areas of interest, methodological approaches, theoretical frameworks, and analytical paradigms, and as a resource for faculty in mathematics departments, who wish to use research to inform mathematics instruction in the university classroom. The RUME COnference Proceedings include conference papers hat underwent a rigorous review by two or more reviewers. These papers represent current work in the field of undergraduate mathematics education and are elaborations of selected RUME Conference Reports.

The proceedings begin with the winner of the best paper award and the papers receiving honorable mention and the pre-journal award winner. These awards are bestowed upon papers that make a substantial contribution to the field in terms of raising new questions or providing significant or unique insights into existing research programs. RUME Conference Reports, includes the Poster Abstracts and the Contributed, Preliminary and Theoretical Research Reports that were presented at the conference and that underwent a rigorous review by at least three reviewers prior to the conference. Contributed Research Reports discuss completed research studies on undergraduate mathematics education and address findings from these studies, contemporary theoretical perspectives, and research paradigms. Preliminary Research Reports discuss ongoing and exploratory research studies of undergraduate mathematics education. Theoretical Research Reports describe new theo- retical perspectives and frameworks for research on undergraduate mathematics education. Poster Reports were quite varied and described curriculum, research and theoretical contributions.

The conference was hosted by West Virginia Univerisity. Their faculty and student provided many hours of volunteer work that made the conference possible and pleasurable, we greatly thank the faculty, students and institution for their support.

Last but not least, we wish to acknowledge the conference program committee and reviewers for their substantial contributions to RUME and our institutions, for their support, the conference would not exist without you.

Sincerely,

Tim Fukawa-Connelly, RUME Conference Chairperson

Nicole Engelke Infante, RUME Conference Local Organizer

Students' Meanings of a (Potentially) Powerful Tool for Generalizing in Combinatorics

Elise Lockwood Zackery Reed
Oregon State University

In this paper we provide two contrasting cases of student work on a series of combinatorial tasks that were designed to facilitate generalizing activity. These contrasting cases offer two different meanings (Thompson, 2013) that students had about what might externally appear to be the same tool – a general outcome structure that both students spontaneously developed. By examining the students' meanings, we see what made the tool more powerful for one student than the other and what aspects of his combinatorial reasoning and his ability to generalize prior work were efficacious. We conclude with implications and directions for further research.

Key Words: Combinatorics, Generalization, Counting problems, Mathematical meanings

Introduction and Motivation

Generalization is a fundamental mathematical activity with which students at all levels engage (Amit & Klass-Tsirulnikov, 2005; Lannin, 2005; Peirce, 1902), and yet there is still much to learn about ways to foster productive generalizing activity. In particular, most of the work on generalization has been with younger children, commonly in algebraic settings (Amit & Neria, 2008; Becker & Rivera, 2006; Cooper & Warren, 2008; Ellis, 2007b; Mulligan & Mitchelmore, 2009; Radford, 2006; Rivera, 2010; Steele, 2008). In the context of a larger study, we sought to better understand students' generalization in the domain of combinatorics which involves the solving of counting problems and provides students with opportunities to engage with accessible yet challenging tasks (e.g., Kapur, 1970; Tucker, 2002). In this paper, we compare and contrast two students' work on a series of combinatorial tasks, during which they each spontaneously introduced a potentially powerful tool for generalization in the combinatorial setting. Each of these students used this new tool, but they varied in the meaning they seemed to make it. As a result, they differed in how effective they were able to be in using the tool generally and solving combinatorial tasks. We seek to answer the following research question: *What meaning do students make of the same spontaneously generated tool (which we refer to as the 11xx structure), and what do these meanings suggest about students' generalization in combinatorial contexts?* The results in this paper help to inform research on students' meanings in the context of both their generalizing activity and their combinatorial thinking.

Literature Review and Theoretical Perspective

Generalization. The act of generalizing is a key aspect of students' mathematical development, and both mathematics education researchers (e.g., Amit & Klass-Tsirulnikov, 2005; Davydov, 1972/1990; Ellis, 2007b; Vygotsky, 1986) and policy makers emphasize its importance (the Common Core State Standards highlight generalization in both the content and the practice standards; Council of Chief state School Officers, 2010). We seek to extend the current work on generalization by focusing on undergraduate students in the context of combinatorics. The tasks were designed with the overall aim of facilitating students' generalizing activity, and for this purpose we follow Ellis (2007a) (who drew on Kaput, 1999) in defining generalization as "engaging in at least one of three activities: a) identifying commonality across cases, b) extending one's reasoning beyond the range in which it originated, or c) deriving broader results about new relationships from particular cases" (p. 444).

We also think of generalization as being closely tied to notions of abstraction laid out by Piaget, especially reflecting abstraction, which "projects and reorganizes, on another conceptual level, a coordination or pattern of the subject's own activities or operations" (von Glasersfeld, 1995, p. 105). We additionally consider generalization in terms of reflected abstraction, which "also involves patterns of activities or operations, but it includes the subject's awareness of what has been abstracted" (p. 105). Broadly, these terms and these notions of reflective abstraction frame the students' generalizing activity we describe in this study.

Combinatorial Reasoning. We chose the context of combinatorics in part to examine generalization in a novel context, but we were also motivated to contribute to previous work on students' combinatorial thinking. There is evidence that students struggle with solving counting problems correctly (e.g., Batanero, Navarro-Pelayo, & Godino, 1997; Hadar & Hadass, 1981), and we hope to contribute to the existing literature by providing instances of meaningful combinatorial reasoning that might ultimately inform instruction. More specifically, we use the idea of a set-oriented perspective (Lockwood, 2014), in which we view attending to sets of outcomes as an intrinsic component of solving counting problems. Other prior research has shown the value of focusing on sets of outcomes, including demonstrating that listing outcomes is positively correlated with correctly solving counting problems (Lockwood & Gibson, 2016) and that outcomes may help students avoid problematic issues in counting such as order and overcounting (e.g., Lockwood, 2013). In our current study, adopting such a perspective means that we value students' work with outcomes and feel that focusing students' attention on outcomes can be a productive way to help foster rich combinatorial meaning.

Students' Meanings. We draw on Thompson's (2013) notions of meanings in this paper. He argues for the importance of developing meaning of the idea of *meaning* (p. 57) and that a greater emphasis on mathematical meaning could contribute to a more coherent educational experience for students overall. Thompson surveys different meanings of "meaning," and we adopt his Piagetian view of meaning as assimilating a scheme (p. 60). Thompson notes that, "From a Piagetian viewpoint, to construct a meaning is to construct an understanding – a scheme, and to construct a scheme requires applying the same operation of thought repeatedly to understand situations being made meaningful by that scheme" (p. 61). Also, importantly, Thompson emphasizes meaning from the students' perspective:

> "The meanings that matter at the moment of interacting with the students are the meanings that students have, for it is their current meanings that constitute the framework within they operate and it is their personal meanings that we hope students will transform" (p. 62).

For this reason, in this paper we seek to understand and interpret students' meanings in order to gain insight about what made their work particularly productive (or unproductive) in the contrasting cases. We use this notion of meanings in this paper because we have a situation in which two students introduce and use a tool that externally seems very similar, but their respective meanings of that tool cause them to use it differently. We thus find it useful to discuss the variety of meanings students had about what appears to be a very similar mathematical phenomenon.

Methods

In this study we conducted a set of single, individual, hour-long interviews with nine calculus students as they worked through a series of tasks we call the Passwords Activity, and in this paper we report on two contrasting cases of students' work. We report on these students who had not been taught combinatorics formally at the college level, who we chose with the hope that we could capture their initial reasoning about accessible yet novel tasks. The main goal of the tasks was to put students in a situation in which we could evaluate their generalizing activity as well as gain insight into their combinatorial reasoning. We begin this section with a mathematical discussion of the tasks, and then we discuss the data analysis.

The Passwords Activity. By offering the trajectory of the Passwords Activity, we hope to highlight how the tasks serve to facilitate generalization in a combinatorial setting, and we also hope to prepare the reader for subsequent discussion of student work.

First, we had students solve the problem, *How many 3-character passwords can be made using the letters A and B?*, and we explicitly directed them to organize their work by completing tables according to the number of As in the password (Table 1).

Number of As	Number of Passwords
0	1
1	3
2	3
3	1

Table 1 – The 3-character A,B table

Students may fill out the entries in the table in a couple of ways. One possibility is simply to list the passwords for each row (or to read the respective numbers of passwords from a previously generated list). The patterns of the respective tables come up in subsequent work, (1, 3, 3, 1 for 3-character passwords, 1, 4, 6, 4, 1 for 4-character passwords, 1, 5, 10, 10, 5, 1 for 5-character passwords, etc.[1]), and students can use previously created tables in subsequent work to engage in both combinatorial reasoning and generalization. Although students need not be familiar with binomial coefficients to fill out these tables, another possible way of generating the table is to recognize that the entries in the rows of the table are binomial coefficients ($\binom{3}{k}$ for k = 0, 1, 2, 3). This is true because for a given number of As in a password, we may choose the positions in which the As will go. The placement of the As determines the password since there are only Bs remaining to fill the empty slots. Once students have completed the 3-character passwords problem, we have them repeat this process for passwords of length 4 and 5, generating Tables 2 and 3 below. There were some opportunities to observe generalization in building up these cases, as students could observe relationships and similarities among the tables or could make combinatorial observations that held across cases. We wanted the students to build (typically through partial or complete listing) the tables to see how they would use them as we progressed to the next part of the tasks.

[1] Again, we recognize that these numbers are rows in Pascal's Triangle, but pursuing the relationship with Pascal's Triangle is not our goal.

[2] We did not push him on this or investigate his understanding of the multiplication principle. This is a potentially important aspect of his combinatorial reasoning and his generalizing activity, but it is tangential to the focus of this

Number of As	Number of Passwords
0	1
1	4
2	6
3	4
4	1

Table 2 – The 4-character A,B table

Number of As	Number of Passwords
0	1
1	5
2	10
3	10
4	5
5	1

Table 3 – The 5-character A,B table

Then, we can have students move on to passwords involving the number 1, and the letters A and B. We had students make tables for 3-character and 4-character passwords, organized according to the number of 1s in the passwords (the 4-character A,B,1 table is in Table 5). Note that we can use the previous tables in the following way: we can think first of determining positions for the 1s (which the previous A,B table provides), and then the problem is reduced to counting passwords involving only As and Bs. For example, in making a table for the number of 4-character passwords with 1, A, and B, for each respective row of the table (0, 1, 2, 3, or 4 1s), we can first think of counting the number of ways of placing the 1s. There are 1, 4, 6, 4, 1 respective ways of doing this, which is reflected in the previous 4-character A,B table. The reason these numbers are the same is that there are the same number of placing, say, two As in a 4-character password as there are to place two 1s. Once this is established, note that for each row in the table, once the ones are placed it is just a matter of counting passwords of length 3 using only As and Bs, reducing the problem to a previous problem (specifically, there are 2^3 such passwords).

Number of 1s	Number of Passwords
0	$1 \cdot 2^4$
1	$4 \cdot 2^3$
2	$6 \cdot 2^2$
3	$4 \cdot 2^1$
4	$1 \cdot 2^0$

Table 5 – The 4-character A,B,1 table

The point is that it is possible, with some combinatorial insight and understanding of the outcomes' structure, to leverage the previous work from the A,B passwords in the more complicated A,B,1 passwords case. Again, in this case if the students do not yet have a formula for binomial coefficients, they can still engage with the task and engage in generalization. They can look back at tables created for 3, 4, or 5-character A,B passwords and use those numerical results for the first stage in the counting process. They can also recognize that for any of the positions that are not 1s, they are simply creating A,B passwords, and again they can leverage previous results to complete current tables.

In order to see the motivation for this set of tasks, and to see where the tasks could ultimately lead, we describe further stages of the task that involve passwords with multiple letters and multiple numbers (although most students did not proceed beyond A,B,1 passwords). We consider one particular example of 5-character passwords consisting of the letters A, B, or C, and the numbers 1 or 2, which we call 5-character A,B,C,1,2 passwords. As before, students could count the total number of such passwords in two ways – first by simply computing the total by arguing about the number of choices for each position, and second by making a table, this time according to number of numbers. There are 5^5 total passwords, because there are five choices (3 letters and 2 numbers) for each of the five positions. The table can be filled out as in Table 6.

Number of Numbers	Number of Passwords
0	$1 \cdot 2^5 \cdot 3^0$
1	$5 \cdot 2^4 \cdot 3^1$
2	$10 \cdot 2^3 \cdot 3^2$
3	$10 \cdot 2^2 \cdot 3^3$
4	$5 \cdot 2^1 \cdot 3^4$
5	$1 \cdot 2^0 \cdot 3^5$

Table 6 - A 5-character A,B,C,1,2 table

To justify the table entries, let us consider one of the rows – the fourth row that counts the 5-character A,B,C,1,2 passwords that have exactly 3 numbers. We can first select places that will be numbers (there are $\binom{5}{3}$ ways to do this, which is 10), and then we can fill in each of those number places with either 1 or 2, giving us 2^3. Then we know that the remaining two positions must be letters, and there are 3^2 ways to filling those positions with A, B, and/or C. The same line of reasoning holds for any of the rows, and summing the rows (which count disjoint cases of how many numbers are in the passwords) yields the total number of passwords.

This line of reasoning can be extended to a general case of counting n-length passwords consisting of x numbers and y letters. In this way, we achieve a general statement of the binomial theorem, which is the potential culmination of the Passwords Activity:

$$(x+y)^n = \sum_{k=0}^{n} \binom{n}{k} x^k y^{n-k} .$$

We had only one student made it to the end of this sequence of tasks (he was a more advanced student is not discussed in this paper), but engagement with the activity still served to facilitate combinatorial reasoning and generalizing activity among all of the students.

Data Analysis. The interviews were videotaped and transcribed, and overall the videos and transcripts were analyzed so as to construct a narrative about the teaching experiment (Auerbach & Silverstein, 2003). We discussed the two contrasting cases with the entire research team and together formulated hypotheses about the students' meaning in each case via repeated viewings of video and reading of enhanced transcripts. In particular, we looked for instances in which students' generated the certain tool (the *11xx* structure described below) and discussed and analyzed what caused students to interact with and use the tool in different ways.

Results

In presenting our results, we describe two different students' meanings of the same phenomenon. We highlight these results both to show an interesting phenomenon that emphasizes a potentially powerful tool toward meaningful combinatorial generalization and to suggest that ascribing certain meanings to such tools may help students leverage them in impactful ways. In this section we describe their work and present the major findings, and we compare and contrast the students' work in the Discussion section.

Example 1 – Tyler. We begin with Tyler, who demonstrated an ability to reason comfortably and easily with outcomes. His method of solving the tasks typically involved some organized listing. For example, in trying to determine the number of 4-character A,B passwords with exactly two As, Tyler made the list in Figure 1 and gave the following explanation:

Tyler: Um. Yeah I guess I started with the first one being A um, and then I did like 2 A's consecutively and then B's, and then moved the B over one, and then, um, moved the next B over one… And then, after that I just start with the B and kind of did the same thing.

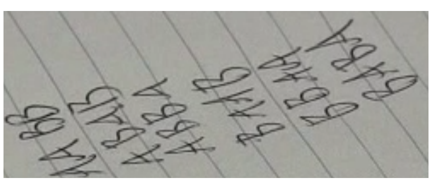

Figure 1

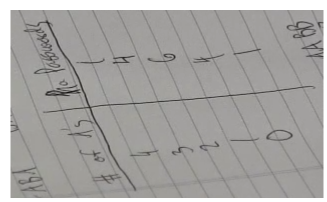

Figure 2

He ultimately correctly created the table for 3, 4 (Figure 2), and 5-character AB passwords. Here we highlight Tyler's willingness and ability to engage with organized listing activity in creating the tables, which suggests to us that he attended to outcomes.

Early in the interview, Tyler had established that there were a total of 2^n n-length passwords using only As and Bs. He established this primarily through noticing a numerical correlation after giving the totals for 3, 4, and 5-length passwords, read from his empirical tables (noticing the 3-character AB passwords table had 1+3+3+1 = 8 total passwords). He went on to write the relationship "*n length = 2^n combos*," but we suspect that he did not meaningfully understand the multiplication principle as a combinatorial way of explaining the expression 2^n.[2]

We then moved on to counting passwords that consist of characters 1, A, or B. Tyler felt that there was more to keep track of, but he persisted with listing outcomes and filling out the table as he had in the previous situations. He managed to list the entire table for the 3-character A,B,1 passwords, and again he used systematic listing used to do so, and he seemed to maintain a combinatorial understanding of the entries in his tables.

[2] We did not push him on this or investigate his understanding of the multiplication principle. This is a potentially important aspect of his combinatorial reasoning and his generalizing activity, but it is tangential to the focus of this paper and thus we do not address it here.

Next, we asked him with to fill out a table with the four-character A,B,1 passwords (organized according to number of 1s). He got started but paused and said, "I can't really think of any pattern," and he seemed to realize that this table would be more difficult to work out than the previous case. We directed him to perhaps start thinking about the rows for zero and one 1's (starting from that end of the table). Tyler then did something unexpected – he introduced a way of describing a general outcome involving 1s and *x*s. Specifically, he wrote out four general outcomes 1*xxx, x*1*xx, xx*1*x*, and *xxx*1 (Figure 3), and he used that reasoning to fill out the table he was working on. He discussed his reasoning in the following exchange, and we highlight that he referred back to his 4-character A,B table in Figure 4.

Tyler: *Yeah. Ok so the 0 [row] was gonna be, what did I come up with here [refers back to the 4-character AB table] 10, 15, 16 if uses, um. And then the 1, so what I was thinking, what I was saying earlier. How there is only a certain amount of spots for it, like it has to be, like I'm just gonna use x cause, um, has to be in one of these spots... [draws Figure 3]*

Int.: *Great.*

Tyler: *So there's, now there's just 3 x's um, and I know that for…3 spots with 2 different letters there's going to be 8 different ways to do it [points back to the previous 3-character AB table, see Figure 4]…Um so I guess 8…there's 8 different of each of those just using this same table umm, there's just 32 so I want to say there's gonna be, um, 32 for just the 1.*

Int.: *Okay and you got, you're thinking of that as kind of the 4 times 8?*

Tyler: *Yeah I, just adding them all up.*

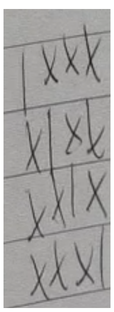

Figure 3

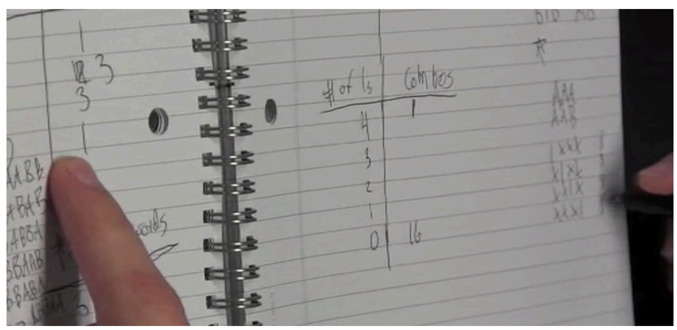

Figure 4

This was a key moment in Tyler's work. He spontaneously introduced a very powerful tool for how to count desirable passwords in the form of a general structure consisting of *x*s and 1s. (For ease of communication, we hereafter refer to the tool as "the *11xx* structure," which is meant to suggest the introduction of the variable of x as a means of representing a more general outcome.) We contend that this was a general representation of an outcome (a password), perhaps a product of his rich facility with listing. He realized that in each case where there was a 1 with three *x*s, there would be 8 such possibilities (because there were 8 total 3-character A,B passwords), and his total would be 32. He was thus able to recognize that he could use his previous case as a part of the more complicated new situation. We can further explore this moment of insight as he continued to use the *11xx* structure in filling out the rest of the 40-character A,B,1 table. Figure 5 shows his listing of x's and 1's in the four-character A,B,1 case, with exactly two 1's. There are exactly 6 of them, and the following exchange demonstrates Tyler's meaning of those six general outcomes as they relate back to his previous work. Specifically, note that he understands why 6 such outcomes would make sense, because he can understand that he is in a situation of arranging two distinct objects, which is what his previous work involving A,B passwords also entailed. He continued to work in a similar fashion for the case of three 1s, and he ultimately arrived at the correct table for 4-character A,B,1 passwords (Figure 6).

Tyler: *Yeah there you go. Is that all of them? Yeah so 6, 'cause that would make sense...*
Int.: *Does that 6 make sense?*
Tyler: *Does it? Uh, well that would that's um, 2 variables like instead of doing 3 things there's 2 umm, with the 4 combo, so 2, was 6 over here [points back to the 6 in the correct entry of the 4 character AB password table], so that's why I thought it made sense.*

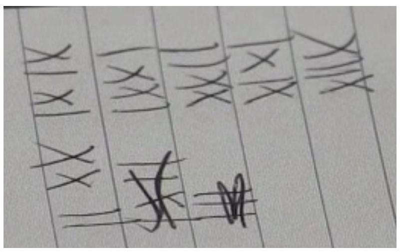

Figure 5

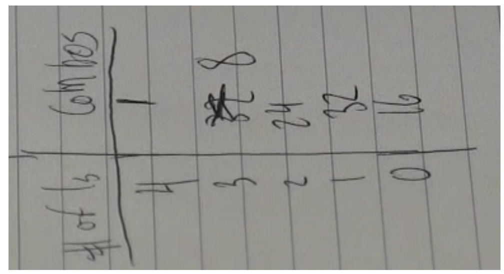

Figure 6

Tyler went on to use the same tool in subsequent cases involving 5-character A,B,1 passwords. Although we do not have space to detail all of his subsequent work, we provide one excerpt to highlight another important aspect of his activity. Specifically, we asked Tyler about creating another table of A,B,1 passwords that are 5 characters long. In the following excerpt he indicates that he would use the previous table that involved the coefficients 1, 5, 10, 10, 5, 1. In the underlined portion of the following excerpt we see that Tyler can think of the A,B,1 and the A,B situations as fundamentally similar because they are both involving combinations of two "things that are changing." We will argue that this is an important aspect of his productive generalizing activity. Tyler seemed to have a robust understanding of how he could use the tool to solve password problems involving more characters and more letters. And, more importantly, he was able to recognize two situations as being "the same."

Int.: *Um, what if I asked, so this same question like one 1, 10 letters but now a length 5 password. Like, what would the total number be?*
Tyler: *Um, I would use 1, 5, 10, 10, 5, 1.*
…
Int.: *And why did you go to that 1, 5, 10, 10, 5, 1…*
Tyler: *Um well these are all the number of combinations I can do, um, with 2 different, 2 things that are changing and this number of letters.*

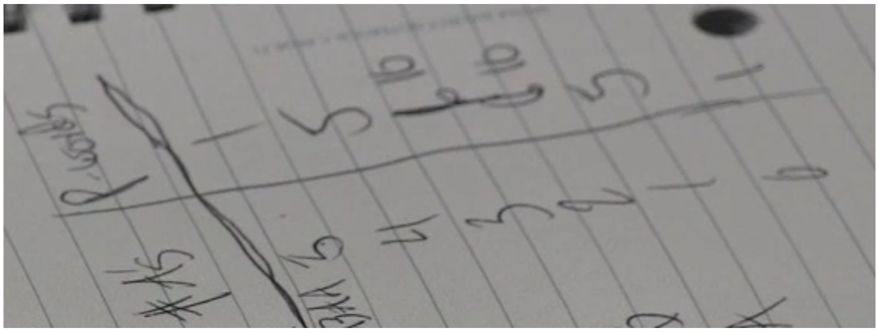

Figure 8

We point out a couple of important features of Tyler's work. First, it is noteworthy that Tyler spontaneously introduced a new, general structure that appropriately represented the situation and the outcomes he was trying to count. This is in and of itself impressive, and his work demonstrates an existence proof of the kind of thinking the Password Activity fostered in terms of combinatorial generalization. Second, Tyler was able to relate that new structure to his combinatorial activity to that point, and this relationship to prior work played a key role in him ultimately being able to solve more problems correctly. Importantly, he seemed to preserve the combinatorial meaning of the tasks and the situations as he related the *11xx* structure with his previous work. In terms of Tyler's meanings, we interpret that he understood the *11xx* structure as a general structure of the outcomes he had been working with, allowing him to relate back to a previous combinatorial situation involving just two objects (specifically, As and Bs). Although he did not demonstrate a deep combinatorial, multiplicative meaning of 2^n, he could recognize the 2^n as being numerically equivalent to a previous case, which he used effectively.

Example 2 – Richie. We now contrast Tyler's work with another calculus student, Richie. Richie, too, spontaneously introduced the *11xx* structure, but we highlight a key difference in that Richie was less successful in leveraging the new tool by relating it to previous circumstances. When making the tables for the A,B passwords tasks, Richie correctly filled out the tables, often using some listing, but it seemed as though he was more attuned to the numerical patterns he observed than in finding a combinatorial explanation that made sense. For example, when making a table for the 5-characer A,B passwords, we had the following exchange. Notice that his justification for why certain entries were in the table was based on the patterns he'd observed. This is not in and of itself problematic, but it shows perhaps that he was not establishing a robust combinatorial meaning but that his meaning was based on observed numerical regularity.

Richie: *So when you get to like the -- the second one, or it's not even like the second one, it's more like the one in the middle of 0 and 5 is going to be the most possibilities. And in previous problems it's been like 2 more than the preceding one.*
Int.: *Okay. Sure.*
Richie: *And I'm just assuming that this is 5, because the previous pattern's like increasing by 1.*

When we moved on to the A,B,1 passwords case, Richie, like Tyler, spontaneously moved toward a new structure involving 1s and *x*s. Figure 9 shows his drawing of the six ways to arrange two 1s and two *x*s. Again, it was somewhat surprising and impressive to us that a student independently generated this general outcome structure.

Richie: *I'm just trying to think of all the different configurations – that 1s can [inaudible] – so like they can be starting with x, or just like that. Or like this or like this. Or like this. And then it could be 1 inside.*

Int.: *Perfect.*

Richie: *So, 1, 2, 3, 4, 5, 6. There's 6 different possibilities for that. And then each of these can have 4 different configurations.*

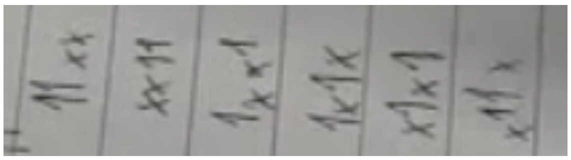

Figure 9

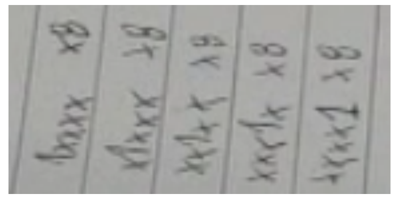

Figure 10

Richie then checked his work and reasoned that for each of those possibilities there would be four possibilities, running through BB, AA, AB, and BA. He concluded, "So 6 times 4 would be – it would be like 6 times all of these really [referring to the six configurations]…Yeah, okay. So I guess they would be 24. So it would be 24 possibilities." Richie then continued to work, and as he progressed to other rows in the table he made more diagrams involving 1s and *x*s.

We then had him move to the 5-character 1, A, B password, and I asked him to start making the table. Here again he made a similar diagram with 1's and x's, but here his work departed from Tyler's. Richie was able to think about there being a certain number of options for each case (each arrangement of the x's), and he knew there were two options for each *x* (A and B), but he added instead of multiplied the number of options, yielding 8 rather than 16 possibilities.

Richie: *So for 5 it would be 32. Same thing. And then for 1 there would be – (writes Figure 8 without the *8's) and so those would each have – this could be A or B, so that would be 2 for that, 2 for that, 2 for that, so these would each have 8 different possibilities [writes the *8's in Figure 8]. So it would be 5 – 5 times – it would be 40 for 1.*

In asking Richie to explain this work, we gain insight into his meaning of the diagram. He made no explicit connection to the previous tables or situations as Tyler had.

Richie: *This, like I made I want to say like a diagram basically of a position so 1 can be. And then I put Xs in for the – where the As and Bs could be, because those are variables that can be either A or B. And then I noticed that for every X it has 2 possibilities, either being A or B, and there's 4 Xs…So then I just multiply that by 2 to get 8. So each – for each 1 position there's 8 different possibilities for the password. And that's how I got 40.*

Richie continued his work and listed out all 10 of the configurations of two ones in a 5-character password. He demonstrated a consistent meaning by again adding the options – saying there were 6 passwords for each configuration, which is 2*3 rather than $2^3 = 8$. At first blush it seems that perhaps Richie simply made a mistake, adding instead of multiplying the options, but we do not feel that he simply made a numerical error. Rather, the evidence seems to point to the fact that he did not make meaning of the new structure as being related to the previous case, at least not directly to the previous tables. Unlike Tyler, he did not recognize that the power of the

11xx structure is that it can be very clearly related to the previous situation. There are two potential points of connection to the prior A,B tables (relating the placement of the 's to the rows of the AB tables, such as 1, 4, 6, 4, 1, and realizing the totals in the previous tables represent the possible number of passwords of a given length), both of which Tyler recognized, and neither of which Richie recognized.

This is not to say that Richie's meanings were unreasonable or that they did not make sense to him – indeed they did. His introduction of the *11xx* structure seemed to serve as a way of simplifying and organizing the problem so he could better break it down, but not in a way that facilitated rich connections to the previous problem. Indeed, we asked him how and why he came up with the structure, and he suggested that he was motivated by efficiency: "I started to write here different configurations for where the 1s could be and where the Bs and As could be, and I noticed that basically the As and Bs were just switching places for wherever the amount of 1s were. So I started putting *x*s there just so I wouldn't have to write as much." Thus, while Richie was motivated by the efficiency, which is justifiable, he did not realize that he could leverage his previous work in order to take full advantage of the tool he had developed.

Discussion

In this section we compare and contrast Tyler and Richie's work, highlighting some salient similarities and differences. We feel that our results offer a theoretical contribution to the research on generalization (by introducing a notion of *recursive embedding*), and we also connect these findings to students' combinatorial reasoning.

First, we highlight what was similar in Tyler and Richie's work. It is noteworthy that they both came up with the *11xx* structure, spontaneously and independently. This tool seemed to be motivated by efficiency for both of them, which suggests that efficiency may be an effective pedagogical idea for facilitating generalization. Also, their generation of this tool suggests a solid fluency with outcomes, which affirms combinatorial research that emphasizes the importance of students' set-oriented perspectives toward counting (e.g., Lockwood, 2013; 2014). Finally, both Tyler and Richie seemed to understand that there were a certain number of passwords "for each" *11xx* outcome they could write. While they used this idea differently (with Tyler using it correctly and Richie incorrectly), this suggests perhaps that they had at least some informal but accurate notion of the multiplication principle in this particular instance.

What, then, set these students apart in their abilities to more (and less) effectively leverage their *11xx* tool? We argue that there are two key differences that explain this phenomenon, and they each have implications in terms of generalization and in terms of combinatorial reasoning. First, Tyler engaged in what we call *recursive embedding*, and second Tyler was able to view AABB and 11xx as essentially "the same" – simply arrangements of two kinds of objects. We describe each of these below.

Recursive embedding. By recursive embedding, we mean that Tyler reflected on prior activity and applied that activity (not just the results of that activity) into a new situation. Specifically, recognized the *x*s in the *11xx* structure in the A,B,1 situation as representing placeholders into which he could embed a previous situation (A,B passwords, for example). Figure 11 demonstrates what we interpret to be involved in recursive embedding in Tyler's work. Note that the *x*s in the problem are replaced with AB passwords, and the prior work is used productively in a new situation.

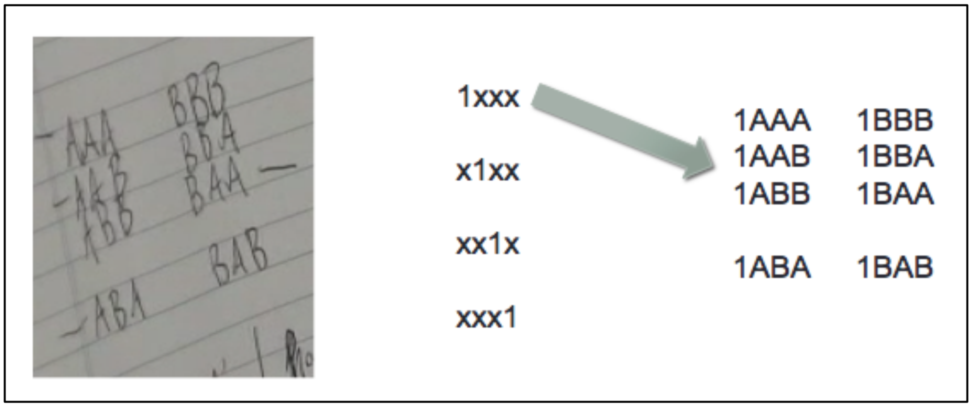

Figure 11

Viewing two combinatorial situations as similar. Another important aspect of Tyler's work is that he was able to recognize similarities between two situations in a way that Richie did not seem to observe. Specifically, Tyler extrapolated a similarity between arranging AABB and 11*xx*, as he recognized that ultimately he was just rearranging two kinds of things – it didn't matter if they are As and Bs or 1s and *x*s. This was a key element of him being able to connect back to prior work and to successfully leverage the *11xx* structure.

In sum, Tyler's activity of recursive embedding and of recognizing key situations as similar has important implications for generalization. In particular, his activity suggests an instance of generalization that is based in reflective abstraction. By embedding results of his prior activity into a new situation, Tyler is projecting and reorganizing, "on another conceptual level, a coordination or pattern of [his] own activities or operations" (von Glasersfelt, 1995, p. 105). This underscores that Tyler's powerful generalization is rooted in reflective abstraction, and it also suggests that fostering reflective abstraction may be a key aspect of helping students to engage in meaningful and effective generalizing activity.

Conclusion and Implications

By examining two students' meanings of the same tool that they each spontaneously developed, we gain insight both into students' generalizing activity and their combinatorial reasoning. Ultimately, we want to help students be more effective in creating productive generalizations, and we want to learn more about how students might effectively solve counting problems. We feel that Tyler's work – not only his production of the *11xx* structure but also his ability to make meaning of it in light of prior activity – is a powerful example of a student-generated general structure that led to progress in challenging combinatorial tasks. Set in contrast to Richie's work (which was also impressive in that he generated the *11xx* structure, but was limited in its lack of combinatorial meaning and connection to the previous situations), we can examine what aspects of Tyler's work and meanings were so efficacious.

The contrasting cases of *11xx* structure shed some light on generalization. We see that the desire for efficiency may motivate generalization, and that reflection on prior activity (and the ability to use that prior activity) was a distinguishing feature of Tyler's work. Specifically, recursive embedding and viewing AABB and 11*xx* as the same were aspects of his activity that facilitated effective generalization. Tyler's case provides an encouraging example of what might be attained through reflective abstraction.

Combinatorially, this is an example of the kind of thinking we want to foster. Tyler's association of AABB and 11*xx* as being the same is hugely important for productive combinatorial reasoning, as we want students to be able to draw out some structure that is not dependent on particulars. The *structure* of the outcome seems to be important to facilitate this association and connection. Indeed, one aspect of his work that was powerful was that he remained grounded in his prior activity, and he had a rich combinatorial meaning of those prior situations. The AB tables Tyler made were combinatorially meaningful for him, in the sense that he reasoned about outcomes and did not lose sight of the combinatorial context. This is in line with previous work that emphasizes the importance of outcomes (e.g., Lockwood, 2013; 2014). We suspect that because Tyler had such a strong sense of outcomes (as seen through his listing activity in his creation of AB tables), the *11xx* structure really did represent to him a more general form of an outcome. It resembled a password (still a sequence of characters on the page), and we posit that this enabled him to maintain his reasoning about the structure of his outcomes and thus a connection to the previous combinatorial situation.

In terms of implications, our findings suggest that students can, on their own, produce potentially powerful tools involving general structures. However, this alone is not sufficient for productive generalizing or counting activity, and these contrasting cases show some of the other reasoning necessary to make full use of such tools. A pedagogical implication is that teachers may need to be vigilant in helping students maintain contact their with their prior activity, as reflecting on one's prior activity seems to be a potentially productive way to facilitate generalization. To engender productive generalizations, we may direct students to reflect on their prior work by having them make explicit connections and statements of similarity or by answering meta-cognitive questions about their activity.

Specifically, in combinatorics this might mean that even as students notice patterns, teachers should help them to connect those patterns to the combinatorial context and not simply to numerical regularity. Combinatorially, another implication of the work is that this sequence of tasks does seem to be potentially useful in helping students to reason about the binomial theorem (or at least its initial stages). Tasks like these could be leveraged to introduce and teach combinatorial identities, which is a building block toward the learning of combinatorial proof.

Our findings show an example of rich generalizing activity in a combinatorial context. These findings emerged in a single interview, but we hope to extend this work through teaching experiments in which students' meanings can be developed and examined over time. Next research steps also include an investigation into more specific instructional interventions that might foster the kind of meanings that proved beneficial for students like Tyler.

Graphing habits: "I just don't like that"

Kevin C. Moore, U. of Georgia
Irma E. Stevens, U. of Georgia
Teo Paoletti, Montclair State U.
Natalie L. F. Hobson, U. of Georgia

We report on clinical interviews to describe U.S. undergraduate students' ways of thinking for graphs as representations of measurable attributes of dynamic situations (e.g., a road trip or an amusement park ride). In particular, we describe students' actions that we interpret to be habitual to their uses of graphs. By habits, we refer to specific schemes and actions constituting students' ways of thinking through which they routinely assimilate their graphing activity. Some habits were problematic in that they inhibited the students' abilities to represent covariational relationships they had conceived to constitute some dynamic situation. For example, we illustrate that some students' ways of thinking for graphs resulted in their experiencing perturbations if neither quantity's value increased or decreased monotonically.

Keywords: Graphing, Covariational Reasoning, Quantitative Reasoning, Cognition, Function

Researchers have persistently suggested that educators take seriously students' graphing activities given the difficulties students have with topics (e.g., function and rate of change) that involve the significant use of graphs (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Johnson, 2012; Thompson, 1994). More pointedly, researchers have illustrated that student difficulties in mathematics relate to students having impoverished experiences reasoning covariationally (Carlson, 1998; Oehrtman, Carlson, & Thompson, 2008; Thompson & Carlson, in press). We respond to the need to better understand students' covariational reasoning by describing undergraduate students' ways of thinking for graphs relative to the extent that they were productive when constructing graphs to represent measurable attributes of a dynamic situation. Specifically, we characterize two categories of students' ways of thinking for graphs. We contend that some students' ways of thinking for graphs entailed habits based in *figurative thought* (Piaget, 2001) that often inhibited their representing a covariational relationship that they conceived to constitute some situation. In contrast, we describe students' ways of thinking for graphs based in *operative thought* (Piaget, 2001), in which students exhibited a sustained focus on coordinating quantities' magnitudes when constructing a graph with figurative aspects of the trace being subordinate to this coordination.

Covariational Reasoning, Magnitudes, and Shape Thinking

Covariational reasoning is "the cognitive activities involved in coordinating two varying quantities while attending to the ways in which they change in relation to each other" (Carlson et al., 2002, p. 354). Whereas some researchers have described covariational reasoning in terms of patterns in successive, corresponding *numerical values* of two sets (see Confrey & Smith, 1995), our approach to covariation adopts Thompson's (2011) description of *quantity*. Thompson (2011) described quantity as an attribute a person conceives to constitute some situation such that the person understands and anticipates the attribute as having a measurable *magnitude* (i.e., amount-ness).[1] We draw attention to Thompson's distinction between a quantity's magnitude

[1] We point the reader to Steffe and Olive (2010) and Thompson, Carlson, Byerley, and Hatfield (2014) for detailed characterizations of different conceptualizations of magnitudes.

and a quantity's measure (or value) because it enables us to describe a person's covariational reasoning in terms of her simultaneously coordinating (continuous) magnitudes in flux (Saldanha & Thompson, 1998). For instance, in a situation involving two corresponding lengths, a person can imagine two lengths in flux while *anticipating* that these lengths have specific measures (with an associated unit) at any instantiation of the covariation.

We do not intend our focus on the covariation of magnitudes to diminish the importance of reasoning with specified measures and patterns. Such reasoning is important for the construction of function classes, quantification of rate of change, and reasoning about limits (see Confrey & Smith, 1995; Ellis, Özgür, Kulow, Williams, & Amidon, 2015; Johnson, 2015; Oehrtman, 2008). Approaching covariation in terms of coordinating magnitudes, however, provides a complementary focus that researchers have found useful in characterizing how students might construct images of covariation that are productive for their reasoning about relationships between quantities in ways not confined to, but instead working in tandem with, reasoning about specified measures (see Carlson et al., 2002; Thompson, 1994, 2011).

Extending the aforementioned research on covariational reasoning, Moore and Thompson (2015) characterized students' *static shape thinking* and *emergent shape thinking*. The authors described that a student engaging in static shape thinking operates on a graph as an object in and of itself (i.e., graph-as-wire), basing her actions on perceptual cues and the physical features of a graph. Moore and Thompson (2015) provided an example of a student's static shape thinking in the form of a student associating rate of change or slope with properties of direction (e.g., a student reasoning that a graph of $y = 3x$ unquestionably implies a line sloping upward left-to-right regardless of coordinate system or orientation). In contrast to a student assimilating a graph as an object in and of itself, Moore and Thompson (2015) characterized that a student engaging in emergent shape thinking conceptualizes a graph as a locus or trace that is produced by coordinating two quantities' magnitudes simultaneously. They explained, "emergent shape thinking entails assimilating a graph as a trace in progress (or envisioning an already produced graph in terms of replaying its emergence), with the trace being a record of the relationship between covarying quantities" (Moore & Thompson, 2015, p. 785). Although this way of thinking requires conveying magnitudes in flux, we provide instantiations of covariation in Figure 1 that are associated with Part II of the task in Figure 2 to illustrate this way of thinking.

A person thinking emergently in response to *GAG Part II* [2] might proceed as follows:

(1) The person conceives that the car starts at a magnitude of zero from Atlanta ($||Y|| = 0$) and some non-zero magnitude from Gainesville ($||X|| > 0$). The person represents these attributes by plotting a point that simultaneously represents both magnitudes (Figure 1a).
(2) The person conceives that, over the first portion of the trip, for any particular magnitude increase in the distance from Atlanta, the car's distance from Gainesville simultaneously decreases by that magnitude (i.e. $|\Delta||X||| = |\Delta||Y|||$). The person conceives the distance from Atlanta increases at a constant rate as the car's distance from Gainesville decreases.
(3) The person represents the relationship constructed in (2) by constructing and imagining two magnitudes covarying along the axes in a way that maintains (2), with a point moving correspondingly to represent simultaneously both magnitudes (Figure 1b-1d).
(4) The person imagines the point leaving a trace representing all instantiated pairs of covarying magnitudes (Figure 1e).
(5) And so on (Figure 1f).

[2] *GAG* is a modification (see Task Design) of Saldanha and Thompson's (1998) task.

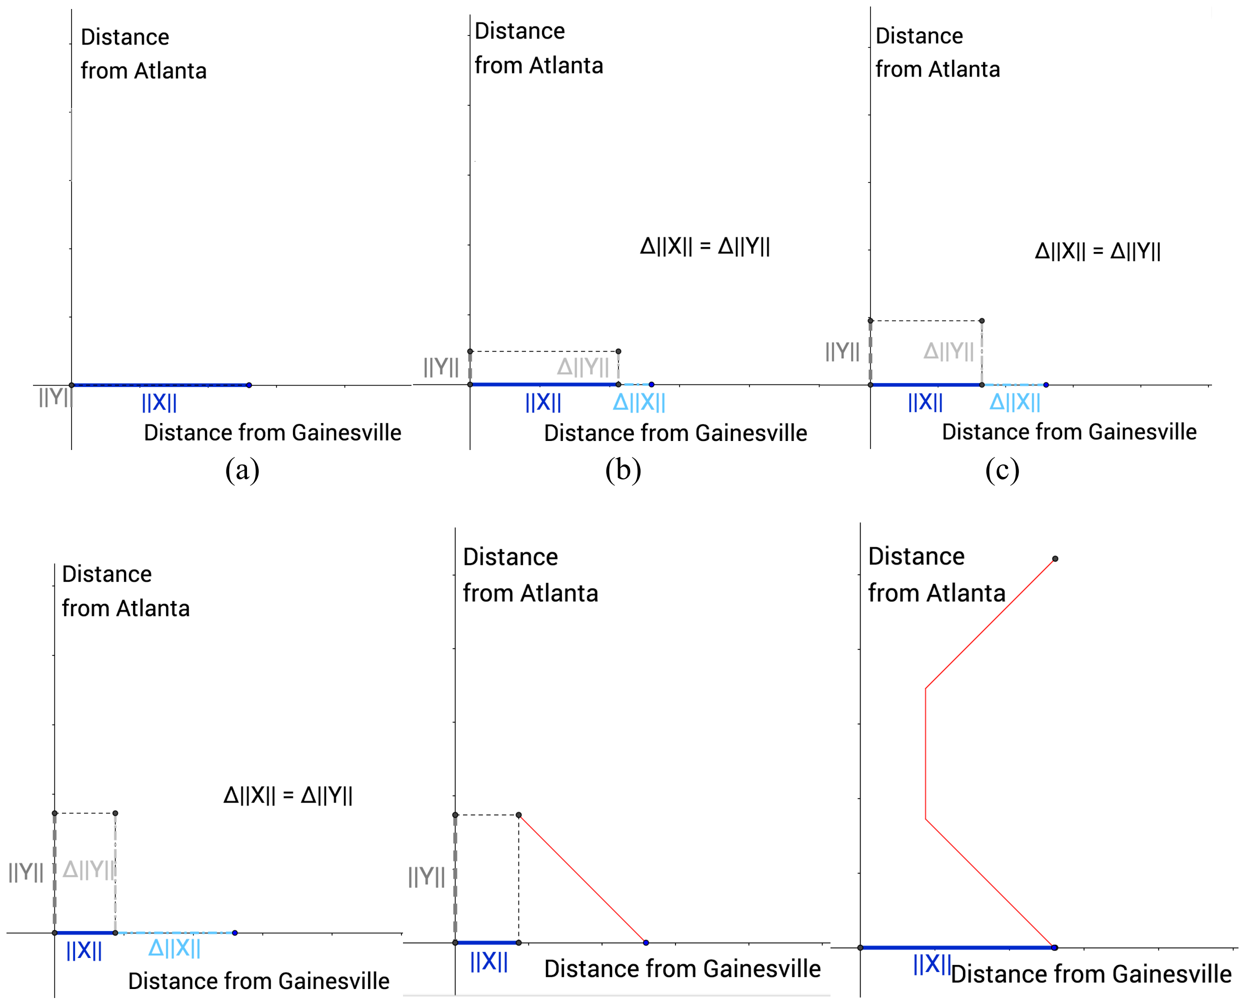

Figure 1a-f. A graph as a coordination of two magnitudes for the trip *there and back*.

Going Around Gainesville Part I

Some Georgia students have decided to road trip to Tampa Bay for Spring Break. Of course, this means traveling around Gainesville on their way down and back. The animation represents a simplification of their trip there and back. Create a graph that relates their total distance traveled and their distance from Gainesville during the trip.

Going Around Gainesville Part II

Create a graph that relates the students' distance from Gainesville and their distance from Atlanta during the trip.

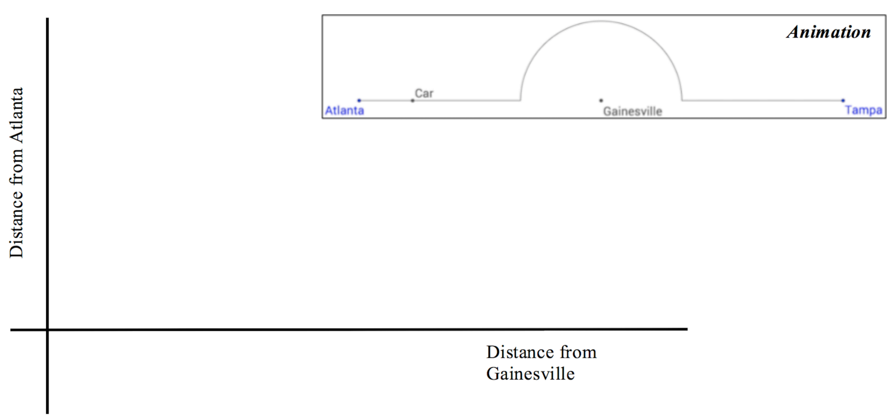

Figure 2. The *Going Around Gainesville* (*GAG*) task.

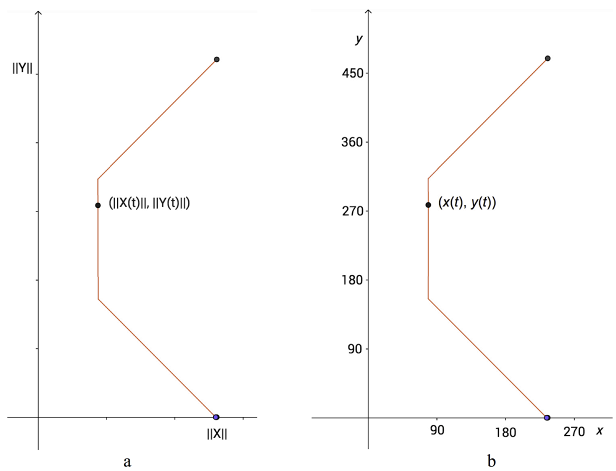

Figure 3a-b. A magnitude graph (a) and a values graph (b) representing a multiplicative object.

A person's actions are not likely to proceed in such a linear progressions, yet this example illustrates that thinking emergently involves sustaining an image of a graph as a uniting of two coordinated magnitudes. Hence, the graph emerges as a locus of points representing a multiplicative object—an "operation of having in mind two attributes of an object simultaneously" (Thompson, 2011, p. 48)—whose magnitudes and properties are equivalent to those of the multiplicative object the person conceives to constitute the situation.

Adopting the notation Thompson (2011) used to represent covariation as a multiplicative object, we can model a person's conception of a graph as an emergent trace with ($\|X(t)\|$, $\|Y(t)\|$), which represents the uniting of two quantities' magnitudes, $\|X\|$ and $\|Y\|$, so that these magnitudes are understood as varying simultaneously with respect to conceptual or experiential time, t (Figure 3a).[3] Upon choosing unit magnitudes for each quantity, a person can determine specified values that represent relative comparisons between these unit magnitudes and each quantity's magnitude at every instantiation of covariation. The result of comparisons between magnitudes and unit magnitudes enables the person to represent the attributes of the multiplicative object in terms of corresponding *values*, x and y (with associated unit magnitudes), thus representing the multiplicative object in terms of the points ($x(t)$, $y(t)$) (Figure 3b, with an associated unit of miles). We emphasize that a person with sophisticated ways of thinking for magnitudes (see Thompson et al., 2014) understands the covariational relationship, and hence the multiplicative object, as remaining invariant among unit choices; that person understands that the choice of unit influences how one partitions the respective axes, the numerical values defining coordinate pairs, and the measures of particular relationships between quantities' *values* (e.g., $\Delta y/\Delta x$), but this understanding is subordinate to the person's understanding that the displayed graph conveys a relationship between quantities' magnitudes invariant among unit magnitudes.

Ways of Thinking and Habits

We are interested in characterizing students' ways of thinking for graphs with sensitivity to their covariational reasoning, and thus it is necessary that we describe our use of *ways of thinking* and the associated terms *meaning* and *habit*. We follow Thompson and Harel's system of knowing, as reported by Thompson et al. (2014), which has its basis in Piagetian notions

---

[3] See Thompson and Carlson (in press) and Stalvey and Vidakovic (2015) for discussions on conceptual and experiential time that are beyond the scope of this work.

including schemes, operations, images, assimilation, and accommodation. Thompson and Harel define *meaning* as the space of implications that results from assimilation (Thompson et al., 2014); it is the system of schemes and operations brought forth (which may be carried out or merely anticipated) in assimilation. For example, in a case that a student assimilates two marks as lines defining coordinate axes, this moment of assimilation might correspond to the student anticipating drawing a number of memorized shapes, plotting points, making a map, etc. Moreover, in assimilating a trace on a page as a displayed graph, the student might anticipate a particular coordinate system, making tables of values, coordinating covarying magnitudes, etc.

Thompson and Harel use *ways of thinking* to refer to a student's meanings that have been repeatedly constructed to organize her experiences to the extent that the meanings have become habitual. In many cases, students' ways of thinking are habitual to the extent that they are essentially a subconscious response or pattern of actions brought forth in the moment of assimilation. Moreover, a student might bring to bear, without perturbation, a way of thinking that *an observer* perceives as incompatible with the situation at hand. If a student perceives this incompatibility, she experiences a perturbation that might require significant effort (e.g., an accommodation) on the student's part to reconcile. In these ways we describe a student's way of thinking as entailing particular *habits*: (mental or physical) actions and schemes that a student essentially subconsciously enacts, or actions and schemes that a student might find difficult not to bring to bear on associated situations despite experienced perturbations. As an example detailed in our results, a student might develop ways of thinking for graphs that entail particular habits with respect to how a graph is drawn (e.g., a graph is drawn from left-to-right) so that she has difficulty accommodating situations she perceives as incompatible with these actions.

We find Piaget's (2001) distinctions between figurative and operative thought useful when characterizing particular actions and schemes (i.e., habits) that constitute a student's ways of thinking for graphs. Piaget distinguished thought based in and constrained to perception and sensorimotor activity from thought based in operational intelligence in which figurative elements are subordinate to mental operations. That is, figurative meanings or ways of thinking are dominated by re-presentations of perceptual material or sensorimotor experience (von Glasersfeld, 1995). In contrast, operative meanings or ways of thinking are not constrained to specific perceptual material or sensorimotor experience; they are meanings dominated by the coordination of mental actions (von Glasersfeld, 1995).

Returning to students' static or emergent shape thinking (Moore & Thompson, 2015), we interpret students' static shape thinking as an example of figurative thought, as such thinking is subordinate to perceptual (figurative) properties of shape. On the other hand, students' emergent shape thinking foregrounds the coordination of actions—specifically that of covarying magnitudes, which Thompson (1994) described as operative—so that figurative elements of their activity are subordinate to that coordination. Further illustrating the distinction between figurative and operative thought in the context of static and emergent shape thinking, Moore and Thompson (2015) argued that in the former case, mathematical objects (e.g., rate of change) become properties of or subordinate to perceptual features (e.g., direction of a line—the graphs in Figure 4 unquestionably imply a positive and negative rate of change, respectively, because the lines slope upward left-to-right and downward left-to-right, respectively). In the latter case, mathematical objects become properties of or subordinate to the coordination of actions (e.g., rate of change as a measure of how quantities change—the graphs in Figure 4 unquestionably imply $\Delta y = 3\Delta x$ because x and y are simultaneously increasing such that the change in y is three times as large as the change of x). We expand on these notions to describe the extent students' actions are subordinate to figurative or operative elements of thought.

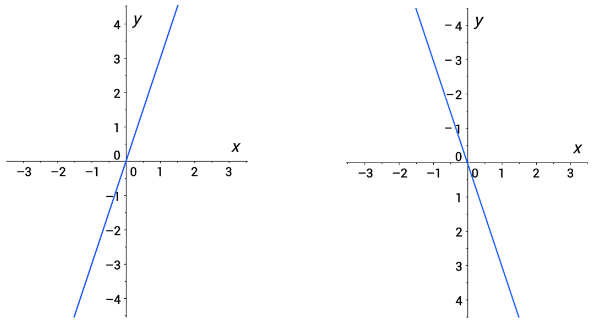

Figure 4. Graphs of $y = 3x$.

Participants, Setting, and Methods

Our participants were 10 prospective secondary mathematics teachers (hereafter referred to as students) enrolled in an undergraduate secondary mathematics education program in the southeastern U.S. The students were juniors to seniors in credits taken and had completed at least one mathematics course past an undergraduate calculus sequence. We chose the students on a volunteer basis and selected volunteers based on their availability. We conducted three approximately 75-minute semi-structured clinical interviews (Ginsburg, 1997) with each student facilitated by the lead author and another member of the research team. Each interview included tasks designed using the principles we describe below. Successive interviews occurred approximately 1.5 months apart over the course of a semester. The time between the interviews enabled us to design subsequent interviews based on retrospective analyses of prior interviews.

We video- and audio-recorded all interviews and digitized student work after each interview. The lead author and fellow interviewer recorded observation notes after each interview. We analyzed the data with selective open and axial methods (Corbin & Strauss, 2008) and *conceptual analyses*–building models of students' mental actions that explain their observable activity and interactions (von Glasersfeld, 1995). Members from the research team (the author team and additional mathematics educators) identified instances that provided insights into each student's thinking. The research team then viewed these selected instances in order to build models of the student's thinking, which they also compared to the observation notes captured after each interview. As the research team developed these characterizations, they continually returned to previously identified instances (across all students) to revise or provide alternative characterizations based on interpretations of latter instances. This iterative process generated themes among characterizations of students' ways of thinking—those meanings that we interpreted to be habitual as defined above—several of which we report in this paper.

Task Design

We designed a series of six tasks (two per interview) that: (1) provided a dynamic, albeit often simplified, situation through video; (2) did not include numerical values for attributes of the situation; (3) prompted the student to graph a relationship between two quantities; and (a majority of which) (4) prompted the student to create a second graph, either between similar quantities or the same quantities under different axes orientations. To illustrate, we used *GAG* (Figure 2) during the second interview with each student. *GAG* entails a video depicting a point representing a car traveling back and forth on a simplified path between Atlanta and Tampa. Reflecting (1) and (2), the task involves a dynamic situation depicted by a video without numerical information. Part I prompts the student to graph a particular relationship between two quantities (i.e., (3)). Part II, which we presented after the student completed Part I, uses the same video and the student graphs a similar relationship with an imposed axes orientation (i.e., (4)).

In general, (1)-(3) reflects Saldanha and Thompson's (1998) description of covariational reasoning with particular attention to students (potentially) simultaneously coordinating magnitudes in the context of both graphs and situations. Slightly modifying Saldanha and Thompson's task, we designed several of our tasks (including *GAG*) to more likely afford students coordinating *amounts of change* (see Carlson et al., 2002, mental actions) between the quantities' magnitudes. Our decision to design tasks based on principle (4) stems from findings from our previous work (Moore, Silverman, Paoletti, & LaForest, 2014) where we identified that students' ways of thinking for functions and their graphs led to perturbations when graphing equivalent or related relationships in different axes orientations, or when graphing relationships that are non-canonical (e.g., neither quantity monotonically increasing or decreasing) with respect to U.S. curricular approaches to functions and their graphs.

Results

We structure the results around several interrelated habits that constituted students' ways of thinking for graphs. When describing a particular habit, we do not imply that the student brought to bear those actions on all graphing situations. Rather, we remind the reader that habits are (mental or physical) actions and schemes that a student subconsciously enacts in some (and possibly related) situations, or actions and schemes that a student might find difficult not to bring to bear on associated situations despite experienced perturbations.

Graphs 'starting' along the vertical axis

Several students constructed a graph by first determining a point along the vertical axis and drawing a graph emanating from that point. Often, upon reflecting on their drawn graphs, *the students* conceived their graphs as incompatible with the relationships they intended the graph to represent. However, *in the moment* of drawing the graph, a student 'starting' her graph along the vertical axis often described her graphing activity in ways that contradicted the relationship *we perceived* the drawn graph to represent (e.g., the student describing that some quantity decreases while drawing a graph that we perceived to represent that quantity increasing).

As an example, we return to *GAG Part II* (Figure 2).[4] Some students immediately marked a point on the vertical axis and anticipated drawing a graph from that point (Excerpts 1).

Excerpts 1. Two students 'starting' graphs along the vertical axis.

[*Both Patricia and Andrea have constructed normative graphical solutions to GAG Part I.*]

Patricia: Your distance from Athens starts at zero [*plots point at origin*] because you're in Athens. Um, so as you get. Mmm, no, you're gonna start up here [*plots point on vertical axis but not at origin to represent a non-zero distance from Gainesville as Excerpts 2 indicates*]. Ignore that [*covering origin*]. 'Cause, oh wait, no, stop [*crosses out second plotted point*]. No, you're here [*points to origin*].

---

[4] One version of the task used Athens in place of Atlanta as a starting city.

Andrea: We're in Athens [*moves to paper and motions along the vertical axis, marks point at origin*], as we're moving away from Athens we're getting closer to Gainesville [*draws segment starting at the origin moving up and to the right,* Figure 5*, and explains that the quantities change at a constant rate with respect to each other*].

A notable feature of both students' actions is that they plotted an initial point by focusing on *one* quantity's initial magnitude and identifying a point on the vertical axis based on that magnitude. Patricia alternated which quantity she considered when plotting the point while maintaining the initial point along the vertical axis. Andrea maintained an explicit focus on the distance from Athens in determining her initial point. As both students continued, and although they both had in mind a (correct) relationship with respect to the situation, they experienced perturbations due to their action of 'starting' the graph along the vertical axis. We explain Patricia's sustained perturbation in the subsequent section (Excerpts 2).

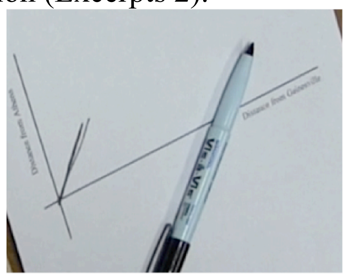

Figure 5. Andrea's drawn graph.

Graphs drawn or read left-to-right

Some students' ways of thinking entailed the habit of drawing or reading graphs left-to-right. When constructing a graph, students drew or imagined drawing graphs by 'starting' at a point (predominantly along the vertical axis) and exclusively moving their pen to the right while allowing for vertical movements. The students' vertical pen movements were either to connect previously plotted points (regardless of the order that these points were plotted) or to capture variation in one quantity. To illustrate, we present two students' activities in Excerpts 2. Karen was working the task presented by Saldanha and Thompson (1998), which includes graphing how a traveler's distances from two cities covary (see Figure 6 for animation and a sketch of a normative graph). Patricia's condensed work is a continuation of that in Excerpts 1.

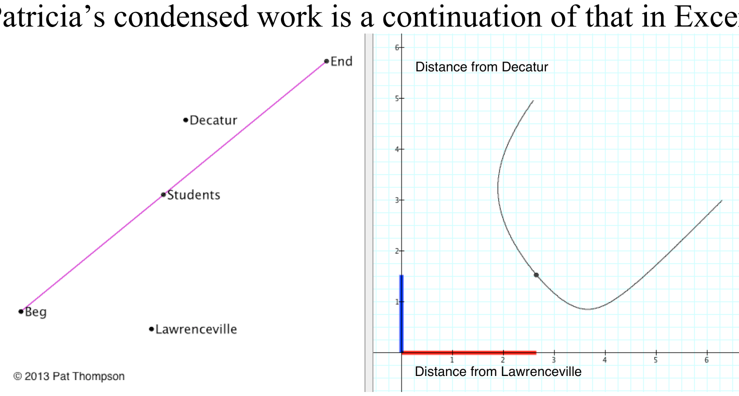

Figure 6. *City Travels* animation and sketched graph (modified from Saldanha and Thompson, 1998), an alternative of which used Dekalb in place of Decatur.

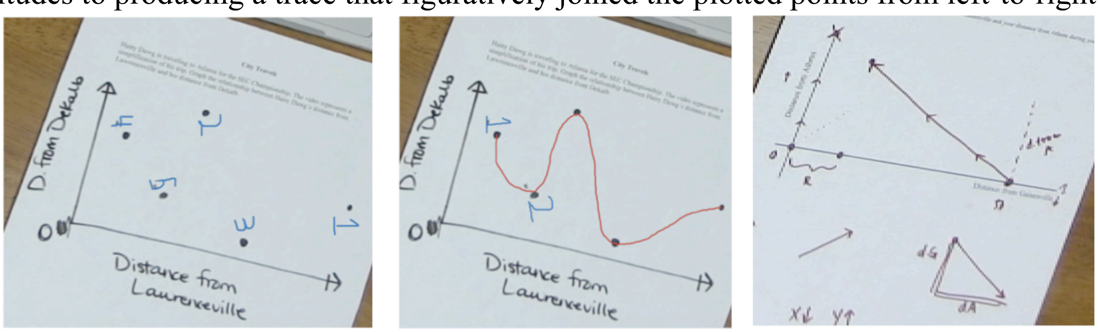
Excerpts 2. Two students drawing graphs left-to-right.

[*Karen has plotted five points corresponding to locations during the trip. She plotted the points in the order we have annotated in* Figure 7a.]

Karen: Okay, wait. This one [*pointing at the leftmost point she plotted*] was when he's closest to Lawrenceville, which happens first [*labels the point '1'*], then this one [*labels the next leftmost point '2', moves pen to the third leftmost point*] so it's something like that [*making a sweeping motion indicating a curve connecting the points from left-to-right in the manner we have annotated in* Figure 7b].

Patricia: [*Patricia has now determined an initial point that is not at the origin but is along the vertical axis. She motions as if drawing a segment sloping downward left to right from this point that she later crosses out—see the crossed out point on vertical axis in* Figure 7c] I wanted to show that the distance was decreasing [*motioning down and to the right from the point plotted on the vertical axis*], but that means that your distance from Athens is decreasing [*tracing vertical axis from the initial point to the origin*]…But your distance from Athens is growing. But your distance from Gainesville is decreasing. So, if that's growing and that's decreasing, so [*draws an arrow pointing downward beside horizontal axis label and then an arrow pointing upwards beside the vertical axis label*, *Patricia then works for six additional minutes without making progress before having an insight*]…Oh, what if I started it like here [*plots point on the right end of the horizontal axis*]. Okay…but I don't want to start like, like I don't like starting graphs. You know, I don't know. Work backwards. That's weird…[*in the next minute and a half Patricia draws in what we perceive to be a correct initial segment of the graph*]… my graph is from right-to-left, which is probably not right…Backwards is traveling from right-to-left. But I think my graph is just, I think I'm just not clicking. I think I'm missing something.

We highlight Karen's immediate move to imagine connecting the points from left to right after ordering *two* points from left to right (Figure 7b), an order that contradicts the order she created the points (Figure 7a) and the order with respect to the animation. Karen did not show signs of considering how the quantities' magnitudes vary between those paired magnitudes (within the situation or graph). Upon plotting the points, Karen's activity shifted from representing paired magnitudes to producing a trace that figuratively joined the plotted points from left-to-right.



(a) (b) (c)

Figure 7a-c. Karen's annotated work (a-b) on the *City Travels* task and Patricia's work (c) for the first portion of *GAG Part II*.

Whereas Karen did not appear to hold in mind a covariational relationship that she intended her graph to represent, Patricia had a developed image of how the two relevant quantities' magnitudes covaried with respect to the situation. However, she experienced a sustained state of perturbation in creating her graph. On one hand, after nearly ten minutes of careful activity (which is notable due to her graphing a similar relationship in an alternative orientation on Part I that she recalled and reproduced in the lower right of Figure 7c), Patricia produced what we perceived to be a correct graph by thinking of the graph emergently (Figure

7c). On the other hand, she reluctantly drew her final graph and then remained perturbed by her completed graph due to figurative aspects (e.g., where the graph "started" and having to "work backward" or "right-to-left") that were not compatible with her ways of thinking for graphs.

Graphs pass the 'vertical line test'

Related to researchers' (Carlson, 1998; Leinhardt, Zaslavsky, & Stein, 1990) observations that students' predominant meaning for function in the context of graphs is the *vertical line test*, some students' ways of thinking for graphs involved students anticipating that their drawn graph must *pass the vertical line test* (i.e., a graph such that each abscissa value or magnitude only corresponds to only one ordinate value or magnitude). In some cases, the students' anticipations were related to drawing graphs exclusively left-to-right. The students understood that drawing a graph exclusively from left-to-right necessarily produces a graph that passes the vertical line test. However, anticipating a graph as satisfying the vertical line test also emerged when students could anticipate graphs as being drawn left-to-right or right-to-left. To illustrate, consider Tara's and Alisha's work on *GAG, Part II* (Excerpts 3).

Excerpts 3. Two students considering graphs that do not pass the vertical line test.

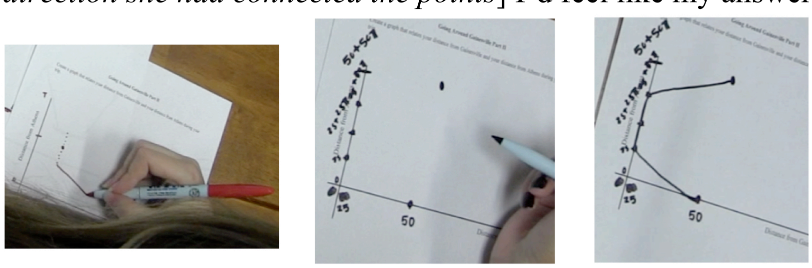
Tara: [*Referring to traveling on the semicircular path*] Your distance from Gainesville isn't changing but your distance from Athens is [*silence for 10 seconds*]. That makes me uncomfortable [*laughs*].

Int.: What makes you uncomfortable?

Tara: 'Cause right here [*motioning at the car as it moves around the semicircular arc*] your distance from Gainesville isn't changing but your distance from Athens is changing…I'm gonna have to like [*making vertical motion representing having to draw a vertical segment*]. I know it's not supposed to be a function and it doesn't matter but it still makes me uncomfortable [*laughs*] to graph things all weird on the vertical axis. [*Hesitantly draws dots aligned vertically, but not a continuous segment, see* Figure 8a]

[*Alisha has plotted five points with three points corresponding to positions on the semicircular path, see* Figure 8b.]

Alisha: So, that's weird [*motions pen indicating segment that would be drawn if she connected the three points*]. I don't wanna connect those dots, but, [*laughs softly*] I really don't like that…I just don't like that [*connects all the points of the graph in order from start of trip to end of trip, see* Figure 8c] my graph looks like this…I dunno. If I was taking a test and I drew that [*quickly motions the pen over the graph in the direction she had connected the points*] I'd feel like my answer was wrong.



(a) (b) (c)

Figure 8a-c. Tara (a) and Alisha (b-c) creating graphs with a vertical segment.

Both students had in mind relationships they intended to represent (i.e., the distance from Gainesville remaining constant as the distance from Athens increases), but their ways of thinking for graphs entailed some habit that they found difficult not to bring to bear when constructing a graph containing a vertical segment. Both students ended the task unable to reconcile the conflict they experienced between thinking that the graphs represented the correct relationship and thinking that the graph entailed figurative aspects that they considered to be incorrect.

Graph features representing some perceived aspect or phenomenon

Iconic interpretation refers to a student associating the physical appearance of a situation with the physical appearance of a graph (Leinhardt et al., 1990). More generally, students in our study frequently sought to represent some perceptual aspect or physical experience associated with the situation using figurative aspects of their graphs. At times, students' associations were iconic in nature (e.g., drawing a graph curved because a Ferris wheel is curved). At other times, students' associations were based in some perceived phenomenon or attribute of the situation that often involved attributes of motion (but not based in the explicit coordination of varying quantities). Thompson (2015) referred to these as thematic associations. A notable example is that many students drew a graph composed of linear segments to represent an object traveling at a constant speed despite their identifying that neither axes represents elapsed time (see *GAG*); these students argued that they needed to change drawn graphs (e.g., either the slope or curvature) if the speed of the car changed. A second example entailed students creating graphs that included perceptual records (e.g., a horizontal segment) of an object pausing in motion despite neither axis representing elapsed time. Patricia explained, "I wanna say kinda like the curved one, kinda like that one [*her graph corresponding to the situation of the ride without pauses*], but I just want like, breaks, like breaks in the graph." Patricia then sought to create a graph with visual "breaks" in order to convey the "breaks" in motion.

Graphs as emergent traces of covariation

Another way of thinking that some students brought to bear repeatedly (although not exclusively; see Tara, Excerpts 3) entailed conceptualizing graphs in terms of emergent traces of covariation; their ways of thinking for graphs entailed the habit of coordinating and uniting two magnitudes represented along the axes so that figurative elements entailed in drawing a graph were secondary to their reasoning covariationally. Excerpts 4 provide two examples of students envisioning graphs as emergent traces. Amy and Tara are both constructing a graph after conceiving how the surface area and height of a growing and shrinking cone covary (Figure 9).

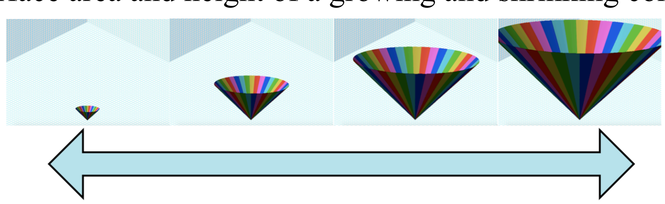


Figure 9. The changing cone.

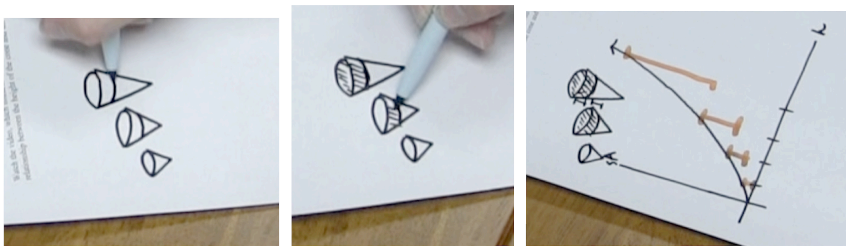
Excerpts 4. Students thinking of graphs as traces of covariation.

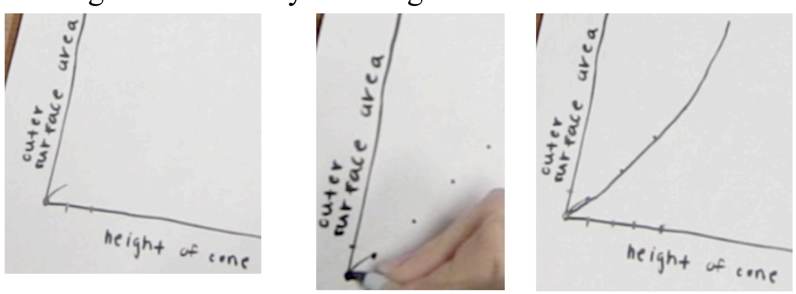
Amy: [*Amy has draw diagrams illustrating how the surface area changes for successive equal changes in height,* Figure 10a-b]. So that means for equal changes in height, the change in surface area increases. [*Amy draws axes labeled as depicted in* Figure 10c]. So for equal changes in height [*marks equal changes along horizontal axis and draws a curve*], I want to see [*draws in vertical segments to verify changes in the vertical quantity increasing for corresponding successive changes along the horizontal axis,* Figure 10c] increased changes in surface area.

Tara: So, for some change of height [*marks point on horizontal axis; see* Figure 11a, it changes like, let's make that smaller [*marks point closer to the origin on horizontal axis*]. It changes some. And then we have like another change in height, and it's gonna grow a lot more. So, there's where it is [*draws a point on her graph and connects the point with line from the origin as in* Figure 11a]. And then for another change in height [*adds a tick mark along horizontal axis*], it's gonna grow a lot more [*plots second point on graph*] and a lot more [*adding another mark along horizontal axis and then another point above it in her graph,* Figure 11b]. So I think it would look something like concave up [*connects her points and makes sweeping concave up motion with hand,* Figure 11c].



(a) (b) (c)

Figure 10a-c. Amy's emergent traces of covariation.



(a) (b) (c)

Figure 11a-c. Tara's emergent traces of covariation.

We note a few important features of each student's actions that we take to indicate her thinking about her graphs in terms of covarying magnitudes. First, Amy and Tara focused on coordinating magnitudes among different instantiations of the situation to draw conclusions about how the quantities change in tandem. They *then* drew a graph *while* focusing on how their graph represented a relationship within its respective coordinate system equivalent to that they conceived as constituting the situation. Second, neither student's understanding of her graph was mediated by reasoning about specified values or formulas. Rather, they both exhibited actions that suggest their reasoning about quantities' magnitudes within the respective representational contexts (e.g., the situation and the graph). Lastly, any indication to a figurative aspect of their graphs only occurred in reference to representing some identified relationship; the figurative aspects of their graphs were implications of and subordinate to their conceived relationships.

Discussion

Notably, the students' difficulties rarely stemmed from underdeveloped images of situations as some researchers have reported elsewhere (see Carlson et al., 2002; Moore & Carlson, 2012). Instead, the students' difficulties more frequently stemmed from their ways of thinking for graphs limiting their ability to represent relationships they conceived to constitute some situation. Carlson et al. (2002) alluded to a similar observation relative to calculus students' covariational reasoning, explaining, "We have provided examples of students who appeared to be able to apply covariational reasoning…in a kinesthetic context but who were unable to use the same reasoning patterns when attempting to construct a graph…for these situations" (p. 376). Our results provide insights into particular ways of thinking that can lead to students experiencing difficulties graphing relationships they have conceived constituting some situation; students' ways of thinking for graphs can entail problematic habits rooted in figurative elements of thought.

In some cases, students' figurative elements of thought entailed issues of perceptual shape (e.g., a graph is not composed of a vertical segment). In other cases, students' elements of thought were dominated by the sensorimotor experiences of drawing a graph (e.g., a graph is drawn or read from left-to-right). Regardless, we interpret these instances to be compatible with Moore and Thompson's (2015) description of students' static shape thinking. That is, a student thinking of a graph figuratively entails her assimilating a graph as an object in and of itself, thus foregrounding perceptual properties and sensorimotor experience. This thinking stands in contrast with a student maintaining an image of a graph as an emergent trace constituted simultaneously by two attributes with properties of shape and sensorimotor experience merely being a product of uniting those attributes. Our results corroborate researchers' (Carlson et al., 2002; Moore & Thompson, 2015) conjecture that ways of thinking that foreground understanding graphs as emergent traces of covarying quantities are more productive for accommodating novel situations and relationships than those ways of thinking that foreground figurative thought. The mental operations that constitute thinking emergently are, at their most fundamental bases, akin regardless of the produced trace and properties of its shape (Thompson, 2011). On the other hand, ways of thinking for graphs that foreground recalling a repertoire of memorized shapes and properties of figurative thought (e.g., graphs passing the vertical line test or graphs being traced left-to-right) are constrained to those situations that are compatible with these shapes and properties.

Another notable finding that underlies several of the habits provided above is students' propensity to focus on one quantity's magnitude without a persistent and explicit focus on a second quantity's magnitude. For instance, a student 'starting' her graph along the vertical axis typically entailed her considering one quantity's magnitude when determining the 'starting' point (see Patricia and Andrea, Excerpts 1), with Patricia alternating between which quantity she considered when determining the point. In the case of drawing or reading a graph left-to-right, several students' activities implied their having an explicit focus on variation in one quantity's magnitude (i.e., the quantity represented along the vertical axis) without attending to explicit variations in the other quantity's magnitude (i.e., the quantity represented along the horizontal axis). Covariational reasoning entails the formation of a multiplicative object through the explicit and persistent tracking of two quantities' magnitudes so that these magnitudes are understood as varying *simultaneously* (Carlson et al., 2002; Saldanha & Thompson, 1998; Thompson, 2011). Our observations of the aforementioned habits suggest these students did not maintain an explicit and persistent image that a change in one quantity necessitated a change in another quantity, or that a particular magnitude in one quantity necessarily implied a particular (or possibly several) magnitude(s) in another quantity.

Lastly, we find the results notable given the extent that some students were unable to reconcile perturbations that stemmed from their constructing a graph they conceived to represent an intended relationship that simultaneously contradicted ways of thinking for graphs based in figurative thought. In these cases, the students questioned the correctness of their graphs (see Patricia, Excerpts 2; Tara and Alisha, Excerpts 3). Piaget (2001) described that a key feature of operational intelligence is that it dominates and transforms elements of sensorimotor experience. Thus, we find the students' difficulties in reconciling their states of perturbation significant and illustrative of the extent that particular perceptual features and sensorimotor experiences were habitual (i.e., durable and somewhat implicit) to their use of graphs.

Closing Remarks

A limitation of the present study is that it was conducted with 10 undergraduate students. We suggest that researchers investigate other populations' responses to tasks designed like the ones in this manuscript. The results of such investigations will not only provide insights into those populations' ways of thinking for graphs, but they will also provide points of comparison for our reported findings. Second, we suggest that researchers both within the U.S. and internationally investigate similar populations to the one reported on here. Researchers who extend this work will provide insights into ways of thinking including comparisons to and extensions of those ways of thinking and habits reported here. One interesting point of comparison would include characterizing differences and similarities among students in various countries, demographics, and academic experience.

Reinventing the Multiplication Principle

Elise Lockwood
Oregon State University

Branwen Schaub
University of Portland

Counting problems offer opportunities for rich mathematical thinking, yet students struggle to solve such problems correctly. In an effort to better understand students' understanding of a fundamental aspect of combinatorial enumeration, we had two undergraduate students reinvent a statement of the multiplication principle during an eight-session teaching experiment. In this presentation, we report on the students' progression from a nascent to a sophisticated statement of the multiplication principle, and we highlight two key mathematical issues that emerged for the students through this process. We additionally present potential implications and directions for further research.

Key Words: Combinatorics, Reinvention, Counting problems, Teaching experiment

Introduction and Motivation

The multiplication principle (MP), called by some "The Fundamental Principle of Counting" (e.g., Richmond & Richmond, 2009), is a fundamental aspect of combinatorial enumeration. Broadly, it is the idea that for independent stages in a counting process, the number of options at each stage can be multiplied together to yield the total number of outcomes of the entire process. It is foundational to many of the counting formulas students learn and is also a much-needed source of justification for why these counting formulas work as they do. In spite of its importance, little has been studied about the MP in and of itself. In order to better understand student thinking about the MP, we had two undergraduate students reinvent a statement of the MP over the course of an eight-session teaching experiment (Steffe & Thompson, 2000). In this paper, we describe their overall reinvention process, presenting their progression of statements. We also introduce and discuss a handful of mathematical issues that are entailed in the MP and that arose for the students (specifically, the independence of stages in a counting process and the need to count distinct composite outcomes). We seek to address the following research goals:

1. *Describe a pair of students' trajectory as they reinvent a statement of the MP, and, in so doing,*
2. *Present mathematical issues in the MP to which the students attended as they reinvented the statement.*

Research about the MP in Combinatorics Education Literature

Previous work has demonstrated the importance of the MP in counting (e.g., Lockwood & Caughman, 2015; Lockwood, Swinyard, & Caughman, 2015), and the lack of a well-developed understanding of the MP appears to be a significant problem and hurdle for students, particularly in terms of their ability to justify or explain formulas. We have found that students can easily assume that they understand the MP in counting because multiplication is a familiar operation for them. As a result, they use the operation frequently but without careful analysis, and they tend not to realize when simple applications of the operation are problematic. Kavousian (2008) suggested that students may conflate operations like addition and multiplication. Although her work does not speak directly to the multiplication principle, it gives evidence that students perhaps do not necessarily understand appropriate operations to use, and this suggests that their understanding of the multiplication principle is not robust. In addition, a number of authors have documented issues that students face in determining the appropriate combinatorial operation, such as permutations or combinations, to use in a given situation (e.g., Batanero, Navarro-Pelayo, & Godino, 1997; Dubois, 1994; Fischbein & Gazit, 1988). Given that the multiplication principle is an underlying component of each of these formulas again suggests, even obliquely, that the lack of a solid understanding of the MP could negatively affect understanding of these broader formulas.

Lockwood, Swinyard, & Caughman (2015) conducted a study in which students reinvented basic counting formulas, and the students in that study did not appear to have a solid understanding of the MP. They worked with outcomes empirically but lacked the understanding of how those outcomes related to the underlying counting process involved with the MP. These authors concluded that their findings indicate that, "the students' work was, surprisingly, not based on the multiplication principle, but instead it was almost entirely based on empirical patterning" (p. 56). In addition, Lockwood, Reed, and Caughman (2015) recently conducted a textbook analysis that examined statements of the MP in university combinatorics and discrete mathematics textbooks (relevant details are outlined in the Mathematical Discussion section below). This study revealed a variety of statement types, raising questions about necessary components of the MP and what kind of statement might be most effective pedagogically for students. All of the studies mentioned above emphasize that the MP is an important aspect of counting and suggest the need for more research that targets students' understanding of the MP as a fundamental counting process.

Theoretical Perspectives

In this section we first discuss reinvention and our general adherence to a view that values students' mathematics. Then, we explore mathematical issues related to the MP in order to provide motivation for our study and to facilitate subsequent discussions of student reasoning about the MP.

Reinvention. Gravemeijer, Cobb, Bowers, and Whitenack (2000) describe the heuristic of *guided reinvention* as "a process by which students formalize their informal understandings and intuitions" (p. 237). From this perspective, students can formalize ideas through generalization of their previous mathematical activity. We had students reinvent statements of the MP because we felt this would allow students to meaningfully understand and articulate a statement, giving us insight into how students come to understand the MP. This is a different approach than first teaching them about the MP and then asking them questions about it. We adopt this approach because we value how students reason about mathematical ideas, and we feel we can learn about students' reasoning by observing how they come to reason initially about an idea. This is in line with other researchers who have used principles of reinvention to gain insight into students' reasoning about a particular concept or definition (e.g., Larsen, 2013; Oehrtman, Swinyard, & Martin, 2014; Swinyard, 2011).

Mathematical Discussion. Lockwood, Reed, and Caughman (2015) studied 64 different textbooks and found a wide variety of statements of the MP (Figures 1, 2, and 3 below all represent differing formulations of the MP), and this variety is surprising given how fundamental the MP is to counting. The wide range of statements raises questions about what mathematical issues should be handled by a statement of the MP, whether various statements are mathematically equivalent, and whether or not there is a particular MP statement (or kind of statement) that would be most appropriate for students to be taught.

Generalized Product Principle: *Let* $X_1, X_2, \ldots, X_k$ *be finite sets. Then the number of k-tuples* $(x_1, x_2, \ldots, x_k)$ *satisfying* $x_i \in X_i$ *is* $|X_1| \times |X_2| \times \ldots \times |X_k|$.

Figure 1 – Bona's (2007) statement of the MP

The Product Rule: *Suppose that a procedure can be broken down into tasks. If there are* n_1 *ways to do the first task and* n_2 *ways to do the second task after the first task has been done, then there are* $n_1 n_2$ *ways to do the procedure.*

Figure 2 – One of Rosen's (2007) statements of the MP

The Multiplication Principle*: Suppose a procedure can be broken down into m successive (ordered) stages, with* r_1 *different outcomes in the first stage,* r_2 *different outcomes in the second stage, …, and* r_m *different outcomes in the mth stage. If the number of outcomes at each stage is independent of the choices in the previous stages, and if the composite outcomes are all distinct, then the total procedure has* $r_1 \times r_2 \times \ldots \times r_m$ *different composite outcomes.*

Figure 3 – Tucker's (2002) statement of the MP

Statement types. Lockwood, Reed, and Caughman (2015) identified three different kinds of statements: *structural*, *operational*, and *bridge* statements. This categorization is based on Sfard's (1991) distinction between structural and operational conceptions. In terms of the MP, Lockwood, Reed, et al. (2015) defined a structural statement as a statement that "characterizes the MP as involving counting structural objects (such as lists or *k*-tuples)" (p. 20). Bona (2007), Figure 1, is an example of a structural statement, because k-tuples are being counted and there is no explicit connection to a process that generates the k-tuples. An operational statement is defined as a statement that "characterizes the MP as determining the number of ways of completing a counting process" (p. 20), because the things that are being counted are operational, like ways of completing a process or procedure. Rosen (2007), Figure 2, is an example of an operational statement, because the nature of what is being counted in this statement is the "ways of completing a procedure." Finally, a bridge statement is a statement in which the nature of what is being counted list structural, but there is a clear link in the statement to a process that generates those objects. Specifically, such statements simultaneously characterize the MP "as counting structural objects and specifies a process by which those objects are counted" (p. 20). Tucker (2002), Figure 3, is a bridge statement because it counts outcomes and yet clearly connects those outcomes to a procedure that generates them.

The distinction between these three statement types is relevant because there are mathematical implications for statements that are strictly structural or operational statements. While we do not delve into the details of these implications, here we emphasize that bridge statements are our preferred statement type. Indeed, although bridge statements may initially seem overly complicated or wordy, they can be appropriately applied to a wide variety of problems while avoiding issues of overcounting. Part of the motivation for the current study, then, is to build upon the textbook analysis by actually studying how students think about mathematical issues that arose in the textbook statements of the MP. The findings from Lockwood, Reed, and Caughman (2015) framed and informed the mathematical issues we pursued with the students, and the following section we discuss these key mathematical issues.

*Key mathematical issues in the MP***.** In the textbook study, there were also a handful of mathematical issues that emerged in the statements of the MP. Here we briefly describe two mathematical issues in the MP. In the Results section we will describe the students' reasoning about these key ideas, and so we briefly introduce them here to facilitate subsequent discussion. First, there is the notion of *independence* of stages in the counting process, which captures the idea that a choice of options at a given stage does not affect the number of outcomes in any subsequent stage. Independence is a necessary condition in order to apply the MP, or else overcounting may occur. To see this, we can consider the Language Books problem: *You have 4 different Russian books, 5 different French books, and 6 different Spanish books on your desk. In how many ways can you take two of those books with you, if the two books are not in the same language?*. It may be tempting to solve the problem in two stages: first pick a first book, and then pick a second book. Note, however, that in this problem, one cannot simply consider that there are just 15 options for the first book in the pair (from 4+5+6 = 15 total books), because subsequent books might depend on what language the first book was. To handle this, a correct solution may break down the problem into cases according to which pair of languages are being chosen. In order to fix this, one can break the problem into cases according to which language book was first, arriving at the correct answer or 4*5 + 4*6 + 5*6 = 74).

Another mathematical issue that arose from the textbook study is that the MP must yield *distinct composite outcomes*, which means that when applying the MP we want to ensure that there are no duplicate outcomes. This qualification, too, prevents instances of overcounting. Specifically, we need to make sure that there are not multiple counting processes that actually yield the same outcome. A problem that highlight this issue is the 3-letter sequences problem (found in Tucker, 2002): *How many 3-letter sequences made of the letters a, b, c, d, e, f contain the letter e, where repetition of letters is allowed?*. Note that a tempting (but incorrect) answer is to specify a 3-stage process – first, pick where the *e* can go (3 options), second, since now we are guaranteed to have an *e*, fill in the next available position with any of the 6 letters (6 options), and third, fill in the last available position with 6 letters (6 options). There are 3*6*6 = 108 total ways to complete the process. However, there is not a 1-1 correspondence between ways to complete the process and the number of desirable outcomes. The process overcounts the total number of desirable outcomes. For example, consider the sequence *eae*. It was counted once when an *e* is placed in the first position in the first stage, then the password is filled out with *a* then *e*. However, it is also counted when *e* is placed in the last position in the first stage, then the password is filled out with *e* then *a*. Thus, overcounting can occur if there is not care to have distinct composite outcomes of the counting process generated by the MP. These examples point to the mathematical subtleties in statements of the MP.

Methods

Data Collection. We conducted a teaching experiment (Steffe & Thompson, 2000) in which a pair of undergraduate students solved counting problems over eight hour-long sessions. The sessions were video and audio-recorded. The students were enrolled in vector calculus in a large university in the western United States, and they were chosen because they had not been explicitly taught about the MP in their university coursework (and thus would not simply try to recall a statement of the MP). The interviews took place outside of class time over a period of four weeks, with approximately two sessions per week. The students worked together at a chalkboard while the researcher and a witness posed problems and, at times, asked clarifying questions. The students were encouraged to talk and work together, and they quickly established a rapport where they could ask each other questions and probe each other's thinking.

The overall structure of the teaching experiment was first to have the students solve a series of counting problems. They were then asked to write down and characterize when they were using multiplication as they solved these problems, and they wrote down several iterations of statements of the MP throughout the teaching experiment. In the last session they were also asked to evaluate textbook statements and compare them with their final statement.

Broadly, the students engaged in four kinds of activities throughout the teaching experiment (summarized in Table 1). First, students solved a set of initial counting problems that involve multiplication. The aim was to have them engage in some joint solving of counting problems that involved multiplication so they could reflect on when and why they multiplied This occurred during Sessions 1 and 2. Second, at the end of Session 2, students were asked to articulate an initial statement of the MP – specifically, how they might characterize when to multiply when solving counting problems. This resulted in an initial statement of the MP. Then, in Sessions 3 through 7, the students solved more counting problems and engaged in iteratively refining their statements of the MP. During these sessions, the overall aim was to have the students develop more sophisticated and rigorous statements of the MP. To facilitate this, the researchers gave students new problems in order to target mathematical issues, they asked students to explain their thinking, and they encouraged students to use more general language. Then, finally, during Session 8, the students were asked to evaluate given textbook statements of the MP.

Session	Emphasis of Session
1 – 2	Solving initial set of counting problems that involve multiplication
End of Session 2	Articulating an initial statement of the MP
3 – 7	Iteratively refining statement of the MP
8	Evaluating given textbook statements

Table 1 – Overall structure of the teaching experiment

Data Analysis. The research team transcribed the sessions, and we made enhanced transcripts in which images from the video are embedded into the text. The videos and transcripts were analyzed so as to construct a narrative about the teaching experiment (Auerbach & Silverstein, 2003). Specifically, we read back through the enhanced transcripts multiple times, recorded the progression of the actual statements themselves, and documented how they had evolved over the sessions. Then, we used prior understanding of the MP that had emerged from the textbook analysis to guide our focus of particular mathematical issues, including independence and distinct composite outcomes. Key episodes involving mathematical issues were flagged and reviewed, and we scrutinized the students' statements of the MP and their explanations for insights about their reasoning. We also examined students' initial work in the sessions prior to articulating their first statement of the MP, with the aim of better understanding how they thought about multiplication prior to being asked to characterize when they multiply.

Results

We organize the results chronologically. We begin by characterizing students' initial conceptions of multiplication during initial problem solving sessions. We then discuss the students' articulation and iterative refinement of statements of the MP in Sessions 3 through 7 (due to space, we emphasize Sessions 4 and 6). In so doing, we highlight the development of key mathematical issues of independence and being attuned to overcounting. Due to space we do not share results from Session 8 of evaluating existing textbook statements.

Students' initial conceptions of multiplication (Sessions 1 and 2). In Sessions 1 and 2, the students were given a number of counting problems that involved multiplication in a variety of contexts. During these sessions, we were able to observe the students using multiplication and describing why they were multiplying. In this section, then, we provide evidence of a couple of conceptions about multiplication that they respectively possessed.

The very first problem states, *A student is going to complete a True/False quiz with 5 questions. How many different possible outcomes are there for how the quiz could be answered?* In answering this question the students almost immediately recognized the answer to be 2^5 = 32, and we asked how they got the answer. Pat used branching language and a tree diagram to reason through why they should multiply. Pat said, "Yeah so you branch, you take the first one and you can have two possibilities and each of those possibilities will have two possibilities, each of those will have two possibilities," and he drew out the tree in Figure 4. For Pat, a tree representation and the notion of branching was a natural to think about multiplication, and he would describe having "options" for different stages in the counting process.

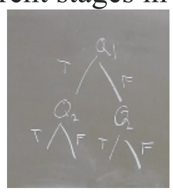

Figure 4 – Pat's initial branching idea

Caleb seemed to focus on a different perspective of multiplication, and he brought up the notion of multiplication as involving groups, which elicits ideas related to multiplication as repeated addition. As evidence of this, we consider the following exchange about the problem *How many ways are there to arrange 4 people in a line?*

Caleb: I think it's multiplied because they're like groups. So you have your first group and then it's like it could be one and two and then that'd be a group (in the first two positions), and then one and two here (in the first and third positions) would be another group. So each time you go like into another level (he made a gesture like he was alluding to the tree diagram) you are grouping them a different way.

Int.: Ok, and so why does multiplication get at that grouping? Or, why when you're having those groups, why multiply?

Caleb: I mean multiplication, isn't that just putting things together in groups?

Thus, we see that options and tree branches were key for Pat, while the idea of groups was important for Caleb. These ideas were important for them as they considered and used multiplication. They seemed open to each other's ideas and language, however, and there were instances in which the students merged their two ideas together.

Initial ideas about independence and overcounting. In the first two sessions, there were also three issues that started to emerge involving independence and overcounting. These issues are central to their refinement of statements of the MP, and we discuss them in more detail throughout the paper. However, it is important to highlight some of their initial ways of thinking about these mathematical issues early on to get a sense of how they were developed.

Independence. As noted above in the mathematical discussion section, independence of stages in a counting process is a key aspect of a statement of the MP (especially an operational or a bridge statement). This came up for students in the Language Book problem discussed above. The students started to reason about whether they could just consider 15 options for which book is first in the pair, but they soon realized that they could not simply multiply 15 by anything to get the answer. As the exchange below shows, they became aware of the issue of dependence. In order to fix this, they broke the problem into cases according to which language book was first, arriving at the correct answer or 4*5 + 4*6 + 5*6 = 74).

Int.: *Um so why... so I think I don't, I mean I think your idea of like the fifteen options for the first one, why did that break, which I think is a good idea, but what, what about the problem made it so you couldn't just do like fifteen times something?*

Pat: *Um because the, whatever you select for the first one, then determines what kind of book you can select for the next one.*

Int.: *Okay.*

Pat: *So there are, technically there are fifteen options for the first book, but you have no way of knowing if they selected a Russian, French, or Spanish. And so then you don't know if you have four times five, or five times six, or six times four as your next option.*

Caleb: *Yeah.*

We will continue to revisit their reasoning of independence and their treatment of it in their statements of the MP. The point here is that they had a meaningful experience early on in a problem in which independence was introduced, and they seemed to realize the importance of accounting for independence in their statement of the MP.

Overcounting. A second mathematical issue that arose even within the first session was overcounting (also described above). In particular, the students were made aware of an overcounting error on a problem that states, *How many ways are there to place two different-colored rooks in a common row or column of an 8x8 chessboard?* To solve this problem, there are 64 options for where to place the white rook, and then there are 14 other spaces for the black rook to go.[1] Note that in this problem, the fact that the rooks are distinct is important, but the choice for whether to start with the white or the black rook does not need to be taken into account in the final solution. We can decide either to place the white rook first and then the black rook, or vice versa, and in either case the answer will be the same. It might be tempting to multiply the answer by 2 to account for whether or not the white or the black rook is first, but that is not necessary and in fact will overcount. As we will see in Pat's discussion below, this is difficult to see. Specifically, in this problem, they had correctly considered options for placing the rooks, but Pat had multiplied by an additional factor of two for which colored rook was placed first. However, the additional multiplication by 2 is not necessary and thus would overcount. We brought this to their attention fairly explicitly, and after quite a bit of reasoning they did have the following realization:

Pat: *That's a good point. Cause if you're saying you put white rook here, and then selecting to put the black rook here, but that would be the same as if saying I selected to put the black rook first here and put the white rook there. So it is, everything is being counted twice this way.*

There is further evidence that this experience of overcounting was meaningful for them, as they subsequently referred to it on other problems. For example, another problem says *How many different numbers can be formed by various arrangements of the six digits 1, 1, 1, 2, 3?*. The students referred back to the Rooks problem, which suggests that they were being careful about overcounting.

Pat: *I feel like that's a way to go. Just thinking about it. Cause the 1's are gonna be the same...*

Caleb: *Yeah exactly. So we have how many spots to put a 2 and a 3 that are different?*

Pat: *Yeah, uh…*

Caleb: *Five spots originally then uh four. So five times four?*

---

[1] An equivalent is to first select one of 8 rows and then to select one of 8 columns in which to place the white rook. Then, there are 14 remaining positions in that row and column for the black rook to go.

Pat: *That equals twenty. Yeah, yeah, that sounds right. That's, uh, will we get the counting twice thing like we did with the chess pieces?*

Caleb: *Uh no. Because if we put whatever number it is, so like say we put a 2 here, here, here, here, here, then we have to, we have five.*

In sum, the students had a formidable experience in which they were exposed to the issue of overcounting. This proved to be a salient point for them to which they returned throughout the teaching experiment. We introduce it here to show the genesis of their reasoning about overcounting.

Articulating and refining statements of the MP – An iterative process involving key mathematical ideas. We now present work that occurred between the end of Session 2 through the end of Session 7. In these sessions the students articulated and then iteratively refined a statement of the MP. We describe this process, and we highlight the progression of statements and the mathematical issues that arose for students. For the sake of space, we focus primarily on Sessions 4 and 6, as these are where most of the development occurred.

Initial Articulation of a Statement of the MP (Session 2). At the end of Session 2, we asked them the following: “So, I'm curious if you can take a stab at characterizing for me, like when you use multiplication when you're solving these problems? Um and actually maybe a more precise way to ask that is let's say you had to write a rule like you're writing a textbook and you're going write a rule for when you're going use multiplication to solve counting problems like this.” We encouraged the students to write down a statement, and they each independently wrote statements on the board. After some time, Caleb wrote an initial statement (Figure 5): *Use multiplication in counting problems when…there is a certain statement shown to exist and what follows has to be true as well.* He explained his work by saying, “Basically I thought it would be useful to write big words, I was like you know I'll try that. So I'm saying basically that if you set like parameters or something that's shown to exist, like you have something and then you want to add on to that. You have to multiply them if you're saying the first one is true.” We observe that this statement is a reasonable first step but is far from a rigorous statement of the MP.

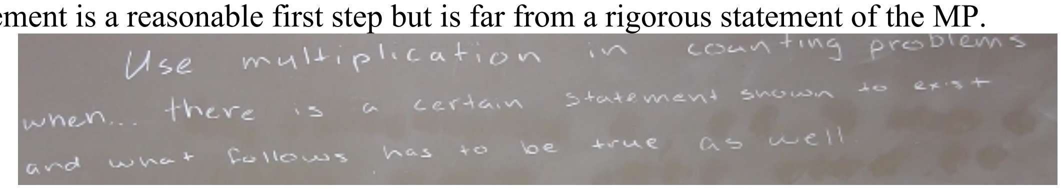

Figure 5 – Caleb Statement 1

After the students had written statements in Session 2, we decided to have them solve problems involving addition/case breakdowns in Session 3. The goal was that the students would be able to make a contrast between problems involving addition and problems involving multiplication. The major reason that we wanted to highlight this, though, was because we were anticipating that independence would be an important mathematical issue that should be incorporated into their statement, and these addition problems highlight the need for independence. While we do not provide examples due to space, the students were able to think about adding and how it related to an operation like multiplication, and they were able to realize that a case breakdown was an effective means by which one could handle issues of independence.

Refining the statement (Session 4). In Session 4, Caleb and Pat spent a good deal of time on a particular problem, and they drew heavily on a representation of tree diagrams to reason through the problems and to articulate a statement at the end of the session. This enabled them, for the first time, to articulate a mathematically correct insight about why multiplication works. As we will see, however, although they made progress toward a rigorous statement there were a couple of problematic issues with their statement. Thus, Session 4 represents some significant progress wherein they clearly articulated when it is appropriate to multiply, but they struggled to identify language that would be meaningful for them. Specifically, Session 4 involved three aspects of their reinvention – understanding multiplication as involving equal sized groups, struggling with language, and addressing overcounting.

Understanding multiplication as involving equal sized groups. We began Session 4 by giving them the following problem: *How many ways are there to flip a coin, roll a die, and select a card from a standard deck?* Pat connected a solution to his initial views of multiplication, which involved options.

Pat: I feel like, I feel as if options leading to other options is the way I'm thinking about it.

Int.: Ok. So say more about options leading to other options.

In response, Pat wrote a tree diagram in Figure 6, which shows branching and options leading to other options. He and Caleb both seemed to understand that the branching in the tree diagram represented the different options for coins, dice, and cards.

Pat: Well I think of, you have your initial condition of flipping a coin, which has two outcomes, you know heads or tails. And for each time you do that, you then have a dice roll no matter what, for each of those dice rolls you have six options. And off of those six possible options there will be 52 options for what cards you can pull from a deck. Uh we won't do those, but there are options there.

Int.: Ok, and 52 for each of those?

Pat: Yeah.

Caleb: Yes.

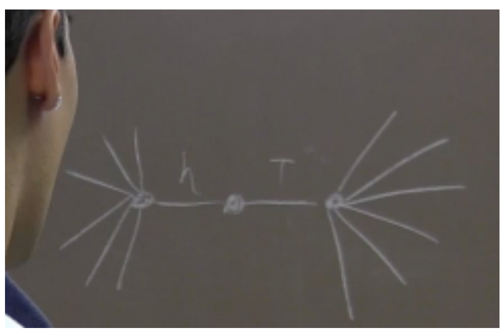

Figure 6 – Part of a tree diagram that Pat drew

We interpret that this tree diagram and their discussion surrounding it established a powerful, shared representation of multiplication, and they seemed to agree on how this representation could be useful in describing when to use multiplication when counting. An interesting discussion emerged about the nature of multiplication and how and why it worked on that problem. As seen in the exchange below, Caleb noticed an important distinction between addition and multiplication. He drew a tree diagram (Figure 7) that has one branch with 5 and the other with 6. He noted that this situation would not by symmetric and would thus entail addition instead of multiplication.

Caleb: The way you did this, I don't know this might be towards addition, I was thinking like if you have two outcomes that are different, like say so this side there's one and then say you have a five sided dice and a six sided dice or something, if it doesn't have symmetry then you do addition.

Pat: *Ok that's fair.*
Caleb: *So like 1, 2, 3, 4, 5, 6. And then there's, it's not symmetrical on either side, so you have to end up doing this one plus this one.*
Pat: *Yeah okay.*
Caleb: *If that makes sense.*
Pat: *I like that.*
Caleb: *So it might have to do with like reflecting or like…(trails off)*
Int.: *Ok awesome.*
Pat: <u>*Yeah I like that. So multiplication is when all groups...*</u>
Caleb: <u>*Are equal.*</u>
Pat: <u>*When all the groups you're talking about are equivalent. Whereas addition is when you have you know non equal groups. Different groups.*</u>

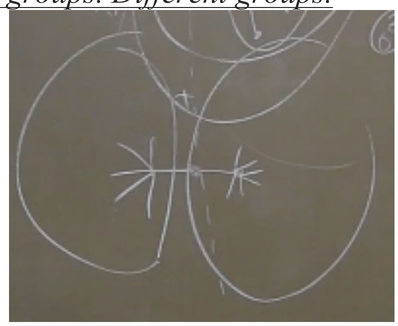

Figure 7 – A diagram showing non-symmetric branching

This was an important moment for them because it established for them mathematically when (and why) it might make sense to multiply versus add (noted in the bold sections of the previous excerpt). We then asked them to articulate their ideas into a refined statement, and this proved to be challenging for them.

Struggling with language. The students recognized that they would want to incorporate this idea of equal groups into their statement. Notice again they reiterate that they associate equal groups with multiplying (in the first bold section). Then, notice that they try to determine if groups are equal or not, and they try to articulate some particular language. The second underlined passage highlights that they found this to be a difficult task.

Caleb: *So let's, we've definitely come to the conclusion that if their groups are equal we multiply.*
Pat: <u>*If we're, if we're combing equal, if we're combing equal groups we're multiplying.*</u>
Caleb: <u>*Yes.*</u>
Pat: <u>*And if we're combing non equal groups it's mult...*</u>
Caleb: <u>*It's addition.*</u>
Pat: <u>*Yeah addition.*</u>
Caleb: <u>*So for multiplication. How would we decide if they're equal or not?*</u>
Pat: *Ok um. If, if for every possible selection, or for every possible outcome there's the same choices after that, for that.*
Caleb: *For every time?*
Pat: *For every possible outcome. Like for, like for the die. For every possible outcome of the die there is the same number of cards to select. And the same cards themselves.* <u>*So like, I can, I can figure out how to say the first part.*</u>
Caleb: <u>*Yeah that's exactly, that's how I feel.*</u>

The students then proceeded to engage in more discussion related to refining of their statements. Articulating an appropriate statement for when to multiply continued to be very difficult for them, and Caleb noted at one point, "It's so hard to think about. It's just something we naturally do." They struggled to articulate language and could not come up with a statement they were happy with after several stops and starts. Given this difficulty with the language, it is perhaps not surprising that they turned to language involving pathways, which was tied to a meaningful representation for them. Caleb said, "Um. What about, let's incorporate the pathway in this one. So for every possible outcome there's a pathway leading to it." Caleb then worked on writing down a particular statement, and he wrote what is written in Figure 8.

Caleb: Alright that's kind of what I'm thinking now. So for each possible pathway to an outcome, there's an equal number of options leading to that path.

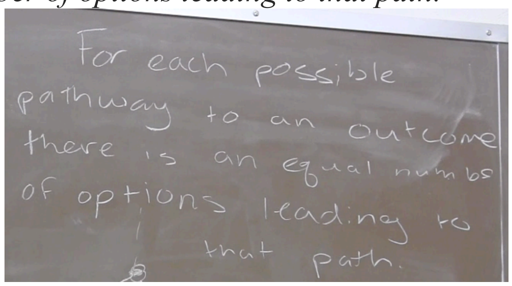

Figure 8 – The students' statement involving pathways

At this point, the students had come to an understanding of when multiplication might be appropriate in terms of groups, and although they struggled to articulate language, they arrived at a statement involving "pathways" language. However, there was still more for them to consider in refining their statement.

Addressing overcounting. The statement in Figure 8 addresses some issues but was still susceptible to overcounting, as there is nothing in the statement that would prevent them from overcounting on the Language Books problem, for example. To address this, I asked them to revisit the Language Books problem. This had the effect of highlighting overcounting, and the following exchange suggests that they did not want to allow for outcomes to be counted more than once.

Caleb: Alright, well I mean that would be without repeating the same pathway. But we still have to talk about how the pathway is multiple different outcomes. But.
Int.: [to Pat] Do you see what he's saying there?
Pat: Yeah I see what's going on.

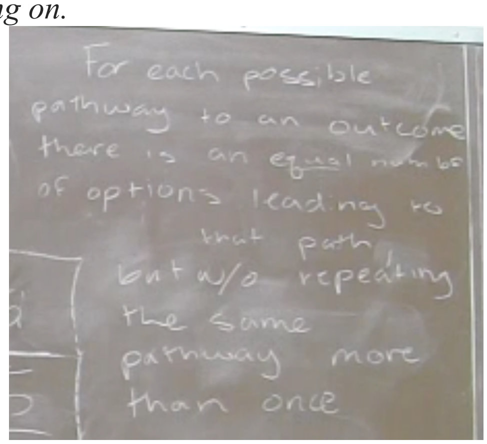

Figure 9 – The students' pathways statement after considering overcounting

There are a couple of conclusions to draw from Session 4. First, in terms of them actually really reasoning about multiplication and why it works, they made good progress due to the tree representation. The idea that multiplication could be thought of as entailing equal groups seemed to be solidified for them, and they wanted to consider an equal number of options as they progressed through. We would argue that the representation itself was an important part of them coming to reason about multiplication in this way. However, in spite of the progress they made during this session their struggle to come up with particular language or terminology seemed to hinder their progress. So they emerged with a statement that was understandably specifically tied to the given representation, but one with which we were not ultimately satisfied.[2]

Developing a mathematically rigorous statement (Sessions 6 and 7). In Session 6, the students made substantial progress toward a correct and rigorous statement of the MP. There are two things that happened in Session 6 that we feel contributed to their refinement of their statement. First, we explicitly asked the students to be more general in their language (moving away from "pathways" language of Session 4). This led them to almost immediately come up with language of options, selections, and outcomes, which they were able to clearly define and use. We pushed them to articulate what they meant by these terms at each step along the way, and this difficult yet valuable refinement of language proved to be helpful for them. Second, the students wrestled through the mathematical idea of independence, in particular a distinction between independence of the *number* of options and not necessarily the options themselves. This engagement with powerful and nuanced mathematical ideas seemed to help solidify their understanding of the statement of the MP and how and why it might need to be refined. Through, they produced the following statement at the end of Session 6 (Figure 10): "If for every selection towards a specific outcome, there is no difference in the number outcome, regardless of the previous selections, then you multiply the number of all the options in each selection together to get the total number of possible outcomes."

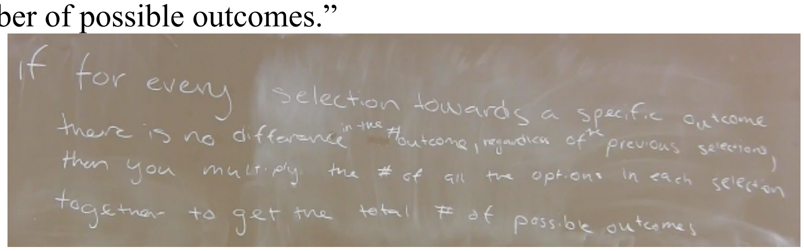

Figure 10 – The students' statement at the end of Session 6

Then, in Session 7 we asked the students for further clarification of language. This led them to offer definitions for "selection," "option" and "outcome," which was very productive. Specifically, they defined selection as "when a choice has to be made"; option as "one of the possible choices for a selection"; and outcome as "one unique combination of all chosen options." This language, which they continued to use consistently throughout the rest of the teaching experiment, was helpful as they continued to reason about their statement. Figure 11 shows how they see the relationship between selections, options, and outcomes.

---

[2] We do not discuss Session 5 in depth, in part because we are restricted by space, and also because it is tangential to the story of the students' the reinvention of the MP. After the students had made significant progress in Session 4, we expected that we could give them a couple of additional tasks that would help to generalize their language (beyond the pathways language). However, we went down an unexpected rabbit trail in this session, as the students focused on order and introduced a less productive representation of the MP. Session 5 came and went with no change to their statement of the MP.

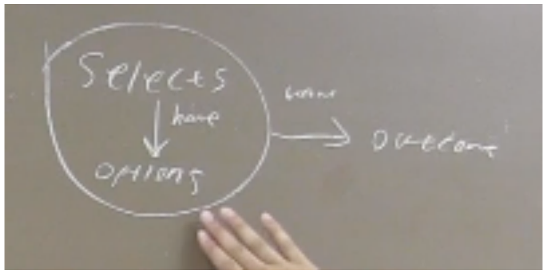

Figure 11 – The interaction between selections, options, and outcomes

Finally, in Session 7 they arrived at the last statement, given in Figure 12. They added the word "unique" after we prompted them again to consider how overcounting might occur. Specifically, we had them revisit a problem that involved overcounting (the 3-letter sequences problem), and they realized that they wanted their statement to explicitly account for potential overcounting. We had the following exchange, and they added the word "unique" to their previous statement. This is a way of taking care of the overcounting issues.

Caleb: We could say without any repeated outcomes.
Int.: Ok. Say more about that.
Caleb: So our problem here is where we're getting like a repeated outcome. If we say um.
Pat: Oh hey we already have specific outcome in there.
Caleb: Yeah.
Pat: So how about we say specific unique outcome?
Caleb: Yeah.

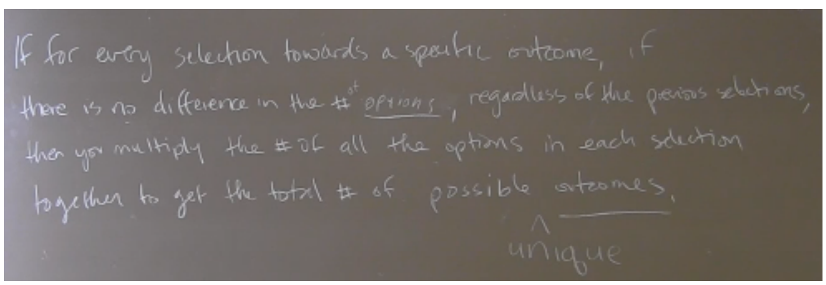

Figure 12 – The students' final statement

With this work, Pat and Caleb arrived at a final statement of the MP. In terms of the statement types identified in Lockwood, Reed, and Caughman (2015) this is a *bridge* statement, because they are counting something structural ("the total number of possible unique outcomes"), and yet those outcomes are tied to a process of making selections. Thus, we note that the students' statement aligned with a bridge statement. And, although we do not have time to provide details, the students were able to make sense of a number of statements we gave to them. In particular, they interpreted Tucker's (2002) bridge statement, from Figure 3 above. They were able to make sense of the statement and relate it to theirs. Caleb said, "That kinda gets back to ours. It addresses the independent choices and the unique outcomes." And said " So each R1 would be the selection and then the sub N M and yeah that's what they used, are like the sub things, would be their options. So this stage would be their selections, and the outcomes in this stage are the options." He concluded by saying "I think if we broke down each of ours we could basically reword them to be the same."

Conclusion and Implications

To summarize our findings, we present the students' broad progression of statements of the MP (Table 2). They key sessions in their reinvention were 2, 4, and 6-7.

Session	Statement
2	#1 – Use multiplication in counting problems when… there is a certain statement shown to exist and what follows has to be true as well.
4	#2 – For each possible pathway to an outcome there is an equal number of options leading to that path but without repeating the same pathway more than once.
6-7	#3 – If for every selection towards a specific outcome, there is no difference in the number outcome, regardless of the previous selections, then you multiply the number of all the options in each selection together to get the total number of possible unique outcomes.

Table 2 – The students' progression toward a statement of the MP

By having students reinvent a statement of the MP, and by closely analyzing aspects of multiplication to which they attend, we gain insight both into how students reason about the MP, and also how productive reasoning about the MP might be developed. In particular, by engaging with particular tasks, the students we worked with were able to come to reason about key mathematical aspects of the MP (such as independence and unique outcomes) that they wanted to include in their statement of the MP. In addition to insights about how they come to understand particular mathematical ideas, we can draw a couple of key conclusions from their overall progression from to a final statement.

First, we have an existence proof that it is possible for students to develop, through guided reinvention, a mathematically rigorous statement of the MP. It is not trivial to characterize many of the subtle mathematical details of the MP, and it is impressive that the students were able to do so. Second, we see that although they were able to accomplish this task, characterizing when to use multiplication in solving counting problems was not a straightforward activity. This is demonstrated most clearly in their first statement, which shows that even after they had successfully used multiplication in counting problems for two sessions, they still struggled with articulating a formal/general statement about it.

Our findings suggest a couple of implications. First, as a fundamental aspect of counting, the MP is invaluable, yet potentially challenging, for students to understand well. Although it deals with a familiar operation, it entails subtle mathematical features, which might take time and effort for students to learn. In terms of research, we plan to continue to explore what might be entailed in a robust understanding of the MP, which includes interviews with more students and also with mathematicians. Based on our findings from this study, especially insights about understanding independence and distinct composite outcomes, we can look to design instructional interventions that might draw students' attention toward such ideas.

Pedagogically, more work is needed to more carefully evaluate how best to teach the MP to students in a classroom setting, but our findings suggest that it may be worthwhile to unpack some key mathematical issues of the MP with students. Instructors should appreciate and seek to understand the mathematical details in the MP and should help students think carefully about when multiplication properly applies in counting situations.

Developing mathematical knowledge for teaching in content courses for pre-service elementary teachers

Billy Jackson

University of Maine

Meredith Muller
University of Maine

Abstract. The article reviews efforts of three iterations over the course of three semesters in developing a written assessment of the mathematical knowledge for teaching (MKT) of pre-service elementary teachers enrolled in a course on number and operations. Content addressed in the items discussed in the article include discourse knowledge (DK) coupled with specialized content knowledge (SCK). Results show that the pre-service teachers can engage in reasoning and justification up to a point and use their discourse knowledge in novel ways and situations, though there appear to be limits in their constructive process.

Key Words: Mathematical Knowledge for Teaching, Mathematical Discourse, Reasoning, Justification

Background and Research Questions

A central tenet of teacher education research has long been identifying the types of knowledge that teachers need to know in order to teach mathematics. Such attempts date back to Shulman's (1986) original proposal of a new type of knowledge that he called *pedagogical content knowledge* (PCK), defined as "the particular form of content knowledge that embodies the aspects most germane to its teachability" (p. 9). Since then, research teams such as Hill, Ball and Schilling (2008) and Hauk, Toney, Jackson, Nair, and Tsay (2014) have worked to conceptualize PCK. Ball and company have developed typologies for the much broader realm of *mathematical knowledge for teaching* (MKT), shown in figure 1, for which PCK is a subconstruct. Note that the left half of the oval consists of subject matter knowledge (SMK) which they claim requires no knowledge of students, thereby distinguishing it from the right half which is PCK. It is worth noting that the Ball model is specifically designed for the K-8 setting; this is important because as Speer, King, and Howell (2014) note, generalizability comes into question when trying to apply the model outside of the K-8 context.

Within the Hill, Ball, and Schilling (2008) model, *common content knowledge* (CCK) is defined as "knowledge that is used in the work of teaching in ways in common with how it is used in many other professions or occupations that also use mathematics"(p.6). In contrast, *specialized content knowledge* (SCK) is specialized in the sense that it is specific to the task of teaching. SCK includes various ways to represent mathematical ideas, provide mathematical explanations for rules and procedures, and examine and understand innovative solution strategies (Hill et al., 2008, p.377). As an example, consider fraction division. Most middle school graduates can readily use the invert-and-multiply algorithm to divide fractions. Thus, this piece of knowledge is CCK. Yet, few can explain to a novice learner *why* the algorithm exists in school mathematics nor why it is justified, thereby making this particular piece of knowledge SCK. Within the realm of PCK are *knowledge of content and students* (KCS) and *knowledge of content and teaching* (KCT). KCS is

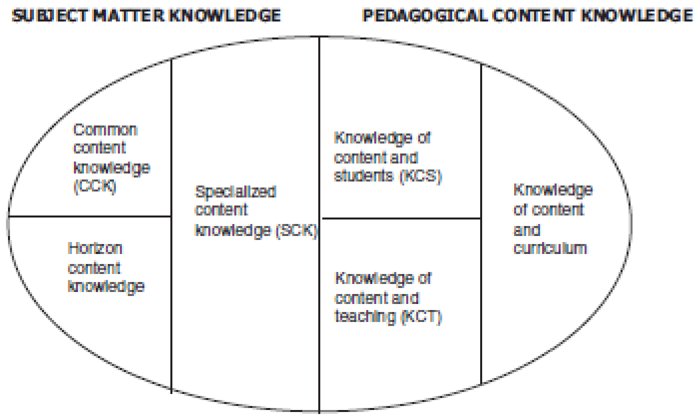

Figure 1. Domain Map for MKT (Hill et al, 2008)

"content knowledge intertwined with knowledge about how students think about, learn, or know this particular content" (p. 375), while they define KCT as a knowledge of teaching moves. So, using our division of fractions example again, a teacher who is aware that students often invert the dividend instead of the divisor is demonstrating KCS, and might use fraction diagrams as a way of scaffolding student understanding of division of fractions by using her KCT.

Implicit in the use of KCS and KCT is an awareness of the words, grammar, syntax, and forms of standard mathematical language in use – what Gee (1996) calls the "little d" discourse of mathematics. Also at work in the teaching of mathematics are nuances about what is valued in mathematical discourse in a mathematics class (as opposed to mathematics in a physics or biology class), the socio-mathematical norms for questions and answering, and myriad other interactions that make a mathematics lesson recognizable in an instant (e.g., by someone listening in or looking through the window of a classroom for just a few seconds). This kind of *situated* "little d" discourse is what Gee called "big D" Discourse. Hauk, Toney, Jackson, Nair, and Tsay (2014) have brought these ideas into a further unpacking of the components of PCK. The extended model, shown in Figure 2, adds a fourth dimension to PCK called *Knowledge of Discourse* (KD). Hauk et al. argue that effective teaching of mathematics includes facilitating student learning of *mathematical discourse* (along with other discourses), which we define as Discourse about mathematics that is enacted in the classroom when students and teacher engage in mathematically appropriate, accurate, and effective communication situated in the context of reasoning and justification of mathematical ideas. Clearly, a rich and textured Knowledge of Discourse is required for teachers to use and promote the valued mathematical skill of justification: engaging in reasoning about and explaining how one knows something is true (Cioe, King, Ostien, Pansa, and Staples, 2015).

Here, we use *accuracy* to denote that the statements in a declaration are in fact mathematically true, while *effectiveness* concerns the degree to which an explanation can fully demonstrate the necessary mathematical ideas and reach its intended audience (e.g. elementary students in the case of K-8 pre-service teachers). *Appropriateness* takes into consideration the level of mathematical sophistication of the argument's audience. As an example, consider the case of a 3rd grade teacher Alicia who is working with her students on even and odd numbers. The students have noticed a pattern: when you add two even numbers, you get another even number. To help the students understand why this is true, Alicia is considering the following two explanations:

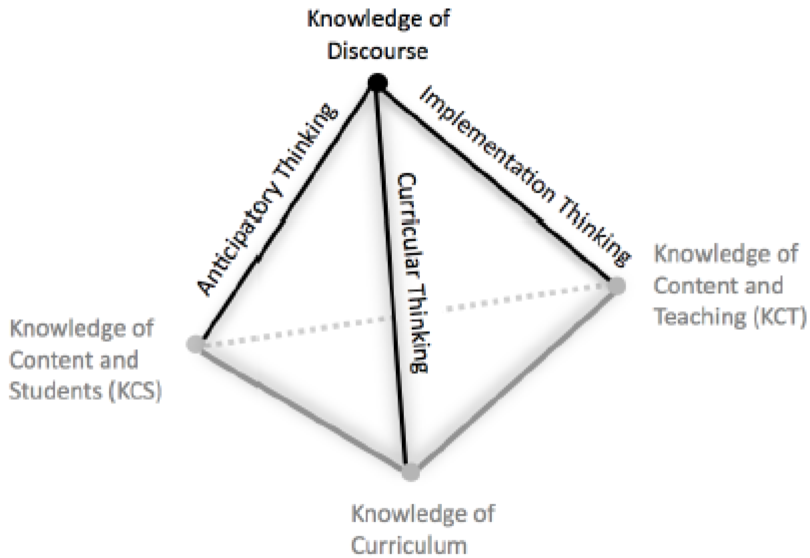

Figure 2. Tetrahedron Model of PCK (Hauk et al., 2014)

Explanation 1: “If you think about it, every even number is 2 times another number: 6=2x3, 8=2x4, and so on. So let’s let the first even number we are adding be 2xm where m is some number. Let’s let our second number be 2xn where n is some other number. When we add them, we get 2 x m + 2 x n , but by the distributive property, we can say that 2 x m + 2 x m is the same thing as 2 x (m+n), so that the new number we get is also 2 x some number, so it must be even as well.’’

Explanation 2: “If you think about numbers as being sticks, then I can always put even numbers into bundles with 2 sticks in each bundle: for example 6 can be put into 3 bundles of 2 sticks each, 8 can be placed into 4 bundles of 2 sticks each, and so on. So if I am adding two even numbers, then the first number can be placed in bundles of 2 sticks each and so can the 2nd number. But when I add up all the bundles of 2, I get a number that still is placed into bundles of 2, so the number I get must also be even as well.”

In the first explanation, we see that Alicia’s reasoning is certainly accurate. However, for most 3rd graders, her explanation will neither be effective nor level appropriate as her audience has not developed facility with the concept of variable. Contrast this to say an 8th grade audience where her first explanation is now accurate, effective, and appropriate as variable quantities arise in the course of solving linear equations, which is a 6th grade standard in the Common Core. As for the second explanation, if Alicia is speaking to 3rd graders, then she is now mathematically accurate, effective, and appropriate. However, if she is teaching an 8th grade audience, the second argument will be accurate and effective, but **not** level appropriate as most of her students are able to reason with the concept of variable (i.e. her argument is now below the level of her students).

It is worth noting that our notions of accuracy, effectiveness, and appropriateness are similar and related to the three components of a *proof* as expounded upon by Styliandes,

Styliandes, and Schilling-Traina (2013). Though we distinguish here between a proof and justification with the latter being on a different level of rigor and generalization than that of the former, the two structures do serve the same purpose in teaching. This distinction between the two and their common goal in instruction is delineated in the third Standard of Mathematical Practice of the Common Core State Standards which states that students should be able to construct viable arguments and critique the reasoning of others. Indeed, the authors note that

> ...Elementary students can construct arguments using concrete referents such as objects, drawings, diagrams, and actions. Such arguments can make sense and be correct, even though they are not generalized or made formal until later grades. Later, students learn to determine domains to which an argument applies. Students at all grades can listen or read the arguments of others, decide whether they make sense, and ask useful questions to clarify or improve the arguments (CCSSO, p. 6-7).

For Styliandes et al., proof does each of the following:

- it uses *a set of accepted statements* in use by the classroom community that are true and available without further justification (our *accuracy)*,
- it employs *modes of argumentation* which are ways of reasoning that are valid, known to, and within the conceptual reach of the classroom community (our *appropriateness),* and
- it utilizes *modes of argument representation* which are forms of communicated expressions that are appropriate, known to, and within the conceptual reach of the classroom community (i.e. our *effectiveness).*

The available justifications a person could provide for an item of mathematical knowledge will be limited by the person's ways of knowing that knowledge. Balacheff and Gaudin (2010) use the term *conception* to model different ways of knowing. A conception has four primary components: a set of problems, a set of operators, a representation system, and a control structure. The set of problems is a collection for which a conception can be utilized to determine their solution (which they call the *sphere of practice* of the conception), while the set of operators consists of those objects needed to transform and/or manipulate linguistic, symbolic, or graphical representations. The representation system contains the linguistic, graphical, and symbolic means by which the person who holds the knowledge interacts with that particular piece of knowledge, while the control structure consists of all the means needed to make choices, to take decisions, and express judgment. Of particular interest to us is the representation system because of its relevance to discourse knowledge. Indeed, Balacheff and Gaudin (2010) note that "Whatever it is, depending on the state of the subject/milieu system, the representation system must be adequate to give account of the problems and to allow operators to perform" (p. 215). In essence, a lack of a sufficient representation system, which includes an appropriate mathematical discourse that acts as a referent for the knower, will fail to allow the operators to perform. For example, if a teacher tells her student that to solve the equation $x^2 = 25$, it is necessary to perform the inverse operation of taking the square root, such an action would have no meaning for the student if they lack an awareness and understanding of what is meant by "inverse," and hence the student is hindered in her ability to take the action of performing the square root operation needed to solve the problem.

To measure PCK and MKT more generally, both the Ball and Hauk research teams developed multiple choice assessments designed for administration to in-service teachers receiving professional development for Ball's team and completing a master's degree for mathematics teachers in the case of Hauk's team. It should be noted that in the case of Hauk's team, the focus was on the PCK development of teachers at the 7-12 level unlike Ball's team. While items in the instrument developed by Hauk's team measured in large extent the syntactic structure of KD and did attempt to measure the teachers' ability to engage in proof validation, neither their instrument nor the items developed by Ball's team measure the larger components of discourse required to engage in reasoning and justification: i.e., neither team tried to specifically measure mathematical discourse more generally. Hence, the current project is designed to address three key missing ideas in the existing literature: (1) How might discourse knowledge development be characterized for pre-service elementary teachers (PSETs) during a semester long course on number and operations? (2) How can discourse skills support reasoning and justification among PSETs? (3) What conceptions about number and operations do PSETs have as they enter a course on number and operations?, How prevalent are these notions among this group of PSETs?, How have these conceptions evolved by the end of the course?

Research Methods

Beginning in the summer of 2011, an instrument was developed to begin measuring different aspects of MKT for PSETs with particular emphasis on items that require some combination of SCK, KCS, and KD. Our emphasis for the current work is on the subset of items requiring a combination of SCK and KD to answer. The teachers must engage in mathematical discourse to justify certain mathematical facts or procedures to answer these items. Examples of the items from the most recent administration of the instrument are given below:

- You have given the multiplication exercise in part (a) [i.e., compute 2.74 x 2.2] to your 4th grade class. Shonte, one of your students, says that she knows where the decimal goes, but she does not know why it goes there. Give Shonte an explanation that she can understand for why the decimal is placed where it is.

- John asks you in math class one day why $4^0 = 1$. Give John an explanation that he can understand for why this is true.

- Nancy, a student in your 5th grade math class, asks you day why she cannot divide 5 by 0. That is, why she cannot do 5 ÷ 0. Give Nancy an explanation that she can understand for why she cannot do this.

- Give an explanation for your 7th grade students that they can understand for why it is that $\frac{5}{6} \div \frac{2}{3} = \frac{5}{6} \times \frac{3}{2}$. That is, why the invert-and-multiply algorithm works for division of fractions.

These items were chosen for inclusion in the instrument because it is well documented in the teacher education literature that the ideas needed for the items' completion are ones with which both in-service and PSETs commonly struggle. For instance, Levenson (2012) discusses in-service elementary teachers' lack of ability to distinguish between definitions and theorems when considering the zero exponent. Wheeler and Feghali (1983) and Russell and Chernoff

(2011) found that both PSETs and in-service teachers tend to have the same conceptualizations of zero as many children do, such as the notion that zero is not a number and/or it means nothing. Even and Tirosh (1995) found that many of their in-service teachers answered that 4 divided by zero is undefined, although none could explain why: most simply stated it is a mathematical rule. However, other researchers (e.g. Crespo & Nicol, 2006; Ball, 1990; Wheeler & Feghali, 1983) have found that many PSETs do not even know that the expression is undefined, let alone know how to explain why it is undefined. Some PSETs remembered a rule of anything divided by 0 being 0, while others reasoned that the answer should be 0 because you are dividing by nothing. Ma (1999) found that among the American in-service teachers she interviewed, only about half could perform the division of two fractions, while most could not create a word or story problem modeled by fraction division. The ones who did perform the division correctly relied almost solely on the invert-and-multiply algorithm and none could explain why the algorithm works. Tirosh (2000) discusses the differences in "knowing that" something is true and "knowing why" something is true; the PSETs in her study also failed to explain why division of fractions behaves in the manner it does algorithmically. Stacey et al. (2001) report an over reliance on rules and facts among PSETs when performing operations with decimals such as occurs in decimal placement in multiplication.

PSETs enrolled in a course on number and operations at a large public state university in the northeastern US were given the instrument upon entering the course as well as upon exiting in a standard pre-post format. During the course, PSETs are expected to consistently engage in mathematical discourse. This discourse generally occurs through reasoning and justification that is deemed as acceptable and appropriate for elementary aged children as this is a socio-mathematical norm exercised in class and group discussions, online homework exercises, and on exams. The instrument contains 13 items (including the four mentioned previously), and the current report focuses on data collected from 6 sections of the course between Fall 2014 and Fall 2015 semesters, with N=113 teachers. In addition to administering the instrument, several teachers were interviewed during this time concerning their answers to 3 of the items to discern their abilities to communicate effectively orally in addition to written formats. Participants were also presented with novel (to them) tasks during the interviews that gauged their abilities to engage in reasoning and justification more generally through proof validation by determining the accuracy of different explanations. For instance, one of the items in the instrument asks for a justification of the invert-and-multiply algorithm. During the interviews, the teachers discussed their own justifications for the algorithm and then were presented with justifications that had not been discussed during the course and were asked to discuss the appropriateness of the justification for an elementary classroom.

Each of the four items for all teachers were coded using a grounded theory approach by a research team consisting of a mathematician, a mathematics educator, and a graduate student enrolled in an education Master's of Science program. Responses were assigned a triple of the form (T, E, A), where the T measures mathematical accuracy on a scale of 0-4, the E measures effectiveness on a scale of 0-2, and the A measures appropriateness also on a scale of 0-2. Our rubric is summarized in Figure 3: note that Yumus (2001) provides a scale similar to ours in the accuracy construct.

Data Analysis and Results

	0	1	2	3	4
Mathematical Accuracy (0-4 scale)	No Response	Restates Item or relies on rule	Attempts to explain but fails	Accurate but lacking details	Accurate with sufficient details
Effectiveness (0-2 scale)	Low Impact	Students not able to follow	Most students could follow		
Appropriateness (0-2 scale)	Low Impact	Is above or below grade level	Is at grade level		

Figure 3. Rubric for the discourse items

After all items for each of the 113 PSETs who took both the pre and post assessment were coded, the intraclass correlation coefficient (ICC) for the items (excluding those coded (0,0,0): i.e. the ones for which responses were not given) was calculated for all three constructs in each item to determine the strength of inter-rater reliability. These coefficients ranged from .842 to .924 in appropriateness, .845 to .947 in effectiveness, and .885 to .940 in accuracy. Hence, good to excellent agreement in the rubric use between the three researchers existed on all four items and all three constructs. The lowest coefficients among the three constructs all came from the item on fraction division. Items were assigned a final code when at least two of the three team members agreed in their initial coding: for those responses for which none of the three researchers agreed, the item was discussed and the team came to a final consensus. This occurred about 10% of the time.

A reliability analysis was also performed on the pre and post assessments for this group of PSETs. Before stating the results, it is worth discussing the choices that the authors have made in their current analysis. It has been well documented in the psychometric literature that Cronbach's alpha, a favorite unit of analysis among social scientists, tends to be a biased estimator of reliability (Dunn, Baguley, and Brunsden, 2014; Green et al., 1977; Green & Hershberger, 2000; Green & Yang, 2009; Huysamen, 2006; Raykov, 1998; Sitsma, 2009;Zimmerman et al., 1993; Zinbarg et al., 2005). Even Cronbach (2004) himself, together with Shavelson, stated that "The numerous citations to my paper by no means indicate that the person who cited it had read it, and does not even demonstrate that he had looked at it" (p. 392). The use of alpha is appropriate when the assumptions of *tau-equivalence* are met, which requires that the items in a measurement essentially have standard deviations that are at least relatively close to one another, an assumption that is rarely met in most psychological measurements (Dunn, Baguley, and Brunsden, 2014). Alpha also tends to be sensitive to normality assumptions in the data, with skewness affecting the resulting statistic (Sheng & Sheng, 2013). Further complicating our current analysis is the fact that our data are ordinal, something which can further bias estimates of reliability by severely underestimating them, especially in the presence of skewness (Gadermann, Guhn, & Zumbo, 2012).

In light of this, many psychometricians favor the use of McDonald's omega (Dunn, Baguley, and Brunsden, 2014; Graham, 2006; McDonald, 1999; Revelle & Zinbarg, 2005; Zinbarg et al., 2005, 2006, 2007) over the use of Cronbach's alpha, especially when data are congeneric rather than tau equivalent. Given that our data are ordinal, skew (as is to be expected at least for the pre assessment), and not tau equivalent (i.e. the standard deviations of the items are significantly different from each other), we calculated McDonald's omega for the current data set and found on the pre-assessment, $\omega_{pre} = .62$, while on the post-assessment, $\omega_{post} = .73$. As is the case with Chronbach's alpha in small N studies, values of .6 or higher are considered acceptable, and so we can be reasonably confident that the items are demonstrating unidimensionality.

As we coded the responses for the four discourse items discussed earlier, several themes about PSET conceptions emerged among them for each item. These themes are summarized in Figures 4-7. As expected, many PSETs entered the course with limited conceptions about the number 0, some thought that the decimal should be placed in the hundredths place in the multiplication exercise, and the few who attempted the fraction division item generally responded with a rule. Thus, we see connections with the existing literature: however, we are also now getting a sense of just how pervasive these conceptions are, at least for this population of PSETs. Note that each of the tables summarizes the frequency counts pre and post of PSETs who held those particular conceptions: this then means that the post counts will differ from the pre counts as many of the PSETs have changed their conceptions, usually to a conception more in line with what is presented in elementary curricula.

Theme	Pre Count	Post Count
Count the # of places	47	21
Reference to place value	7	40
Estimation	4	2
Line the numbers up	8	2
Other (to test the children, pizza/apples, as part of the algorithm)	3	1

Figure 4. Summary of themes for conceptualizations for the decimal item

Each item has its own interesting and intriguing conceptions. For decimals, many PSETs generally entered the course by stating the rule for counting the number of places after the decimals in the problem and then placing the decimal that many places from the right in the answer. Others made a vague reference to place value in saying that the decimal distinguishes the ones place from the tenths place. Note that many of the 40 PSETs who mentioned place value in the post test also gave answers that were conceptually sound and therefore considered accurate, appropriate, and effective. A few PSETs gave size arguments (i.e., the idea that the decimal must follow the 6 because 60.28 is too large since the answer should be close to 6), while others thought that the numbers had to be lined up as they are in addition and subtraction, and then the decimal would be placed after the 0 since the answer will have hundredths.

Theme	Pre Count	Post Count
0 power means you aren't multiplying by anything	15	1
0 is not a real number	3	2
How many fours do we have?	4	1
Answer is 0/4/There is no answer	3	1
Pattern is Divided by 2	2	2

Figure 5. Summary of themes for the zero power item

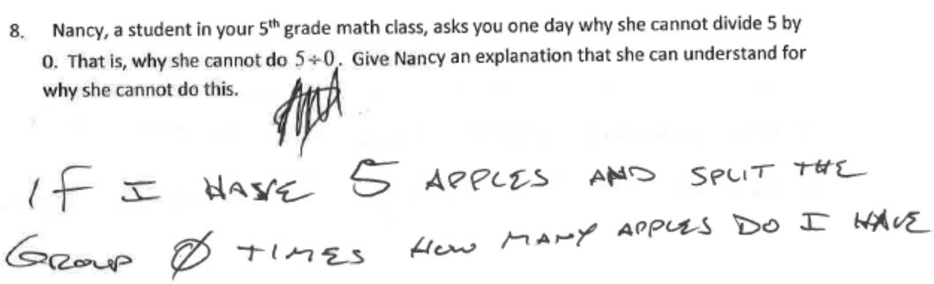
In the zero power item, some PSETs exhibited 'nothing; or 'nonnumeric' conceptions of zero. This is of particular interest here because in terms of Balacheff and Gaudin's (2010) framework, the PSETs' representation systems seem to be impacting their understandings significantly. If, because of linguistic constraints, I say that because 0 means the absence of something, or likewise that zero means nothing, then my cognition is going to be stable when I think of exponents as repeated multiplications: i.e., in Piaget's terms, cognitive disequilibration does not automatically occur as I can give meaning to a mathematical idea that occurs *on the boundary* or *at an extreme* of applying a definition for exponents that seems to fit with my current understanding of what zero is. Students in calculus courses face a similar issue in trying to understand infinite limits: in linguistic terms, if one says that a limit *is* infinite, then should not that limit exist? Interestingly enough, many PSETs are faced with a challenge to this line of thinking about the zero exponent for the first time in these courses: it is not uncommon for one or more of their classmates to hear this line of reasoning and ask why the answer is not 0 then, which of course accounts for a few of the other responses given in the pre-assessment. These are precisely the moments when cognitive disequilibrium first occurs for many of the PSETs, and they begin to realize that their representation system for the number 0 does not suffice to respond to such a challenge. Blake and Verhille (1985) agree that the "zero is nothing" interpretation "effectively prevents the teaching of the deep, complex structure of zero" (p. 37) : this is due in large part, they claim, to the linguistic structure of the representation system for 0 (i.e. in particular the use of common language creates a superficial understanding of what zero actually is).

The division by zero item saw reinforcements of the notions that the number 0 is not a real number or that it means nothing, as expected. However, we now have an idea of just how pervasive such conceptions are among this student population: of the N=113 PSETs who took the pre and post assessments, almost half (48.67%) mentioned these ideas in their responses. Such a finding clearly has implications for the teacher educator as it shows how important it is to help teachers redefine their representation system for the number zero as mentioned earlier. Several PSETs tried to use what Levenson (2009) calls *practically based explanations* (PBEs),

Theme	Pre Count	Post Count
Apples/Pizza	25	2
Can't divide something by nothing	40	7
0 is not a real number/undefined number	15	5
Dividing by zero doesn't make sense	2	1
The answer is 0 or 5	9	4
Multiplication and division are inverses	0	8
There are infinite or 2 answers so undefined	0	9

Figure 6. Summary of the conceptional themes for the division by zero item

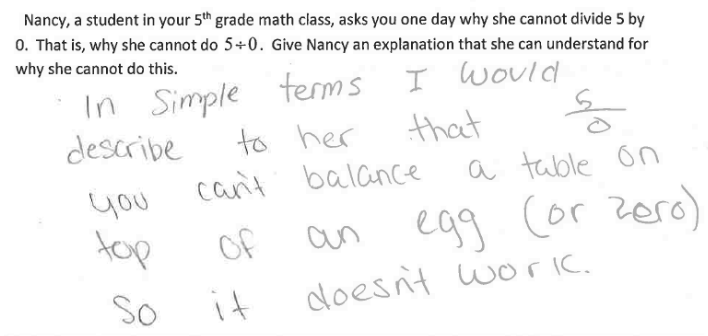
where daily contexts and/or manipulatives "give meaning" to mathematical expressions. PBEs are in contrast to *mathematically based explanations* (MBEs), which are based on mathematical definitions or previously learned mathematical properties and hence often use mathematical reasoning. Levenson (2009) found that although in some instances 5th graders preferred PBEs, almost all unequivocally were capable of and actually produced MBEs. Now, like Levenson, we do not argue that PBEs are not to be used in all cases, since as Dreyfus (1999) notes, "for mathematics educators there appears to be a continuum reaching from explanation via argument and justification to proof" (p. 102). However, in the case of division by zero, PBEs can lead to problematic conceptions because many of these explanations often are based on the representation of zero as meaning nothing, which then leads to the belief that the answer should be 0 or 5, as we saw occurring in our data. For example, consider the following explanation offered by one of our PSETs on the pre-assessment:



8. Nancy, a student in your 5th grade math class, asks you one day why she cannot divide 5 by 0. That is, why she cannot do $5 \div 0$. Give Nancy an explanation that she can understand for why she cannot do this.

IF I HAVE 5 APPLES AND SPLIT THE GROUP Ø TIMES HOW MANY APPLES DO I HAVE

This example brings out several intriguing points. First, whereas Ma (1999) discusses the tendency of American elementary teachers to use circular foods when discussing fractions, similarly we found almost a fifth (22.12%) of our PSETs used a PBE that included some reference to apples, such as this student (who actually tended to be quite capable mathematically during the course interestingly enough). Second, as Levenson (2009) and Levenson, Tsamir, and Tirosh (2007) note, a common response from elementary students could be that you did not actually divide in this case by this line of thinking so the answer should be 5, or some others might say that you end up with 0 groups and so the answer should be 0. Again, it is likely this line of reasoning that nine of the PSETs used when they indicated initially that the answer is 0 or 5. The division by zero item, unlike the other three items, also brought out new conceptions in the post assessments. Some PSETs realized that understanding the division by zero item has something to do with connecting multiplication and division as inverses but failed to explain this connection in this particular instance, while others tried to use the notion that for an arithmetic expression to be defined, there should be one and only one value that can be assigned to that expression for consistency: they of course failed to see that while true, this idea does not apply in this particular case. The team also found the following pre-response particularly intriguing:



Nancy, a student in your 5th grade math class, asks you one day why she cannot divide 5 by 0. That is, why she cannot do $5 \div 0$. Give Nancy an explanation that she can understand for why she cannot do this.

In Simple terms I would describe to her that $\frac{5}{0}$ you can't balance a table on top of an egg (or zero) So it doesn't work.

This is obviously a PBE that is essentially rule bound: however there is an attempt to explain and so we coded this response (2,0,0). This PSET has a rather fascinating representation system for the problem: the division symbol represents the table top and the 0 is the egg. For her, her conceptualization is adequate to convince a 5th grader of the inability to divide by zero. She has not been challenged with the thought of the egg being extremely large and the table extremely small (say the size of a table in a dollhouse), so that one could indeed balance the table on top of the egg. Thus again, cognitive disequilibration does not occur for her because her conceptualization makes sense to her and is hence very stable. It is worth noting that as division by zero has become a rule for her, this rule is now an operator for her conceptualization.

Theme	Pre Count	Post Count
Multiplication and division are inverses/ opposites	8	5
It's the same as cross multiplying	8	6
Keep/switch/flip	4	3
Use decimals/double negative	2	0
It's easier than dividing	0	2
Division is repeated subtraction	0	1

Figure 7. Summary of conceptualization themes for the fraction division item

Table 7 summarizes the different conceptions for the fraction division item. Not surprisingly, this item proved to be the most challenging of the four items for the PSETs, both pre and post. Many of the PSETs chose not to complete the item, although about a third made an attempt in the post test. Again, we see that some of the PSETs have rule bound conceptualizations in which the rules have become operators. Some mentioned that multiplication and division are inverses, though they could not explain how this fact helps to reason about the invert-and-multiply algorithm.

Each of the four items were discussed during the course at some point, and so the PSETs were exposed to arguments for them that are commonly seen in elementary curricula. The instructor at one point in the Fall 2015 semester decided to give an item as a bonus on the first exam that had not been discussed in class to see how many PSETs could use their discourse knowledge to reason in a novel (for them) situation. To this end, the students were presented with the following:

> You are introducing decimals for the first time to your 4th grade class. As the class talks about the place values of digits after the decimal, Tomeka, one of your students, asks you the following:
>
> "So we go from the 100s place to the 10s place to the 1s place to the 10ths place to the 100ths place. Why is there no 1ths place? I mean, to the left of the decimal we went from 10s to 1s, so why do we go from 1s to 10ths; why not go from the 1s place to the 1ths place?"
>
> Give Tomeka a mathematically accurate, effective, and level appropriate answer for why there is no 1ths place.

Almost 20% of students gave explanations that were considered acceptable. Two of the representative responses are shown below:

Because we go from the 10^2 to the 10^1 to the 10^0 to the 10^{-1} which is the tenths place. There is not place in between 10^0 and 10^{-1}. Plus, if we have oneths place, it would be the same as the ones place Because any whole number over one is in the ones place – i.e. $\frac{8}{1} = 8$.

There is no 1^{ths} place because we can represent a decimal as $\frac{1}{10}$ for the tenths, or $\frac{1}{100}$ for the hundreths. We would therefore represent the 1^{ths} as $\frac{1}{1}$, which would give us 1.

Of course, these responses only show that there is a possibility that these PSETs are reasoning in novel situations because it is quite possible that they had previously been exposed to this very situation and so were already aware of an appropriate, effective, and accurate response. However, at the very least the responses demonstrate that some PSETs are developing discourse knowledge and using it in commanding ways to communicate intricate ideas.

A paired samples t-test was performed on all four items for each of the three constructs to gauge changes in means. Statistically significant learning gains occurred in all four items for each construct with all p-values of .000. The largest gain in accuracy was in the zero power item, while the smallest gain in accuracy from pre to post was in the decimal item. The largest gains in effectiveness and appropriateness were in the zero power item, while the smallest gain for these two constructs was in the fraction division item. Hence as a whole group the 113 PSETs showed growth in their ability to engage in mathematical discourse and use it to engage in reasoning and justification.

Implications and Conclusions

PSETs have a myriad of conceptions when it comes to number and operations, especially about the number zero. Our data suggest that these conceptions (which are well documented in the literature) are very prevalent among PSETs. Courses for PSETs must include attention to helping PSETs redefine their representation systems as often times such courses will be the last chance many of these PSETs have to construct conceptions that are useful for the classroom before they actually begin teaching. There appears to be some hope that such efforts can be successful as we saw that at least some of the PSETs moved away from conceptualizations in which rules acted as operators for them to conceptualizations in which a rich mathematical discourse knowledge allows them to justify claims, perhaps even in novel situations such as the oneths place example. The data on decimals suggests an even more problematic concern in that it shows that some PSETs not only lack the SCK necessary to teach this topic, but they also lack the necessary CCK as they cannot actually do the multiplication upon entering the course, often lacking the awareness of where the decimal is placed in the answer, let alone why it goes there.

While our instrument is one of the first to try and measure discourse knowledge for PSETs, the items we included only measure one aspect of discourse knowledge: in particular, that part of knowledge that teachers "have" which is very stable and is very much in the sense of MKT that Hill, Ball, and Schilling (2008) discuss. According to Hauk et al. (2014), there is also a more dynamic side to discourse knowledge that actually comes from attending to and being responsive to student productions and discourse that occurs in problem solving and justification. Hence, future item development should include attending to measuring this dynamic side of discourse knowledge in robust ways. The importance of developing and measuring both facets of discourse knowledge becomes evident when one considers the vision of the mathematics classroom set forth in the Common Core Standards of Mathematical Practice.

Further analysis and consideration of PSETs' conceptions based upon Balacheff and Gaudin's (2010) framework is also needed. Understanding the nature of these conceptions will be crucial for aiding teacher educators in creating learning environments that are conducive to helping PSETs reinvent those conceptualizations.

Eliciting mathematicians' pedagogical reasoning

Christine Andrews-Larson
Florida State University

Valerie Peterson
University of Portland

Rachel Keller
Virginia Tech

Given the prevalence of work in the RUME community to examine student thinking and develop instructional materials based on this research, we argue it is important to document the ways in which undergraduate mathematics instructors make sense of this research to inform their own teaching. We draw on Horn's notion of pedagogical reasoning in order to analyze video-recorded conversations of over twenty mathematicians who elected to attend a workshop on inquiry-oriented instruction at a large national mathematics conference. In this context, we examine the questions: (1) How do undergraduate mathematics instructors engage in efforts to make sense of inquiry-oriented instruction? (2) How does variation in facilitation relate to instructors' reasoning about these issues? Our findings suggest that the nature of participants' engagement with the mathematics was related to their subsequent pedagogical reasoning, and that differences in facilitation appear to have played a role in how participants engaged in the mathematics.

Key words: mathematicians, pedagogical reasoning, instructional change

National organizations have called for instructional change in undergraduate Science, Technology, Engineering, and Mathematics (STEM) courses, relating poor instructional quality to a lack of student interest and persistence (e.g., Fairweather, 2008; PCAST, 2012; Rasmussen & Ellis, 2013). In response to this need, undergraduate mathematics education researchers have developed and documented student-centered instructional approaches that are related to greater conceptual learning gains, as well as the development of more productive and equitable student attitudes and dispositions when compared with classes in which lecture is the dominant form of instruction (e.g. Kogan & Laursen, 2013; Kwon, Rasmussen, & Allen, 2005; Larsen, Johnson, & Bartlo, 2013). A recent meta-analysis of 225 studies in undergraduate STEM identified drastically different student outcomes between lecture-based courses and courses that actively involve students as learners; students in lecture-based classes were 1.5 times as likely to fail as students in classes with active learning, and students in active learning classes outperformed those in lecture-based classes on concept inventories by almost half a standard deviation (Freeman et. al., 2014).

While these findings certainly create impetus for instructional change, the fact remains that instructional change is incredibly difficult to achieve at scale. In fact, we posit that the question of how to achieve instructional change at scale is one of the most central, pressing questions facing mathematics education researchers today in both K-12 and undergraduate contexts. The undergraduate context has the potential to provide fresh insights into this issue, as many of the challenges faced in the K-12 context (e.g. lack of instructor autonomy, weaknesses in content knowledge) are likely to be less of an issue when dealing with mathematics instructors at the undergraduate level. Given the prevalence of work in the RUME community to examine student thinking and develop instructional materials based on this research (e.g. Wawro et. al., 2013; Larsen, Johnson & Bartlo, 2013; Rasmussen & Kwon, 2007), we argue it is essential that our community consider issues related to the dissemination and use of findings from our research – with an eye toward engaging this broader question of how to achieve instructional change at scale. This work aims to serve that goal by examining our efforts to engage practitioners (instructors of undergraduate mathematics) in thinking about research-based, inquiry-oriented instructional materials for undergraduate mathematics courses.

Literature

It is well documented that instructional change is difficult to achieve at scale. In particular, after reviewing 191 relevant articles, Henderson, Beach & Finkelstein (2011) highlight the fact that the development of research-based instructional materials is a common but ineffective way to support instructional change at scale, and argue that their review of the literature suggests that effective change strategies should be sustained over time and seek to align with or change individuals' beliefs while taking into account their institutional setting. We put these findings in conversation with the work of Nardi (2007). In the context of mathematics, Nardi (2007) suggests that one possible explanation for the disappointing adoption of such curricular materials and pedagogical techniques is the fragile relationship between the mathematics education researchers who develop the approaches and the mathematicians who might implement them. On one hand, mathematics education researchers frequently draw on qualitative research methodologies, which can seem both methodologically and epistemologically distant from traditional mathematics research. On the other hand, Ralston (2004) argues that mathematicians sometimes display negative attitudes regarding the mathematical background of mathematics education researchers. Artigue (1998) contended that this tension can be heightened in that research in mathematics education "often exposes [mathematicians] to the weaknesses of [their] teaching and [their] complicity in the malfunctioning and ineffectiveness of the educational system" (p. 483).

Fortunately, in the years since Artigue's claim, there is evidence (Hurtado, et al., 2012) that suggests a sizable number of faculty in undergraduate STEM fields *are* making efforts to offer their students the kinds of student-centered learning experiences supported by mathematics education research studies. Indeed, though 61% of STEM faculty report they use extensive lecturing when they teach, a full 49% of STEM faculty report they incorporate cooperative learning into their courses (Hurtado et. al., 2012). Brown (1998) proposed that a way to keep these doors of communication open was to talk to mathematicians about mathematics: "Apart from gaining credibility with mathematicians, mathematics education researchers who stay in touch with the subject are likely to maintain a more vivid sense of what the encounter with mathematics feels like and are thus in a good position to develop empathy with the learners their work is intended to support" (as quoted in Nardi, 2007, p.270).

Considering the rates at which STEM faculty now report use of cooperative learning in their instruction, we argue that there is a pressing need to document and leverage the pedagogical reasoning of those faculty who are working to implement these kinds of instructional approaches. The work described in this paper aligns with Henderson et. al's (2011) recommendations by aiming to gain insights into the beliefs and reasoning of those who might implement research-based curricular materials in undergraduate mathematics – in order to inform sustained efforts at providing a system of supports for instructional change organized around such content-specific instructional materials. This work also aligns with Brown's (1998) recommendation by engaging mathematicians in the curricular tasks and the mathematics underlying them; in this way workshop facilitators attempted to leverage mathematical conversations into pedagogical ones. In this paper, we explore two research questions: (1) How do instructors of undergraduate mathematics (who are interested in inquiry-oriented instruction) reason about instructional issues, particularly in the context of inquiry-oriented mathematics instruction? (2) How does variation in facilitation relate to the ways in which instructors engage in reasoning about these instructional issues?

Theoretical Perspective

To answer these questions, we follow Rasmussen & Kwon's (2007) characterization of inquiry-oriented instruction in which students are actively inquiring into the mathematics (e.g., by developing, justifying, and generalizing their own solution methods to open ended problems) and instructors are actively inquiring into students' thinking about the mathematics so as to build on students' informal and intuitive ideas to help them make sense of and engage in more formal and conventional forms of mathematical reasoning.

We take a situated perspective, in which we view knowledge and learning to be evidenced in the interactions among members of a community (Lave & Wenger, 1991) – in this case, the community of instructors of undergraduate mathematics. As such, we look to document mathematicians' pedagogical reasoning by examining their conversations about instruction. We follow Horn's (2007) characterization of pedagogical reasoning, considering it to be instructors' reasoning about issues or questions about teaching "that are accompanied by some elaboration of reasons, explanations, or justifications" (p. 46). Analytically, we draw on the vertices of the instructional triangle (teaching, students, and mathematics) as a conceptual tool for organizing our analysis of these conversations about instructional issues.

Data Sources and Methods of Analysis

The data under consideration in this study were collected from a workshop conducted as part of a national mathematics conference, and these data are part of a broader project that is developing and analyzing a set of ongoing instructional supports for undergraduate mathematics instructors interested in inquiry-oriented (IO) instruction. The workshop was organized around research-based curricula that have been developed in the areas of linear algebra, abstract algebra, and differential equations. The workshop lasted a total of four hours, which was split across two 2-hour sessions on consecutive days. On each day, about half of the time was devoted to content-specific work in breakout groups (self-selected by the participants), and the other half of the time was spent discussing issues of inquiry-oriented instruction that cut across all three curricula. On Day 1, facilitators planned to engage participants with an overview of inquiry-oriented instruction, followed by time to engage in mathematical tasks from the curricula in the area of participants' selected breakout group. On Day 2, the focus was to be on student thinking related to the Day 1 tasks and instructional moves intended to help instructors implement IO curricula.

The workshop included 25 participants, 21 of which responded to a workshop pre-survey that provided us with information about their background and home institutions. All participants except one were housed in mathematics departments, and the group represented a diverse set of institutions and positions (see Figure 1). Less than a third of survey respondents reported that they prefer to lecture most of the time, more than 70% reported that they like to have students work in groups on problems in class, and more than 60% report they frequently ask students to explain their thinking to the whole class when they teach. This was significant to our research because it suggests our sample is part of the sizable subset of undergraduate STEM faculty working to teach in student-centered ways, and the choice to attend the workshop also points to an interest, outside the RUME community, in research-based instructional approaches.

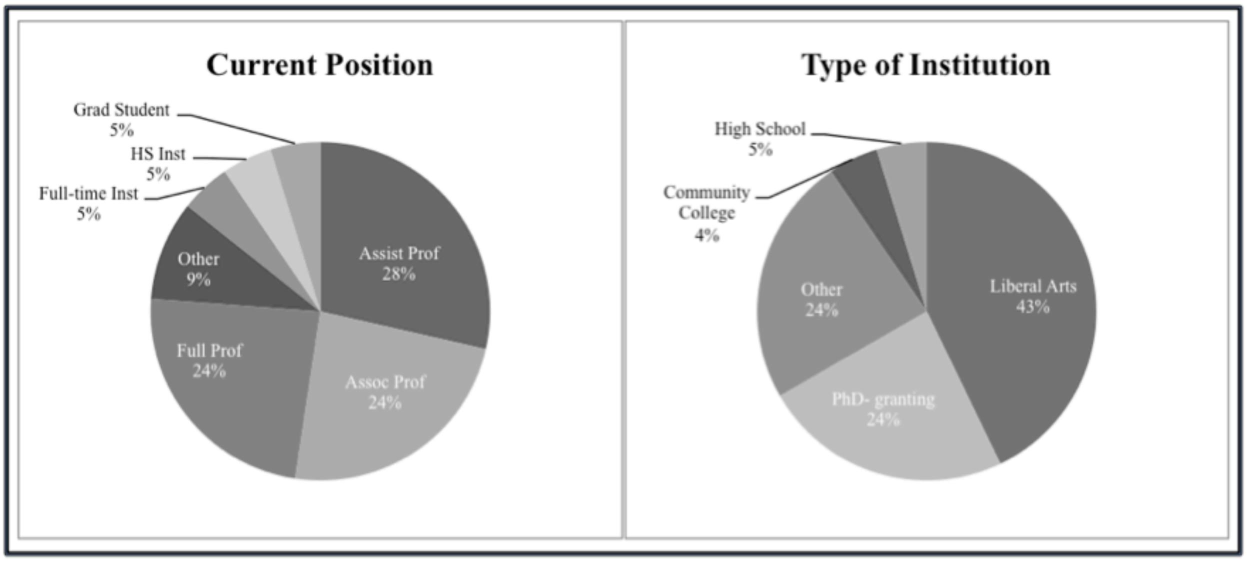

Figure 1. Position and Institution Types of Survey Respondents

In each of the two 2-hour workshop sessions, all whole-group and breakout segments were video- and/or audio-recorded for subsequent analysis. Our first phase of analysis was to analyze recorded data by generating content logs to document the sequence of events in each segment of the workshop. Each content log was organized in a table with four columns: timestamp, description of events, focus of talk, and other comments. The 'focus of talk' column aimed to help us track whether the focus of talk was on the mathematics (M), the teacher (T), or students (S), and whether it was the facilitator or participants who were doing that talking. From these content logs, we generated summaries of each session to describe the focus and use of the time along with initial characterizations of the participants' pedagogical reasoning. We noted stark differences in the conversations of the linear algebra breakout group as compared to those in the abstract algebra group, so we decided to conduct our analysis as a comparative case study of these two groups (Yin, 2003).

In our second phase of analysis, we drew on our content logs to code talk into six categories: logistics (e.g., "Does everyone have a handout?"), participant introductions, implementation questions (e.g., "How many times a week does your class meet?"), pedagogical moves (e.g., "I have them present their work as soon as we finish a task"), discussing mathematics (e.g., "They [students] came to different conclusions based on whether or not they considered all linear combinations"), and doing mathematics (e.g., "We want to show the additive inverse we'd expect from the big group stays in the small group"). In this way, we quantified the conversational focus of each group in terms of the amount of time spent.

In our third phase of analysis, we drew on content logs to identify conversational moments in which participants talk focused on the vertices of the instructional triangle: mathematics, students, or teaching. These moments were transcribed for closer analysis in order to examine participants' pedagogical reasoning, identify differences between the two groups. In our fourth and final phase of analysis, we identified facilitator moves that may have contributed to differences observed between the two groups.

Mathematical Tasks in our Study Context

The mathematical activities that were the focus of participants' time during content-specific breakout groups are research-based task sequences taken from the IOLA (Inquiry-Oriented Linear Algebra; http://iola.math.vt.edu) and TAAFU (Teaching Abstract Algebra for Understanding; http://www.web.pdx.edu/~slarsen/TAAFU/home.php) materials. More specifically, the abstract algebra group drew on the definition of "subgroup" (a subset of a group that is itself a group) in order to (1) show 5Z is a subgroup of Z (under addition), (2) find a simpler way than checking all the group criteria to check if a subset of a group is a subgroup, and (3) show the identity of a subgroup is the identity of the group.

The linear algebra group worked on activities from a sequence of tasks set in a context intended to help students develop and coordinate geometric and algebraic ways of symbolizing linear combinations of vectors in order to support their learning about span and linear independence. The context for this work is shown in Figure 2. The sequence of four tasks entails (1) determining if and how a given pair of vectors in $\mathbb{R}^2$ can be weighted and combined to "reach" a particular location in the plane, (2) determining if there is any location in the plane that *can't* be reached using that pair of vectors (to set up formalization of span), (3) determining if three given vectors in $\mathbb{R}^3$ can be combined to represent a journey that starts and ends at the origin (to set up formalization of linear independence), and (4) generating examples of sets of vectors that satisfy particular properties (e.g. give an example of a set of two vectors in $\mathbb{R}^2$ that form a linearly dependent set), as well as conjectures about generalizations that emerge from this example generation work.

You are a young traveler, leaving home for the first time. Your parents want to help you on your journey, so just before your departure, they give you two gifts. Specifically, they give you two forms of transportation: a hover board and a magic carpet. Your parents inform you that both the hover board and the magic carpet have restrictions in how they operate:

We denote the restriction on the *hover board's* movement by the vector $\begin{bmatrix}3\\1\end{bmatrix}$.
By this we mean that if the hover board traveled "forward" for one hour, it would move along a "diagonal" path that would result in a displacement of 3 miles East and 1 mile North of its starting location.

We denote the restriction on the *magic carpet's* movement by the vector $\begin{bmatrix}1\\2\end{bmatrix}$.
By this we mean that if the magic carpet traveled "forward" for one hour, it would move along a "diagonal" path that would result in a displacement of 1 mile East and 2 miles North of its starting location.

Figure 2: Context for the linear algebra group's task sequence

Findings

We found that there were marked differences in the conversational foci of the two groups – both in terms of how much time was spent focusing on particular topics and issues, and in the nature of talk. In this section, we first provide examples of the way in which participants in each group talked about mathematics (M), students (S), and teaching (T). We then describe facilitator moves that may have contributed to these differences. Overall, we contend that the nature of participants' engagement with the mathematics was related to their subsequent pedagogical reasoning about student thinking and possible instructional moves, and that differences in facilitation appear to have played a role in how participants engaged in the mathematics.

As previously mentioned, the facilitators of both the linear algebra and the abstract algebra group intended for the first day's breakout group to be focused on working through the mathematics in the respective task sequences. However, our content logs revealed the Abstract Algebra group spent a much larger portion of their hour-long breakout session on the this day of the workshop working through the math (86% of the time spent working through the math) than did the Linear Algebra group (30% of the time spent working through the math). Figure 3 summarizes each breakout group's conversational focus on during the first day's breakout groups.

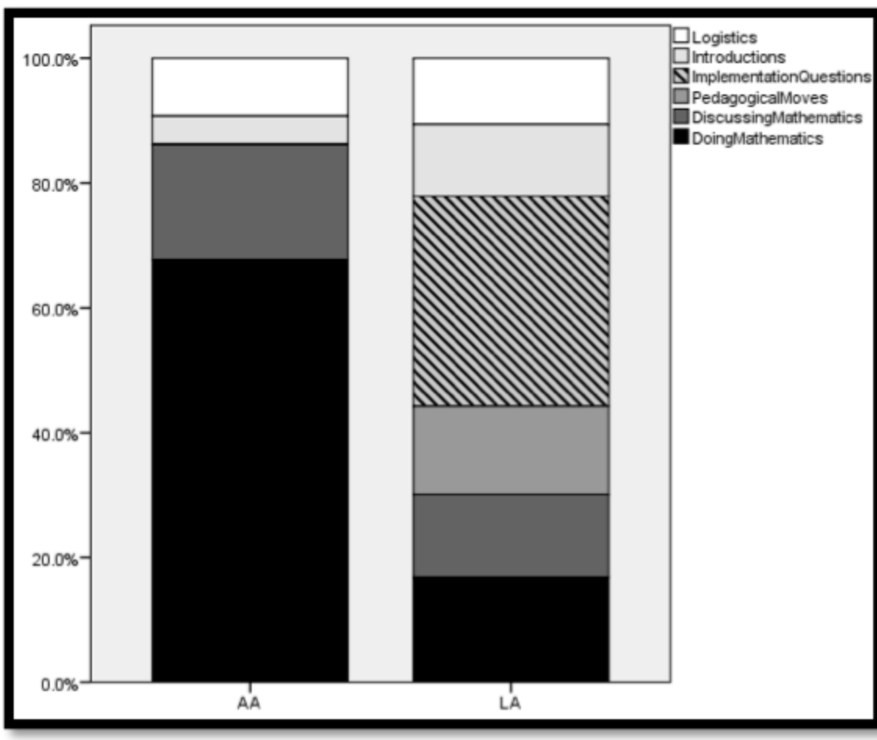

Figure 3: Conversational focus during Day 1 Breakout Groups

Trajectory of Participant Engagement: Abstract Algebra group

In this section, we highlight *how* participants engaged in the mathematics, and argue that this initial, deeply focused mathematical engagement is related to participants' subsequent reasoning about student reasoning and the role of the instructor. In particular, we highlight a trajectory of talk in which participants first engage in the mathematics (single vertex M), then discuss students' reasoning about that mathematics (two vertices M+S), and finally discuss moves they might make as an instructor in order to advance students' thinking beyond how they are currently reasoning about the mathematics (all three vertices M+S+T).

On the first day of the workshop, abstract algebra participants spent nearly the entire one-hour breakout session discussing how to apply the definition of a 'subgroup' (i.e., a subset of a group that is itself a group) in various contexts. First, they used the definition of 'subgroup' to demonstrate that 5Z is a subgroup of Z under addition. They then drew on this definition in order to develop a different, more efficient method (i.e., the subgroup criterion) for deciding when a subset of a group is a subgroup. An example of a quote that is typical of how participants engaged in reasoning through this math is, "I combined closure and inverses. We need to check for all *a* in *H* that negative *a* is in *H*. Negative *a* is in *G* because *G* is a group and it is unique, so just need to check it is in *H*." Note that this highlights our previous distinction between *'doing* the math' and '*talking about* the math' -- the participant is actually reasoning through the math directly from his/her own point of view.

On the second day of the workshop, the abstract algebra breakout group was shown a video of students explaining their partial progress in thinking about ways to develop a more efficient way to check if a subset of a group is a subgroup. Following this video, participants reasoned about how students in the video were making sense of the mathematics. For example, one participant argued:

> The group was concerned about, is the identity the same? Are the inverses the same? … Partial arguments were also generated for both including the inverse and closure gives you identity, and the identity of the subgroup has to be the identity of the group. They weren't full arguments, the students were just generating reasons that they thought that had to be.

This comment highlights participant reasoning that coordinates two vertices of the instructional triangle: *students* reasoning about the *mathematics*. While the comment doesn't fully characterize the nature of these partial arguments that were generated, it does synthesize the participant's assessment of students' mathematical contributions and reasoning. We note that the mathematics that is the subject of students' reasoning is the same as the mathematics the participants had engaged in during the previous day of the workshop.

After discussing students' reasoning about ways to develop a more efficient way to check if a subset of a group is a subgroup, workshop participants brainstormed what they would do next if they were the instructor and the whole class discussion they had just watched on video had just happened in their own classroom. The comments made by several participants evidenced a layering of reasoning involving all three vertices of the instructional triangle: the mathematics, students' reasoning about the mathematics, and what the teacher can do to help students advance their reasoning about the mathematics. The exchange below highlights this layering of reasoning:

Participant: I'm assuming they have already shown the identity is unique.
Facilitator: They have shown the identity is unique.
Participant: So, and I'm, if they haven't shown that the inverse is unique, then I would ask can an element have more than one inverse. And then I would ask what can you say about a subset of a group if it is closed under inverses.

This participant's comment shows evidence of pedagogical reasoning that attends to the mathematics (with a great degree of specificity), what students know, and what the instructor might do next to advance students' reasoning about that mathematics. We posit that participants' own deep engagement with this mathematics themselves on the first day of the workshop supported this nuanced coordination of the vertices of the instructional triangle.

Trajectory of Participant Engagement: Linear Algebra group

In addition to the fact that far less of the time of the Day 1 linear algebra breakout session was spent doing mathematics than the abstract algebra session, we observed that the nature and quality of mathematical and pedagogical conversations differed between these groups. In abstract algebra conversations, the talk followed a clearly identifiable trajectory of discourse relative to the instructional triangle, beginning with a thorough exploration of the mathematics, followed by a structured discussion about how students reasoned about the mathematics in a video clip, and finally a discussion of possible in-the-moment instructional moves that might be productive based on how students were thinking about the mathematics in the video clip. In contrast, Day 1 conversations in the linear algebra group did not follow this clear trajectory of topics, and repeatedly turned toward issues related to implementation. Due to frequent shifts in the focus of conversation of the linear algebra group, our initial impression was that participants' talk about mathematics (and consequently their subsequent talk about student reasoning about the math and possible instructional moves) was not at the same level of depth as that of the linear algebra group. A more careful analysis revealed there were examples of participants engaging in mathematical talk, but this talk was less sustained and of a somewhat different nature. We also identified distinct examples of linear algebra group members discussing student reasoning and identifying potential instructional moves in the context of the mathematical tasks posed. In this section, we highlight examples of talk from the linear algebra group that parallel examples presented for the abstract group – by first offering examples of the way in which participants talked about the mathematics, and then presenting examples of how participants reasoned about student thinking and possible instructional choices after watching a video clip of a classroom where students explained their approaches. We then consider the facilitation moves that help explain these observed differences.

Day 1: As previously mentioned, facilitators of the breakout groups collaborated to structure workshop activities so as to focus on each vertex of the instructional triangle in turn, starting with mathematics and building to consider student thinking and the role of the teacher, a structure that was reflected in the trajectory of conversation in the abstract algebra group. As in the abstract group, linear algebra participants were asked to engage in specific tasks from the curricular materials and work through the math together on the first day of the workshop. The first mathematical task the linear algebra participants were asked to engage in was whether it was possible to use two specific vectors (that were linearly independent) to "get everywhere" in the plane by "travelling" on each for different amounts of "time." Here is how one participant spoke about possible solutions to the task:

> So what they can do is, once they get a parallelogram, they can generate a new vector that is on one of the opposite sides of the parallelogram, so they can generate all of these very easily because all they have to do is take this and add one of these, or they can do the same here...

This participant's strategy for finding a solution is valid, but it is interesting that he frames his response in terms of a student's perspective without first discussing how he would himself solve the problem. Though this demonstrates a connection between mathematics and students' reasoning, it is framed hypothetically. This is in contrast with the abstract algebra participant's description of students' mathematical contributions (partial arguments for including the inverse and closure) were framed in terms of the core mathematical issue with which students were wrestling (is the identity the same) – though that comment was made after watching video of student reasoning, is perhaps unsurprising that the framing was not hypothetical.

Immediately following the parallelogram comment made by a participant in the linear algebra group, another participant shifted the focus somewhat, asked "Do they have problems dealing with the fractional? Because it might be the case that they have to ride one for a fractional amount of time…." This seemed to move the group away from doing mathematics and toward a discussion of common student responses. One participant who had previously used the materials described common student approaches, which led to a conversation of issues related to the different prerequisites for linear algebra in various departments. In an attempt to redirect the conversation and have people work through the mathematics, the facilitator once again invited participants to consider the mathematical task, this time explicitly from the perspective of a student. The first response to this, however, was "I can't think of any other way than how I would do it."

Eventually, most members of the linear algebra group worked through the task more or less completely on Day 1. They also came together for a more focused discussion about participants' own mathematical strategies, and again the conversation turned toward issues of implementation as they related to student thinking. The following excerpt highlights one of the more extensive math-focused exchanges from the Day 1 linear algebra transcript. It is noteworthy that the prompt by the facilitator at the outset of this conversation is the third such invitation for participants to share their mathematical thinking.

Facilitator: Let's start by discussing strategies because they were actually different when people solved it for themselves.

Participant 2: I immediately put the numbers in a matrix and solved for an arbitrary vector (x, y)

Participant 3: So, I am rusty on my linear algebra so I went back to the analogy, if I am given a location (x, y) that I need to get to, how long using each mode of transportation. And so I built a linear combination and then turned it into a matrix and row-reduced by hand. That way, given x and given y, I knew how long to ride this and how long to ride that. [...]

Facilitator: Were there other approaches when people solved it for themselves? [...]

Participant 4: Since the pre-req for my class is precalc and we go over systems of equations, I turned it into a system of equations, but I don't think my students would do that because it is a system with two unknowns and that would probably freak them out.

These quotes are indicative of the conversation and the types of comments heard across both days of the linear algebra breakout sessions in that when participants did speak about their own solutions to the mathematical tasks (which was infrequent compared with the abstract algebra group), their statements about math were often tied either to student thinking or to comments and questions about instructional decision-making. In other words, participants in the linear algebra group rarely made comments that were located solely on the 'math' vertex of the instructional triangle. Importantly, LA participants' engagement with the mathematics tended to be framed in terms of what "they" (students) might do, rather than in terms of their own mathematical reasoning. This stands in contrast to mathematical comments made by abstract algebra participants, who talk directly about their own solutions to the tasks, rather than referencing hypothetical student solutions and course prerequisites. While this may not in and of itself be a bad thing, it certainly seems to be a pattern that impeded the linear algebra group's deep, sustained engagement in the mathematics of the task sequence.

Day 2: During the linear algebra breakout group on the second day of the workshop, participants examined artifacts of actual student work and watched video in which students explained their reasoning. Participants were encouraged to consider pedagogical strategies in the context of teaching with these materials. For example, a participant discussed students' reasoning about three vectors in $\mathbb{R}^2$:

> If they were relating to systems of equations, then they would recognize that they would have two unknowns and three equations and if they relate it back to that then they will think, 'ok, if, assuming these aren't all scalar multiples of each other, then I am already over-determined.' Since we did systems of equations first, then they might already have some intuition about that if they relate it back to that.

We interpret this quote as evidence that this participant is coordinating two vertices of the instructional triangle (mathematics and students' reasoning). This quote was made shortly after the group viewed video clips of students talking about their solutions to this task, so it is interesting to note that the language used in this quote is hypothetical ("*If* they…, then they *might*…"). One possible explanation for this disconnect is that, having not worked carefully through the mathematics from their own perspective, it may have been difficult for participants to make sense of students' reasoning in the video if they were still thinking through the mathematics themselves as they watched.

After watching this video, participants are asked to describe how they would introduce the concept of span if students were reasoning in the way shown in the video they had just watched. One participant responded in terms of what conclusions the class had made about what locations in the plane you can reach with (linear combinations of) the given pair of vectors:

> If the consensus becomes 'everything' then you set the tone, you can go into the animation, and the definition can be using linear combinations and… all possible ways of scaling the first one and adding the second, and then scaling the second one and adding the first one… then you're primed to talk about… all possible linear combinations and it spans $\mathbb{R}^2$ in this case.

This participant's comment involves all three vertices of the instructional triangle. Similar to the "next pedagogical move" quote provided the abstract algebra group, this participant frames the next pedagogical move in terms of a relevant mathematical consensus of the class. This comment differs however, in that it is framed more in terms of what the instructor would tell the students rather than what the instructor would ask students to think about to move their reasoning forward.

Ultimately, then, there were two main points of contrast between abstract algebra and linear algebra participants' contributions during the breakout sessions. First is the clear difference in how breakout groups spent their time during sessions, with far more mathematical engagement evidenced from the abstract algebra participants. Second, while abstract algebra participants' conversation across the workshop cleanly mirrored the trajectory of the workshop activities themselves (mathematics, students' reasoning, the role of the instructor in building on students' reasoning), linear algebra participants' talk during the breakout sessions was more scattered. In the linear algebra group, multiple vertices of the instructional triangle were present throughout their conversations in a way that suggested this group consistently reasoned from an instructional perspective. We posit that this lens may have functioned to impede deep, sustained mathematical engagement among the linear algebra group and ultimately constrained an exploration of more nuanced mathematical issues as they relate to student thinking and pedagogical moves in the context of the content-specific instructional materials.

Differences in Facilitation

There were a number of differences in facilitation between the linear algebra group and the abstract algebra group, in particular with regard to the setup of participants' initial engagement with the mathematics. In this section, we detail differences we noted that might help explain differences in the nature of conversations (and thus pedagogical reasoning elicited) between the two groups. A summary of these differences is shown below in Table 1.

Linear Algebra Group	**Abstract Algebra Group**
Asked participants to introduce themselves and their teaching contexts	No whole-group introductions; participants put in pairs to work
Overview of instructional sequence given	No overview of instructional sequence
Began with second task in sequence	Began with first task in sequence
Engaged pedagogical questions throughout	Postponed pedagogical questions 'til end

Table 1: Differences in set-up of mathematics

Of particular note are differences in the way facilitators of the two groups asked participants to engage in the mathematics. For instance, the linear algebra facilitator initiated the breakout group by asking participants to sit in a circle and introduce themselves and their teaching context, pointing out that "linear algebra courses differ widely by institution… if you have one that serves mostly engineers then the goal is different than one serving math majors." After these introductions (which lasted about 6 ½ minutes), the facilitator offered an overview of the sequence of tasks (which lasted about 9 minutes), highlighting how the mathematics was intended to emerge from the sequence of tasks in the magic carpet ride context, before asking participants to begin by working through the second task in the instructional sequence:

> So, one of the things I wanted us to do was to dive in and solve Scenario 2 – not because it is particularly mathematically difficult, but so you could think about solving it and then think about it from the perspective of a student who has seen one day of linear algebra and seen linear combinations and turned it into a system of equations and solved it and that is the extent of his linear algebra – try to solve it from that perspective.

This facilitator prompt marks a clear request to consider what students might do as they engage in the mathematics – which suggests that this trend in participant engagement is clearly tied to the facilitator's framing of their work with the mathematics. Additionally, we argue that the facilitator fostered a setting that had the potential to create professional risk for participants by trivializing the mathematics involved in the activity. This professional risk might have been amplified by the fact that participants were not provided with the opportunity to work through the mathematics in the first task of the sequence, which might have been important for participants to become familiar with the task setting.

In contrast, the abstract algebra facilitator initiated that breakout group by asking participants to sit with a partner and work through the mathematics, giving them a handout with the sequence of task statements. Interestingly, the first question in the packet in some ways paralleled the introductions done in the linear algebra group. This question asked participants how they normally teach subgroups or were taught subgroups -- but this question was only answered individually or between partners (rather than discussed amongst the larger breakout group) and those captured on camera spent less than 3 minutes on this question. The first interruption to this partner work came from the facilitator about 11 minutes into the breakout session:

> This is how we start the class. A subgroup is a subset of a group that is itself a group. Use this to prove 5Z is a subgroup of Z. I get to assume 5Z is a subset. Fill in the proof.

In this way, the facilitator clearly framed how participants were asked to engage in the mathematics – namely, from a mathematical perspective.

One might conjecture that differences in participants' engagement with the mathematics arises from differences in participants' personalities, preferences, or experience with the mathematics. However, we argue that the facilitator played an important role in framing the way participants were asked to engage in the mathematics. In addition to the differences in how the two facilitators framed participants' initial engagement with the mathematics, there is additional evidence that suggests differences in participant engagement was tightly linked to facilitator moves. For example, after participants in the linear algebra group noted that they weren't sure how their students would approach the mathematics in the given task, the facilitator suggested they solve the problem from their own point of view -- a suggestion that proved fruitful for participants' mathematical engagement:

Facilitator: First why don't we hear the strategies because they were actually different when people solved it for themselves…

Participant 1: I immediately put the numbers in a matrix and solved for an arbitrary vector xy

Participant 2: I am rusty on my linear algebra so I went back to the analogy, if I am given a location (x,y) that I want to get to, I want to know how long using each mode of transportation and so I built a linear combination and then turned it into a matrix and row-reduced by hand, that way given an x and given a y, I knew how long to ride this and how long to ride that…

In contrast to the shifting expectation seen in the linear algebra group with regard to how participants should engage in the mathematics (e.g. as mathematicians or as instructors thinking from the perspective of students), the facilitator of the abstract algebra group maintained a consistent press on the first day of the workshop with regard to how participants were expected to engage in the mathematics. Examples of facilitator press that support this claim are shown below.

Facilitator: It doesn't just have to be from a student's perspective. Why does a subgroup have to have the same identity as the one in the group? [Day 1, 48:03]

[…]

Facilitator: I want to ask you as mathematicians… is your doubt removed? [Day 1, 61:10]

This sustained press to approach the tasks in the instructional materials from a mathematical perspective appears to have been a fruitful one, given the amount of time the abstract algebra group spent engaging deeply in the mathematics and the rich connections these participants were subsequently able to make with regard to student reasoning and pedagogical moves.

Discussion

Our findings suggest that when mathematicians' pedagogical reasoning is engaged through a content-specific mathematical lens, rich and layered connections among their own mathematical reasoning, students' mathematical reasoning, and possible instructional moves can be forged in a relatively short period of time. In the context of our study, these forms of reasoning were most prominent when participants engaged deeply in particular mathematical tasks before watching video of students reasoning about those same tasks, and finally discussing possible in-the-moment instructional moves that could help students move forward their mathematical reasoning. This is not to say that these conversations will lead to immediate or sustained shifts in practice, but it does suggest that mathematicians' pedagogical reasoning is a complex, understudied resource that has great potential to advance efforts aimed at instructional change in both undergraduate and K-12 mathematics – as mathematicians are the people who most fundamentally shape students' mathematical learning experiences in post-secondary educational settings.

However, the differences we noted between the abstract algebra and linear algebra groups also suggest that the way in which mathematicians are positioned to engage in this pedagogical reasoning plays an important role in the kinds of reasoning that are developed, even within the context of a short, four-hour workshop spread across two days. Importantly, we argue that engaging mathematicians' pedagogical reasoning *through the lens of mathematics*, rather than through the lens of instruction, draws on the unique strengths that mathematicians bring to the work of teaching – in particular, the resource of deep disciplinary knowledge. As noted in our findings, the facilitator plays an important role in framing mathematicians' engagement with the mathematics in a context such as the workshop in which our data were collected. Additionally, the facilitator plays an important role in managing the professional risk that these settings like these workshops can entail for mathematicians who may not often work on unfamiliar mathematics problems in public spaces without first thinking about such problems privately.

Nardi (2007) quoted Sfard's call for this kind of work in mathematics education research: "Math ed research needs to study more extensively and more systematically the mathematician's ways of thinking as they can be substantial and illuminating" (p. 265). The data presented in this paper offers a glimpse into the thinking of mathematicians interested in instructional change, and points toward what is possible when mathematics education researchers work with such mathematicians. We further argue that a way to move toward achieving instructional change at scale is by forging sustainable alliances between mathematicians and mathematics education researchers, and that these alliances should be structured so as to leverage mathematicians' deep disciplinary knowledge and teaching experience in ways that support robust instructional change. If we can learn to productively build these kinds of relationships, we can reorganize our notion of unidirectional dissemination of findings from mathematics education research into a vision of a dialogue that has the potential to mutually inform the work of those who do the bulk of undergraduate mathematics teaching as part of their broader work as mathematicians and those who research issues of teaching and learning at the undergraduate level. Alliances with mathematicians have the potential to be drivers of instructional change, and if we as a field can learn to leverage the unique resources and insights brought to these alliances by both mathematicians and mathematics education researchers, we will be far better equipped to implement changes that will more effectively support the mathematical learning of students.

Exploring student understanding of negative quantity in introductory physics contexts

Suzanne White Brahmia
Rutgers, the State University of New Jersey

Andrew Boudreaux
Western Washington University

Recent studies in physics education research demonstrate that although physics students are generally successful executing mathematical procedures, they struggle with the use of mathematical concepts for sense making. In this paper we investigate student reasoning about negative numbers in contexts commonly encountered in calculus-based introductory physics through the lens of a cognitive blending framework. We describe a cross-sectional study (N > 700) involving two introductory physics courses: calculus-based mechanics and calculus-based electricity and magnetism (E&M). We present data from assessment items that probe student understanding of negative numbers in physics contexts. Results suggest that even mathematically well-prepared students struggle with symbolizing in physics, and that the varied uses of the negative sign can present an obstacle to understanding that persists throughout the introductory sequence. We discuss the implications for instruction and directions for future work.

Keywords: quantity, negativity, minus sign, integers, physics, mechanics, electricity, magnetism

Introduction and Background

In physics, signed numbers have varied meanings and carry rich information about physical context. For students, the operations of addition and subtraction (represented by the symbols "+" and "−") can easily be confused with the descriptors, positive and negative, that characterize the opposite natures of a quantity (e.g. charge) or the value of a quantity relative to a reference (e.g., potential energy). Furthermore, mathematical representations of the intricate relationships between quantities can involve multiple meanings of the negative sign in a single expression.

Developing flexibility with negative numbers is a known challenge in math education. Vlassis used written diagnostic questions and interviews to investigate the understanding of negative numbers of Belgian algebra students (Vlassis, 2004). She found that full understanding of the concept of a negative number required that students develop flexibility with the various ways negative numbers are used in context, i.e., with the "negativity" of the number. Vlassis created a "map" in tabular form that describes these different uses (reproduced in Table I.) She based her map on one developed earlier (Gallardo & Rojano, 1994), and enhanced it by including additional signifiers from others' work (Thompson & Dreyfus, 1988; Nunes, 1993).

Table I: Negativity: A map of the different uses of the negative sign in elementary algebra; the triple nature of the minus sign. (Vlassis, 2004)

Unary	**Binary**	**Symmetrical**
Structural signifier	*Operational signifier*	*Operational signifier*
Subtrahend Relative number Isolated number Formal concept of negative number	Completing Taking away Difference between two numbers Movements on the number line	Taking opposite of, or inverting, the operation

Few studies have been published that focus on student understanding of negativity outside of mathematics courses. We describe here the most relevant related studies that were done in the context of physics.

Sherin observed patterns in student reasoning by studying successful problem solving behaviors of 3rd semester engineering students taking physics at a highly selective university (Sherin, 2001). Regarding negativity, Sherin uses the symbolic form "competing terms cluster" to describe the quantification of opposites in physics. This form includes the notion of zero to represent balance, and positive and negative quantities as competing terms in an expression. He observes that flexibility with the competing terms cluster is a feature of expert problem solving. We interpret use of this symbolic form as demonstrating flexibility with the symmetrical nature of the minus sign.

Bajracharya and colleagues (Bajracharya, Wemyss, and Thompson, 2012) investigated student understanding of integration in the context of *P-V* diagrams in introductory physics. Their results suggest difficulties with the criteria that determine the sign of a definite integral. Students struggle with the concept of a negative area, and with positive and negative directions of single-variable integration. We interpret this struggle to be rooted in an incomplete understanding of the symmetrical nature of the minus sign in the calculus context.

These observations of advanced undergraduate physics students struggling with the nuances of negativity resonated with our own informal classroom observations, and led us to pose the research questions below. The remainder of this paper describes our preliminary work in addressing these questions.

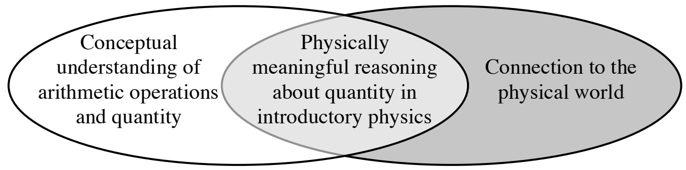
1. *After instruction, what themes are evident in student understanding of the unary, binary and symmetrical ways that negative signs are used in the context of physics?*
2. *Are some contexts (e.g., nature of physical quantity, nature of the minus sign) more challenging for students than others?*

Theoretical Framework: Cognitive Blending

The theoretical framework of cognitive blending (Fauconnier & Turner, 2008; Bing & Redish 2007) supports our view that an interdependence of thinking about the mathematical and physical worlds is necessary for quantifying effectively with negative quantity in physics. Figure 1 illustrates a *double scope negative quantity reasoning blend*, in which two distinct domains of thinking are merged to form a new cognitive space that is optimally suited for productive work.

We draw attention to prior work by Czocher (Czocher, 2013) who conducted a study of several engineering students enrolled in a differential equations course and observed them solving a variety of physics problems over the course of the semester. She reports that successful students functioned most of the time in a "mathematically structured real-world" in which they moved back and forth fluidly between physics ideas and mathematical concepts. Czocher describes this space as being between the "real world" and the "math world",

Figure 1: Double scope negative quantity reasoning blend



We suggest that deep understanding in introductory physics is best supported through a completely homogeneous blend (as observed by Czocher), such that there is no distinction between the physics and the arithmetic worlds. We propose a thinking space in which physical sensemaking is essential for, and integrated with, mathematical reasoning. Our experimental design and assessment item development emerge from a cognitive blend framework. Correct responses depend on students reasoning about negativity correctly, with the further constraint that their response is also consistent with the real world. We analyze our results using this framework and draw conclusions that can inform both instruction and curriculum development.

Methods

As part of a larger assessment project, we had access to two large-enrollment, introductory, calculus-based physics courses taught during Fall 2015. To examine trends in student reasoning about the negative sign in physics contexts, we designed a set of six written questions and administered them at the end of the mechanics course, which students take as their first semester of physics, and the E&M (electricity and magnetism) course, which students take as their third semester of physics. (No students saw the questions twice.) The questions were ungraded, and bundled with concept inventories that are routinely given as part of end-of-semester assessment. A portion of the sample reported on here from each class received multiple-choice versions of the items (n=210 in Mechanics, n=402 in E&M), while the remainder received free-response versions (n=84 in mechanics, n=138 in E&M.) The free-response versions allowed us to evaluate the extent to which the multiple-choice distractors are clear and aligned with student reasoning.

The six items cluster into two sets of three, one set involving mechanics contexts and one involving E&M contexts. Within each set, the first item probes student understanding of the unary nature of the negative sign, the second probes the symmetrical nature, and the third, the binary nature (see Table I). On the first item of each set, students must interpret the sign of a vector component (either acceleration, for the mechanics context, or electric field, for the E&M context). On the second item, which assesses the ability to quantify opposite actions, students must interpret the sign of either the work done by an agent (for the mechanics context) or the transfer of electric charge (for the E&M context). Finally, on the third item, designed to probe the ability to coordinate a measured quantity with its reference, students must interpret the sign of either position (mechanics) or potential difference (E&M). Table II presents all six items. We note on EM2 that the only physically correct answer is (a); only negatively charged particles transfer easily by rubbing matter - (II) makes mathematical sense, but not physical sense.

Table II: Multiple choice assessment items and the percentage of students who selected each answer. The correct answers are in boldface type.

	Unary structural signifier	Symmetrical operational signifier	Binary operational signifier
MECHANICS	*direction of a vector component*	*signifying that work is done by the block as opposed to being done on the block*	*position relative to an origin*
MECHANICS	***Mech 1:*** An object moves along the x-axis, and the acceleration is measured to be $a_x = -8\ \text{m/s}^2$. Consider the following statements about the "–" sign in "$a_x = -8\ \text{m/s}^2$". Pick the statement that best describes the information this negative sign conveys about the situation. a. The object moves in the negative direction. *(8%)* b. The object is slowing down*(26%)* c. **The object accelerates in the –x-direction (26%)** d. Both a and b *(6%)* e. Both b and c *(34%)*	***Mech2:*** A hand exerts a force on a block as the block moves along a frictionless, horizontal surface. For a particular interval of the motion, the hand does W = – 2.7 J of work. Consider the following statements about the "–" sign in the statement W = –2.7 J. The negative sign means: I. *the work done by the hand is in the negative direction* II. *the force exerted by the hand is in the negative direction* III. *the work done by the hand decreases the mechanical energy associated with the block* Which statements are true? a. I only *(17%)* b. II only *(17%)* **c. III only (23%)** d. I and II only *(29%)* e. II and III only *(14%)*	***Mech 3:*** A cart is moving along the x-axis. At a specific instant of time the cart is at a position x = –7 m. Consider the following statements about the "–" sign in "x = –7 m". Pick the statement that best describes the information this negative sign conveys about the situation. a. The cart moves in the negative direction *(6%)* b. **The cart is to the negative direction from the origin (67%)** c. The cart is slowing down *(6%)* d. Both a and b (*19%*) e. Both a and c *(2%)*
ELECTRICITY AND MAGNETISM	*direction of a vector component*	*signifying a specific type of charge that is opposite of positive charge*	*potential at one location relative to another*
ELECTRICITY AND MAGNETISM	***EM 1:*** At a location along the x-axis, the electric field is measured to be $E_x = -10$ N/C. Consider the following statements about the "–" sign in "$E_x = -10$ N/C". Pick the statement that best describes the information this negative sign conveys about the situation. a. The test charge is negative *(16%)* b. The field is being created by negative charge *(21%)* c. **The field points in the –*x*-direction (36%)** d. Both a and b *(12%)* e. Both b and c *(14%)*	***EM 2:*** Valeria combs her hair in the winter and there is a transfer of charge such that $\Delta Q_{comb} = -5$ mC. Consider the following statements about the "–" sign in the mathematical statement $\Delta Q_{comb} = -5$ mC. The negative sign means: I. negative charge was added to the comb. II. charge was taken away from the comb. III. all of the electric charge in the comb is negative Which statements could be true? a. **I only (33%)** b. II only *(28%)* c. III only *(18%)* d. I and III only *(15%)* e. II and III only *(5%)*	***EM 3:*** In physics lab, a student uses a voltmeter to measure the voltage across the terminals of a battery. The voltmeter reads –5V. Consider the following statements about the "–" sign in the voltmeter reading "– 5V". Pick the statement that best describes the information this negative sign conveys about the situation. a. the voltage is in the opposite direction as the current (*32%)* b. there are 5V of negative charge in the battery *(14%)* c. the voltage is in the negative direction *(18%)* d. **the voltage at one terminal is 5V less than the voltage at the other terminal (33%)** e. this battery has negative voltage *(3%)*

Results

Table II presents the fraction of students selecting each distractor on the multiple-choice versions of the questions. Table III presents examples of student reasoning for each item, drawn from responses to the free-response versions. Finally, Figure 2 summarizes the results reported in Table II by comparing the correct response rates on the multiple-choice versions.

Table III: Sample incorrect student reasoning from the open-ended version of the assessment items.

	Unary structural signifier	Symmetrical operational signifier	Binary operational signifier
MECHANICS	*direction of a vector component*	*signifying that work is done by the block as opposed to being done on the block*	*position relative to an origin*
	Mech 1: *"It means that the acceleration of magnitude 8 m/s^2 is acting in the opposite direction to the direction of the motion the object currently has"* *"This negative sign means the opposite of an increasing speed so a decreasing speed"*	***Mech2:*** *"A negative simply means that the block is going in the negative direction"* *"the hand is applying … a force to the block towards the left"* *"the work was done using negative force - a force that goes against positive force"*	***Mech 3:*** *"It is moving in the opposite direction. If moving right indicates +7 m, then this cart is moving left."* *"That means it is traveling left or the cart is starting from a distance > -7 and is going right (-7 away from origin)"*

	EM 1: *"The electric field is moving in the negative x-direction"* *"every Coulomb of charge experiences 10 N of force in negative direction"*	***EM 2:*** *"The charge from the electrons that transferred from the comb gives Valeria's hair a negative charge"* *"charge has been transferred from comb to hair. Comb lost 5 uC of charge."*	***EM 3:*** *"The voltage moves from the negative terminal to the positive"* *"The negative signifies the direction of the voltage"* *"The voltmeter is attached backwards"*

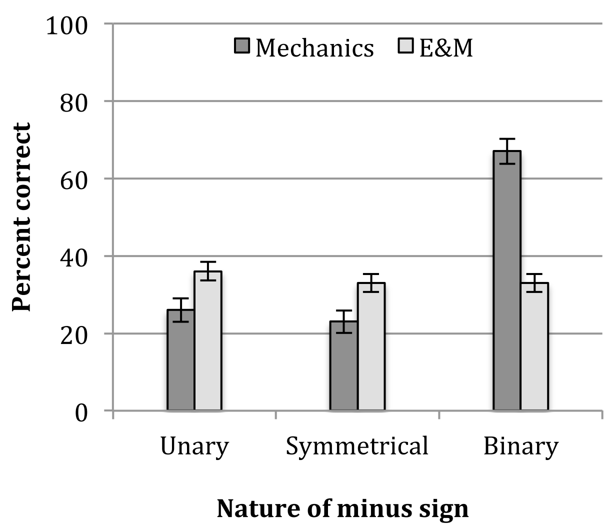

Figure 2: The percentage correct for each multiple-choice item, grouped by the nature of the minus sign and by course. Error bars represent standard error of the mean for binomial variables.

Discussion

We discuss the results in the context of the research questions:

RQ1: After instruction, what themes are evident in student understanding of the unary, binary and symmetrical ways that negative signs are used in the context of physics? We observe from the free response answers that students seemed to struggle less with unary natures than with binary or symmetrical. Their answers suggest intuition on unary items, but the reasoning is not robust. Strong multiple-choice distractors can derail reasoning, which we believe explains the low unary correct response rates seen in Figure 2. We consider students' cognitively blended conceptual understanding on unary items to be emerging, but tenuous, as can be seen in the fact that 3^{rd} semester students are statistically better than their first semester counterparts in the face of strong distractors at recognizing the meaning of the negative sign that can be part of a vector component. We observe both in the multiple choice and free response versions that students struggle especially with the symmetrical uses in physics and note that this is the use that Sherin (Sherin, 2001) observed as being a hallmark of successful problem solvers in physics.

RQ2: Are some contexts more challenging than others? We see three important trends that emerge relating to the cognitive blend of negativity and physics from our results. We observe that, even after instruction, introductory physics students often erroneously associate negativity with an action (e.g. moving, pushing.) They also struggle to make sense of negative scalar quantities (e.g., work, voltage.) They commonly assign a direction to a negative scalar quantity (e.g. the work is acting in the negative direction.) In the context of work they typically associate negativity with the direction of one or both of the vectors that combine to create a scalar product (e.g. negative work is done using a negative force.) In the context of voltage, they commonly treat voltage as having a "direction", confounding it with current or electric field. And lastly, we observed significant struggle to combine more than one nature of negativity in a single calculation (e.g., removing negative charge.) The students were prone to associate the negative sign with "taking away " in that context.

In general, the students struggle with negativity in the ways that it is typically and commonly used in physics for quantification. We observe that student interpretations of negative numbers are often associated with negative position. We note that by comparison to the other physics contexts, students did anomalously well on item Mech3 that asks about one-dimensional position – which is essentially the number line context seen in pre-algebra. In the next section we discuss the need for a cognitively blended learning space in which negativity, and its varied uses, continues to be part of the discussions both in mathematics courses beyond pre-algebra and in physical science courses. We also discuss, through example, some implications of the challenges posed by combining multiple natures of negativity in a typical physics context.

Implications for instruction

We interpret student responses to physics questions through a lens of the three natures of the minus sign, emphasizing that sensemaking with the physical quantities involved is neither entirely physics cognition nor entirely mathematics cognition. A deep understanding requires thinking in a blended cognitive space in which students use conceptual understanding in each domain to fully understand the nature of the physical quantity.

Seen through the lens of the three natures of the minus sign, we can see the complexity of the symbolizing that is a normal part of physics instruction and the additional cognitive load it places on students. Negativity is deeply embedded in the meaning of physical quantities, and the negative sign takes on varied meanings in context. Oftentimes physical quantities are constructed using multiple negativities in the same statement, and we've seen that this practice is not readily assimilated or appreciated by the students. Take for example electric potential energy, *U(r),* of two particles separated by distance *r*. Electric potential energy is an extremely important quantity in E&M:

$$U(r) = \frac{\text{(a physical constant)} \bullet \text{(charge 1)} \bullet \text{(charge 2)}}{r^2} + \textit{any constant}$$

- As *r* increases, the interaction force does *negative* work if the interaction is *attractive* (*opposite* electric charges), and does *positive* work if the interaction is *repulsive* (*like* charges)
- Thus *U increases* with *r* for *attractive* interactions and *decreases* with *r* for *repulsive* interactions
- By convention, $U(r) = 0$ when $r = \infty$ for both types of interaction, implying that if *U(r)* is non-zero it is negative for attracting particles and positive for repelling particles

Note the cognitive blend associated with the distinct uses of the negative sign: a negative scalar quantity (energy) measured relative to a reference point (binary operational signifier), involving other negative quantities (charges) associated with the quantification of opposites (symmetric operational signifier)

We find that at the end of calculus-based physics courses, students commonly both appropriately and inappropriately associate the negative sign with *spatial direction* or *opposition*, but do so without the nuance and flexibility characteristic of expert practice exemplified above – they appear to be associating meaning to the negative sign perhaps based on contexts learned in their pre-algebra courses. We observe that, in general, they struggle to interpret signed quantities in new physics contexts, *even after* relevant physics instruction that is focused on learning the quantities.

While experts interpret *negative* flexibly while symbolizing, many students are unable to do so, even after taking introductory physics. Instruction that explicitly targets student ability to distinguish the three natures of the negative sign, and to make symbolizing decisions using signs, could enhance students' quantification in physical science. Such instruction would be most likely to succeed if it is intentionally distributed and coordinated between mathematics courses and physics courses. Without such explicit attention to negativity, our results suggest that students may not spontaneously adopt an expert perspective. Instruction should challenge students to make sense of varied uses of the negative sign in a variety of physical contexts, and to blend multiple natures of the negative sign in the same overall mathematical context.

This paper describes a preliminary investigation. We intend to conduct individual student interviews and classroom observations to further explore the associations students seem to make between some sort of action or movement and negativity. We plan to repeat the current study using positive quantities to determine the extent to which student difficulties are associated with negativity, *per se*, or with signed numbers in general. Ultimately, we hope to explore, develop, and classroom test instructional interventions, both in the context of mathematics courses and physics courses, that can help students develop the blended thinking space necessary to make sense of signed physical quantities.

Why research on proof-oriented mathematical behavior should attend to the role of particular mathematical content

Paul Christian Dawkins
Northern Illinois University

Shiv Smith Karunakaran
Washington State University

Because proving characterizes much mathematical practice, it continues to be a prominent focus of mathematics education research. Aspects of proving, such as definition use, example use, and logic, act as subdomains for this area of research. To yield content-general claims about these subdomains, studies often downplay or try to control for the influence of particular mathematical content (analysis, algebra, number theory etc.) and students' mathematical meanings for this content. In this paper, we consider the possible negative consequences for mathematics education research of adopting such a content-general characterization of proving behavior. We do so by comparing content-general and content-specific analyses of two proving episodes taken from prior research of the two authors and by re-analyzing the data and results presented in one instance of research from the field. We intend to sensitize the research community to the role particular mathematical content can and should play in research on mathematical proving.

Keywords: Proving, mathematical meanings, comparative analyses

Since at least the time of Euclid's geometry, proving has been understood to characterize mathematics as a discipline. Inasmuch as mathematics educators endeavor to engage students in authentic mathematical activity, they have expended much effort to provide students with meaningful proving experiences and document the emergence of proving as a mathematical practice among novices. While we certainly endorse this agenda for instruction and research, we are concerned that framing mathematical proving as a single, content-general practice may inappropriately downplay the role particular mathematics content plays therein. We observe two trends in the research literature on mathematical proving: 1) making content-independent claims about mathematical proving using data from a particular mathematical context (i.e. analysis, algebra, number theory, geometry) or 2) eliciting the proving behavior of the same students in multiple mathematical contexts in order to make content-independent claims about proving. In this paper, we consider the possible consequences for research on mathematical proving of downplaying the role of particular mathematical content. We do not at all intend to deny the validity or value of prior research framed in a content-independent manner (some of which we authored), but rather seek to sensitize the community to possible blind spots induced by common lenses applied to research data and to endorse a research agenda focused on the interplay between proving and particular mathematical content. Furthermore, if we are to advance the agenda of proof as a process through which students develop key mathematical understandings (Reid, 2011; Stylianides, Stylianides, & Weber, in press), our research lenses for mathematical proving must accommodate the specific mathematics being learned.

To portray such blind spots induced by a research lens, this paper presents dual analysis of three proving episodes taken from prior studies. One episode presents our analysis of another researchers' data and the other two episodes each appear in one of the two authors' prior research, respectively. In each case, we compare 1) a content-general analysis focused on common constructs from proof-oriented mathematics education research – example use, definition use, proof production, logic – with 2) a content-specific analysis focused on explaining students' proving behavior in situ. We use these comparative analyses to reflect on researchers' interpretive process itself and how the framing of research questions non-trivially influences the nature of the phenomena observed and the results of such research on proof-oriented behavior.

Motivating trends and questions

It is common to frame both the research questions and findings using these content-independent constructs such that they form informal subdomains of proof-oriented research. One can find numerous examples of studies on proof-oriented mathematical activity that make content-independent claims about

- example use – Alcock & Inglis, 2008; Karunakaran, 2014; Sandefur, Mason, Stylianides, & Watson, 2013,
- definition use – Alcock & Simpson, 2002; Ouvrier-Buffett, 2011,
- proof production – Dawkins, 2012; Raman, et al., 2009; Stylianides & Stylianides, 2009,
- logic – Epp, 2003; Selden & Selden, 1995, and
- understanding of proof – Sowder & Harel, 2003; Stylianou, Blanton, & Rotou, 2015.

It is not our goal to critique these studies per se, but rather to sensitize mathematics education researchers to the consequences of consistently investigating proving while downplaying the mathematical meanings that populate the arguments that students produce.

Why do many proof-oriented studies downplay mathematics content? Even if this question had one answer, no available evidence reveals it. Nevertheless, we proffer some possible explanations. One explanation is psychological. Proof's role in mathematics as a discipline and the mathematics education community's emphasis on mathematical process both lead researchers themselves to conceptualize proving in real analysis as one instantiation of a broader phenomenon. Because we as experts see consistencies across our broad experiences with proving, we assimilate instances of proving into our general understanding. Dewey (1902) similarly described the asymmetry between experts' and novices' perspectives of academic disciplines. While adults recognize the internal structure of and distinctions between disciplines, children may learn them in an integrated way. Dewey emphasized that these structures are the results of learning, but may not appropriately describe the process of learning itself.

A second explanation involves empirical findings. The growing body of evidence of students' difficulties interpreting, producing, and assessing proofs compels mathematics educators to improve proof-oriented instruction. Students perceive the transition into proof-oriented courses as a difficult transition, so it seems natural to partition such courses apart from other aspects of the curriculum (though we agree with Reid's, 2011, argument that proving should become and is becoming integrated as a ubiquitous means of mathematics teaching and learning). Because students' patterns of proving behavior that diverge from mathematical practice can be documented within multiple mathematical domains (i.e. the problems are content-general), we may falsely assume that these challenges can and should be addressed independent of particular content (the solutions are content-general).

A third explanation relates to the analytic process itself. Mathematics educators frequently use localized data to make analytic generalizations (Firestone, 1993) by constructing frameworks and in-depth characterizations of relatively few cases. While such studies rarely make explicit claims to sample-to-population generalizations (or even claims that the same student would exhibit similar patterns of proving behavior on a different proving task), it remains unclear how to situate the resulting empirical claims about student behavior. Our first dual analysis of a proving episode exemplifies this tension. Case studies are instances, but it is up to researchers and readers to determine what they instantiate.

Comparative analysis 1: Indirect proof in planar geometry

Antonini (2003) presented findings suggesting conditions under which students may spontaneously produce proofs by contradiction (or indirect proofs more generally), which previous studies report that students find particularly challenging. He draws upon the Cognitive Unity (Mariotti et al., 1997) theoretical framework, which characterizes students' proving by attending to interplay between informal arguments and proofs. Antonini (ibid.) further highlights the form of the task as an influential factor in the emergence of indirect proof ("*given an hypothesis A what can you deduce?*", p. 50). The data presented in the paper are limited to students' exploration of a geometric conjecture involving transversal configurations (two lines intersected by a third line), but the author nevertheless frames his research hypothesis in the following way:

> In task like "given A what can you deduce?" the conjecture can be produced via the analysis of a non-example. The argumentation that justifies the fact that the generated example is a non-example can be re-elaborated and become part of the argumentation of the conjecture. In this case, the argumentation takes an indirect form. (Antonini, 2003, p. 50)

We find this hypothesis striking in its generality. While we do not intend to devalue Antonini's characterization of a phenomenon of proving behavior, we question how researchers should interpret the scope and purpose of such characterizations. Is Antonini's hypothesis merely a description of an (possibly general) indirect proving phenomenon that others may call upon to characterize other episodes, or does it purport to be an *explanation* of why the argumentation took an indirect form? Over the course of this paper, we shall elaborate this dichotomy between general(izable) *descriptions* of proving phenomena and *explanations* for particular instances of those phenomena. To motivate our distinction in the case of Antonini's data, we propose an alternative, content-specific explanation for the reasoning pattern he observed.

Episode 1: Classifying relationships between pairs of lines

The task presented to Antonini's (2003) research subjects was, "Two lines *r* and *s* on a plane have the following property: each line *t* intersecting *r,* intersect *s* too. Is there anything you can say about the reciprocal position of *r* and *s*? Why?" (p. 51). The given property (which the author abbreviates as "A") is equivalent to saying that lines *r* and *s* are parallel. The two students featured in the paper (Valerio and Christina, age 13) justified this by showing that the lines *r* and *s* cannot be *perpendicular* or *intersecting*, because in those cases there would be a line *t* that intersected *r* but not *s*. Valerio and Christina seem convinced of the generality of their claims regarding perpendicular and intersecting lines and justified that the lines *r* and *s* must be parallel because they cannot be intersecting.

Content-specific analysis of Episode 1

How might the geometric context, and transversal configurations in particular, influence the emergence of this indirect line of reasoning? Certainly it was easy for the pair to generate and test cases by visualizing and rotating lines, but we notice another aspect of this context that we hypothesize as relevant to the emergence of indirect proof. In school mathematics, there are three basic relationships between two non-identical coplanar lines: parallel, intersecting, and perpendicular. Two of these properties are implicitly negations of one another. To be non-intersecting is to be parallel and vise versa. Valero and Christina may have been taught that parallel means "non-intersecting," or they may have a less formal meaning thereof. Inasmuch as indirect proof entails negating mathematical conditions, we hypothesize that it was important in

Antonini's (2003) proving episode that Christina and Valerio were familiar with properties that exactly characterized the pairs of lines exhibiting property A and those not exhibiting A.

In recent studies on students' reinvention of truth-functional logic, Dawkins and Cook (2015) documented some students' reluctance to reason about negative properties (not [X]); such students instead exhibited preference for familiar categories. This was especially true in geometric contexts where students often paraphrased "[a triangle] is not acute" by saying "it is obtuse" or "[a quadrilateral] is not a rectangle" with "it is a parallelogram." In the former case, *obtuse* is a familiar category of triangles that has empty intersection with but is not the complement of the class of *acute* triangles (i.e. *obtuse* is not a proper negation of *acute*, but all obtuse triangles are "not acute"). In the latter case, the set of *parallelograms* is neither mutually exclusive to the set of rectangles nor equivalent to the complement of the set of rectangles. It is important to note that in neither case is there a familiar (non-negative) category that corresponds to the given negative property. Dawkins and Cook (2015) hypothesized that this pattern of behavior revealed 1) an aversion to describe geometric shapes according to properties they lacked and 2) an implicit reliance on the familiar organization of these shapes according to categories taught in school ("acute, right, and obtuse" rather than "acute and not-acute").

Both of the patterns of students' reasoning about geometry Dawkins and Cook (2015) hypothesized are relevant to Antonini's (2003) proving task. First, students' preference for familiar categories (if applied to Antonini's subjects) suggests that Valerio and Christina explored perpendicular and intersecting lines because they are two of the three familiar relations between two lines. Furthermore, we have no evidence whether their initial investigation of these two properties, rather than parallel, was strategic or idiosyncratic. This suggests that they may not have been asking the question Antonini (2003) cites as central to indirect argumentation: "...if it were not so, it would happen that..." (p. 49). It seems implausible that Christina and Valerio first investigated perpendicular lines as non-examples of property A because they were unfamiliarity with property A. We hypothesize they merely explored the familiar properties of pairs of lines – perpendicular, intersecting, and parallel – in that order.

Second, the availability of two properties that corresponded perfectly with A and not-A allowed the students to use indirect argumentation without using negative properties. If these or other students were working on a similar task whose solution depended upon the properties rectangle and non-rectangle, would indirect proof have emerged as easily or at all? For instance, consider the similarly framed task "Given that a quadrilateral has congruent diagonals that bisect each other, what can you conclude? Why?" Students may begin the task by exploring the diagonals of familiar shapes, but none of those classes of shapes would correspond to non-rectangles to afford a contrapositive argument similar to the one developed by Christina and Valerio. We acknowledge that this analysis of Antonini's data relies on a generalization of reasoning phenomena from very different data (Dawkins & Cook's interviews with college students), but it is warranted for our purposes because 1) this generalization is comparable to Antonini's own citation of other studies on students' production of indirect proofs and 2) we provide this *plausible* explanation to justify our contention that the specific mathematics in the task may be essential to explaining Valerio and Christina's proving behavior. Whether this pair or other students would exhibit similar patterns of proving behavior on alternative tasks of a similar form is an empirical question, and researchers must make use of Antonini's (2003) analysis with this in mind.

These observations about the particular affordances of Antonini's (2003) chosen mathematical content do not necessarily undermine the utility of his characterization of a phenomenon of proving behavior, but we posit that they demonstrate how his characterization likely falls short of fully explaining the students' reasoning behavior and why it emerged. We could sympathetically interpret Antonini's hypothesis regarding tasks of the form "given an hypothesis A what can you deduce?" by inferring an implicit comparison to the alternative proof task prompt: "given the hypothesis A, prove that B must be true." In this case, Antonini (2003) suggested that the former, open task prompt may invite more indirect reasoning since the latter prompt would focus students' attention on A and B (rather than not-A and not-B). Our intention is not to dispute this content-general claim. Rather, we want to emphasize to the research community the relative importance of the mathematical content of A and B if we want to document and explain these type of phenomena of students' proving behavior. Furthermore, we argue that the operative research framing (indirect proof, Cognitive Unity, the sense in which two tasks are "like" one another) can non-trivially influence 1) the ways we interpret students' behavior, 2) those aspects of the situation to which we do not attend, and 3) which types of phenomena we take observed behavior to instantiate.

Comparative analysis 2: Logic and inference regarding transversal configurations

This and the following sections set forth two empirical episodes, each taken from one of the authors' prior research, and dual analyses thereof. Episode 2 occurred during a sequence of task-based interviews as part of the first author's investigation of student learning of neutral, axiomatic geometry. It features two undergraduate mathematics majors trying to prove the equivalence of Euclid's Fifth Postulate (EFP) and Playfair's Parallel Postulate (PPP). Analysis of Episode 2 also appeared in Dawkins (2012). The second episode appeared during a sequence of task-based interviews with expert and novice mathematics students conducted by the second author. For the sake of brevity and clarity in this theoretical paper, we omit presenting the full methodology of the study, which is available in the cited reference.

Episode 2: Proving the equivalence of geometric postulates

For reference, the students' statements and diagrams for EFP and PPP appear in Figure 1. As part of a homework assignment prior to the interview, Kirk and Oren had each proven the equivalence of the two postulates using the auxiliary claim we shall call Theorem *, which states "Given two lines cut by a transversal, if the same side interior angles sum is 180, then the two lines do not meet on that side of the transversal." When asked to explain the postulates, the pair found themselves using language from each of the two statements to explain the other. Oren noted this circularity and attributed it to the fact that the statements implied one another. Kirk expressed a similar sentiment, but did so by simply claiming the postulates "are the same." Oren explained the meaning of each postulate by extending his forearms to represent parallel lines and noting that any amount of rotation from the parallel position would cause the lines to intersect. While EFP characterized that rotation in terms of angle sums and PPP did so in terms of deviation from the one parallel line through *P*, Kirk and Oren seemed convinced of the unity between the claims. Interestingly, this arm gesture also provided Oren's initial response about what it *meant* for two lines to be parallel. It appeared that he took other properties such as intersecting and equidistant to be consequences of that arrangement, such that the term *parallel* was, for him, defined in an inherently spatial way.

Euclid's Fifth Postulate (EFP): "Given two lines cut by a transversal, if the two interior angles on one side of the transversal sum to less than 180°, then the lines intersect on that side of the transversal."	Playfair's Parallel Postulate (PPP): "Given any line and a point not on that line, there exists only one line through the given point that does not intersect the given line."	

Figure 1: Kirk and Oren's statements and diagram for EFP and PPP

The students began the task intending to prove that EFP ⇒ PPP. The students' argument depended upon dividing the line arrangements into three cases, depending upon the angle sum $\alpha + \beta$. They successfully argued, using EFP and Theorem *, that:

- if $\alpha + \beta < 180°$, lines *l* and *m* meet on that side of line *n*,
- if $\alpha + \beta = 180°$, lines *l* and *m* do not meet,
- if $\alpha + \beta > 180°$, lines *l* and *m* meet on the other side of *n*.

Upon completing their three-case argument, Kirk and Oren disagreed about their relative progress toward constructing a proof. Kirk considered this argument sufficient to prove PPP because it guaranteed that there was only one instance in which the lines *l* and *m* are parallel. He said, "Playfair's Postulate basically states that there's only one instance or case where the lines will not meet." Oren disagreed because he was concerned about how the choice of lines through point *P* (in PPP) corresponded to the angle sums (in EFP). Through their discussion, Kirk adopted some of Oren's concern about the sufficiency of their argument saying, "It's just hard because Playfair's doesn't include this line *n*, so you are trying to find a way to go from having this line *n* to not having this line *n* in Playfair's." Once it appeared they had reached an impasse, the interviewer invited the students to begin their argument with the diagram for PPP. The pair then was able to use their three cases argument to complete the proof. Oren showed great attention to the warrants necessary for constructing the transversal line and for relating each line through the point *P,* to a unique angle sum. Despite their work prior to the interview, Kirk and Oren's proof production took over 40 minutes.

Analysis 1 of Episode 2. The study in which this episode occurred sought to investigate students' interpretation and use of conditional ("if…then…") statements in proof-oriented mathematics. The first author used this task because it contained at least three conditional claims:

- EFP: "Given two lines cut by a transversal, if the two interior angles on one side of the transversal sum to less than 180°, then the lines intersect on that side of the transversal."
- PPP: "If *P* is a point not on a given line *l*, then there exists only one line through *P* that does not intersect *l*."
- If EFP, then PPP (EFP ⇒ PPP).

Kirk and Oren's initial difficulties in proving EFP ⇒ PPP can be reasonably attributed to the logical structure of their argument, specifically the proof frame (Selden & Selden, 1995). Zandieh, Knapp, and Roh (2008) also reported on students' difficulties with this proof and others with similar logical form. They explain that students do not adopt a Conditional-Implies-Conditional (CIC) proof frame in which the proof proceeds from the hypotheses of the consequent statement (in this case the point and line arrangement of PPP) to the conclusions of that statement (exactly one parallel through *P*). Kirk and Oren displayed difficulties similar to those reported in Zandieh et al. (2008) because they adopted the standard conditional proof frame that begins with hypotheses (EFP) and ends with the conclusion (PPP). Kirk's was convinced they had produced an adequate proof with this proof frame, which could be modeled by the valid syllogism: EFP (and Theorem *) ⇒ Three Cases, Three Cases ⇒ PPP, therefore EFP ⇒ PPP. However, this argument failed to prove that the conclusions of PPP are implied by its hypotheses, as the CIC proof does. In Raman et al.'s (2009) language, Kirk understood the *key idea* of the proof (the Three Cases argument), but lacked the *technical handle* (the proof frame) to construct a valid proof. Ultimately, the interviewer had to prompt the pair to begin with the diagram from PPP, which implicitly introduced the CIC proof frame. This modification allowed the students to produce a valid and normative proof.

Analysis 2 of Episode 2. Several aspects of Kirk's behavior in the episode are not explained by the absence of an appropriate proof frame. For instance, why was Kirk convinced by his 3 Cases argument while Oren was not? Also, when Kirk described their intention to prove PPP from EFP, he appeared to metonymize (Zandieh & Knapp, 2006) the two statements by their diagrams. To get from EFP to PPP, one diagram needed to be transformed into the other, which required removing a transversal. We posit that a viable explanation for these phenomena requires attention to the geometric nature of Kirk's reasoning (in a visuo-spatial sense). Much like Oren's explanation using his forearms to observe the possible arrangements of two lines, Kirk seemed to interpret the postulates as describing geometric possibilities. For him, these conditional statements were not so much warrants for possible inferences in a chain of deduction as they were articulations of occurrences among lines in a plane. This explains why Kirk so closely linked the postulates to their diagrams and said the two postulates were "the same": the two statements pointed to geometric phenomena and described the same set of three possibilities. Oren provided a stark contrast to Kirk's reasoning inasmuch as he attended closely to how warrants in the body of theory afforded individual steps in proof construction. Oren's hypothetico-deductive mode of activity led him to recognize the insufficiency of their three cases argument when Kirk could not within his visio-spatial mode of reasoning.

This account of Kirk's reasoning suggests that a more honest rendering of his understanding into the language of logic would be the invalid syllogism: "EFP (and Theorem *) ⇒ Only One Instance, PPP ⇒ Only One Instance, therefore EFP ⇒ PPP." The deeper implication of our second analysis is that propositional logic is a poor tool for modeling the nature of Kirk's reasoning. This can be seen in the way that each "implication" in this supposed syllogism has a distinct meaning. Kirk perceived the claim that there was Only One Instance (of a parallel through *P*) as an implication of EFP via the Three Cases argument. He viewed Only One Instance as a paraphrase of PPP rather than a consequence of it. Finally, his reasoning did not display clear directionality in the relationship between EFP and PPP (Dawkins, 2012). It appears that Kirk's empirical reasoning convinced him that the 3 Cases argument proved that EFP and PPP were equivalent because they entailed the same geometric possibilities. Framing his reasoning thus as a quasi-empirical report on the set of geometric possibilities described by the two postulates provides a better explanation for various aspects of his behavior. We thus conclude that this description is more faithful to the nature of the underlying reasoning process.

Comparative analysis 3: Examples and expertise in real analysis

Episode 3 occurred during a comparative study of the proving behaviors of expert and novice mathematicians. This episode features a graduate student in mathematics, designated an expert prover, attempting a novel analysis task about sequences. Analysis of Episode 3 also appeared in Karunakaran (2014), which presents the fully methodology of the study.

Episode 3: Proving and disproving conjectures about sequences of real numbers.

Upon being asked to validate or refute the claim given in Figure 2, Zander quickly stated, "So, the first thing that I would do is to see if [the series] obviously doesn't converge." When asked to elaborate his goals, Zander stated that he would search for a counterexample to the statement. That is, he would look for a sequence $\{a_n\}_{n=1}^{\infty}$ of real numbers satisfying the condition that $0 < a_n \leq a_{2n} + a_{2n+1}$, such that the series $\Sigma_{n=1}^{\infty} a_n$ does not converge.

Task 1
Validate or refute the following statement: Let $\{a_n\}_{n=1}^{\infty}$ be a sequence of real numbers such that $0 < a_n \leq a_{2n} + a_{2n+1}$ $\forall n \in \mathbb{Z}$ & $n \geq 1$. Then the series $\sum_{n=1}^{\infty} a_n$ converges.

Figure 2. The statement of the original Task 1 statement as presented to Zander.

Zander quickly generated the valid counterexample sequence $a_n = 1\ \forall\, n$. At this juncture, the interviewer asked Zander to prove a slightly modified version of statement in Task 1. The modified version negated the conclusion to state, "Then the series $\Sigma_{n=1}^{\infty} a_n$ ***diverges***." As before, immediately after being given the modified task statement, Zander stated, "Ok. Uh well … right so then I would have to find an example where it converges." Upon being asked, Zander confirmed that he was looking for a counterexample to the modified statement. Also, Zander quickly considered and discarded the use of various convergence and divergence tests (e.g. ratio test; comparison test) because he anticipated that none of the tests would "guarantee divergence."

Then, Zander recalled a convergent series with which he seemed familiar: $\Sigma_{n=1}^{\infty}\left(\frac{1}{2^n}\right)$. He stated his intentions for choosing this example saying, "maybe we can find a way to make a sequence where a_n [the sequence in the task] is equal to $\frac{1}{2^n}$ or smaller than or something like that. Cause then that would converge as well." However, he noted that the sequence $\left\{\frac{1}{2^n}\right\}$ does not satisfy the inequality condition $0 < a_n \leq a_{2n} + a_{2n+1}$. To work around this, he attempted to generate a counterexample by modifying his example sequence such that $a_0 = a_1 = a_2 = a_3 = 1$ and then each of the terms for $n > 3$ were constructed using the rule $a_{2n} = \frac{1}{2} a_n$ and $a_{2n+1} = \frac{1}{2} a_n$. At this point he argued that "halving" the terms was the "best–case scenario" for satisfying the inequality since "it's sort of the cutoff I mean because if we take it to be any smaller a half, say like a tenth of a tenth and then it no longer fulfills this second inequality."

Zander stated that he now believed the modified task statement to be true. Zander attempted to use the harmonic series to prove that the modified statement is true. However, he realized that the harmonic series does not satisfy the inequality condition, and he explained that he would like to show that the terms of the harmonic series (or some variant of it) would be a necessary lower-bound to the corresponding terms of the series in the task and thereby the series in the task would also have to diverge (using the comparison test).

Analysis 1 of Episode 3. The study in which this episode occurred focused on finding similarities and differences between expert and novice's proving behaviors. As such, the original analysis characterized Zander's proving behaviors across the various real analysis tasks provided. Zander repeatedly used the strategy of searching for a counterexample on this and other tasks. When asked about why he did so, he replied, "Because the counterexample might tell you why it always diverges … or rather the inability to find a counterexample might tell you why it always converges." So, on multiple tasks Zander used this strategy of searching for a counterexample to either successfully find a counterexample invalidating the statement or to gain knowledge about why the statement is valid through the inability to find a counterexample. However, Zander's choice of sequences/series appears strange since neither was a counterexample of the original or modified claim. This is because neither satisfied the inequality condition in the hypothesis. The interviewer asked Zander why he called on the series $\left\{\frac{1}{2^n}\right\}_{n=1}^{\infty}$ and the harmonic series, even though neither one satisfies the inequality condition. He explained that he routinely looked for examples that were relevant to the task and provided him with "a picture" or a "prototypical" example that helped him understand the task better. Zander's use of the term "prototype" seems inconsistent with its use in mathematics education as an example central to a category. Since Zander engaged in a process of example generation similar to Antonini's (2011) *example transformation*, he may use the term "prototype" to refer to his starting example that he modifies to satisfy the conditions in a task.

Thus, this episode supports the general claim that Zander's proving strategy often included searching for counterexamples (regardless of whether he believes one exists). He was aware of this strategy and valued it because it aided him either in disproving the claim (by counterexample) or proving the claim (using some insight from the example search). Furthermore, Zander's work within this episode also supported the claim that he routinely used what he considered "prototypical" examples or visualized "pictures" to gain insight into why a particular claim is true, consistent with previous finding associating visualization and examples with conviction and insight (e.g. Alcock & Simpson, 2004).

Analysis 2 of Episode 3. Even though we can make the content–general claims present in Analysis 1, this may not account for Zander's "expertise" or his relative success on this task. We observe nuances within Zander's search of counterexample and his choice of sequence/series ($\left\{\frac{1}{2^n}\right\}_{n=1}^{\infty}$ and the harmonic series) that provide insights about his use of his content-specific knowledge about series. Throughout the task, Zander paid particular attention to the growth patterns of various series, which can rightly be considered a conceptual link between the inequality condition and the convergence of monotone increasing series. To find a counterexample to the modified task, Zander called on the series $\Sigma_{n=1}^{\infty}\left(\frac{1}{2^n}\right)$ because he knew this to be a series that converged. A minimal way to satisfy the inequality condition is for $a_{2n} = a_{2n+1} = \frac{1}{2}a_n$, and $\left\{\frac{1}{2^n}\right\}$ similarly halved its adjacent terms. Zander noted that $\left\{\frac{1}{2^n}\right\}$ did not satisfy the inequality condition, but examining the rate at which its terms decreased prompted him to search for "a way to make a sequence where a_n is equal to $\frac{1}{2^n}$ or smaller than or something like that … then that would converge as well." Zander deduced that "halving" the sequence terms would be the "best–case scenario" since,

> "if we take it to be any smaller a half, say like a tenth of a tenth and then it no longer fulfills this second inequality [and] if we take something that was bigger than a half then that's only more problematic because you're just throwing in bigger numbers into the sequence … I think this if I'm right in saying that this sequence always diverges this actually might be a key to the reason why."

In what ways was this scenario "best?" Zander wanted to find a series that converged, so the added terms must decrease, but the inequality limited the rate at which they decreased. Zander's modified example was his "best" possibility to have a minimal growth rate (so as to converge) while satisfying the inequality condition in the task. We infer that Zander's analysis of the series $\Sigma_{n=1}^{\infty}\left(\frac{1}{2^n}\right)$ convinced him that the modified task statement was true because he perceived that no sequence satisfying the inequality condition could decrease fast enough for the associated series to converge. He called upon the harmonic series (even though it is not a series that satisfies the inequality condition) as a "prototypical" example of a divergent series with a small growth rate. Part of what made Zander's proving successful (his "expertise") was his ability to interpret the conditions in the task as constraints on the growth rate of the sequence/series and call upon canonical examples that displayed particular growth behaviors. Both his knowledge and use of the prototypical examples point to his analysis-specific knowledge of series, growth rates, and comparison proof methods.

Discussion and Conclusions

We present dual analyses of these three proving episodes to portray the alternative insights gained by content-general analysis (of direct and indirect argumentation, logic, example use, etc.) versus content-specific analysis (of exploring the reciprocal relations between lines, the possible arrangements of transversal configurations, growth rates of sequences and series, etc.). These three studies reflect common research paradigms within mathematics education: 1) documenting the emergence of proving from student argumentation while solving well-designed tasks, 2) task-based interviews intended to elicit instances of mathematical behavior related to a general topic of interest and 3) comparing and contrasting expert/novice mathematical behavior. While the latter two studies employed grounded theory methods, affording these various analyses, they both began with guiding questions and theoretical framings (as no investigation can avoid being, on some level, theory-laden). Regarding Episode 2, it was only after attempts to generally characterize Kirk and Oren's interpretations of conditional statements failed that the author attended to the broader differences between the ways they interpreted the statements and the task at hand. This helped explain Kirk and Oren's very different proving behaviors and their assessments of their progress on the task. Regarding Episode 3, the second author designed the study to include tasks in various mathematical contexts, but later refined the study tasks to only include real analysis tasks. While the content-general claims about Zander's proving expertise are supported by Zander's proving practice and his self-reflection, they may also hide the role and value of Zander's extensive experience with real analysis. In other words, content-general claims will necessarily fail to characterize what it means to be an expert in real analysis and how that expertise plays a role in the observed proving. We may conclude from cases like Zander that experts use examples more and differently than novices, but we must focus on content-specific ideas such as growth-rates and convergence to truly characterize how Zander used those examples productively. One must specify what category an example instantiates for the learner, as Zander productively used series that did not satisfy the task constraints, but exemplified various growth rates.

In what follows, we present our arguments about why research on proof-oriented mathematical behavior should attend to the role of particular mathematical content. We organize our observations around two main points each of which highlight the role of content in proving behavior: 1) distinguishing when research *describes* from when it *explains* the emergence of proving behavior and 2) attending to the role researchers play in identifying and framing observed phenomena. We then provide some recommendations for future research regarding the interplay between proving and mathematical meaning.

Description versus explanation

As we stated before, our goal is not to deny the value of content-general proof research, but rather to sensitize the mathematics education research community to the limitations and possible liabilities of content-general research lenses (i.e. questions and theoretical frameworks). As was discussed previously in the paper, we find it helpful to distinguish whether a study's analysis provides *descriptions* of student proving phenomena or *explanations* for the emergence of those phenomena. We contend that one may *describe* many recurrent phenomena of student proving in a content-general way, but *explaining* the emergence of the observed reasoning in most cases requires attending to students' understanding of the mathematical content at hand. This is because, generally, students reason about mathematics while they solve mathematical tasks!

Many frameworks in mathematics education set forth categories that *describe* patterns in student proving behavior. These categories are useful inasmuch as they provide language for further investigation and tools for the formulation of testable hypotheses and inferences regarding student learning. Indeed, one does not necessarily need underlying mechanisms and explanations to identify and document recurrent phenomena in students' proving behavior. However, such descriptions of recurrent student behaviors also should not be confused for explanations of the reasoning processes that lead to their emergence. It seems obvious to claim that students are thinking about the mathematics at hand when proving. This suggests that any explanation of their proving behavior must account in some way for students' meanings (Thompson, 2013) for that mathematics. Accounts of proving phenomena that are not content-specific are likely to capture epiphenomena that emerge at the chosen level of analysis, but whose underlying causes or mechanisms remain as-of-yet unspecified.

How can we observe this distinction between description and explanation in each of our three episodes? Regarding Antonini's (2003) account of the emergence of indirect proof, we provided an alternative account of how the particular geometric task afforded the students' line of reasoning. Our account suggests that any use of Antonini's hypothesis that open-ended proof tasks invite indirect reasoning may require careful attention to students' familiarity with the properties in the task and their negations. Based on our analysis, we hypothesize that even traditionally stated proof tasks that involve negative properties may invite indirect proof, such as "Prove that any number that is not a multiple of 4 is not a multiple of 12." In cases such as Antonini's (2003) where both direct and indirect argumentation are viable, open-ended proof prompts may elicit indirect argumentation. The task frame alone falls short of explaining why it does so. Regarding Episode 2, analyzing proof frames or imposing a hypothetico-deductive structure on Kirk's arguments both reveal deficiencies in his proving. One can describe his reasoning to show that it was non-normative, but this fails to reveal the subjective rationality of Kirk's behavior. These forms of analysis do not provide insight into how his engagement in the proving process differed qualitatively from Oren's. Because Kirk's reasoning was intrinsically tied to the visuo-spatial representations, one cannot explain the emergence of his reasoning without attending to the geometric nature of the task. Regarding Episode 3, the strategic use of examples may provide an observable, qualitative difference between experts' and novices' reasoning, but that does not mean differences in example use constitute the nature of expertise in this proving arena. Our second analysis of Zander's reasoning demonstrated how he used examples as implicit measures of rates of convergence, which we argue may be closer to an explanation of the nature of his expertise in sequence and series convergence.

Our distinction between description and explanation is of greatest import when using and applying the results of prior research. We acknowledge the appeal of reporting local findings in a content-general way because it maximizes the possibility that other researchers may use the results of a study. However, comparing phenomena across studies involves (at least implicitly) generalizing those phenomena across individuals and often generalizing across age, learning background, and mathematical content. We hypothesize that our field's implicit invitations to overgeneralize empirical findings are partly to blame for the confusing and seemingly contradictory claims available in the literature on proof (e.g. Reid & Knipping, 2010). We offer our caution about *explaining* mathematical proving behavior in terms of mathematical meaning as a call to respect how situated students' mathematical knowledge is.

Distinguishing signal from noise

Our second point focuses on how researchers' framing of their investigations influences data analysis. A brief survey of mathematics education literature attests to the fact that students' mathematical reasoning is an incredibly multi-faceted and complex forum for investigation. No single study can account for all of the dimensions of variation at play, and thus researchers must choose how to separate signal from noise in observed data. The broad prevalence of qualitative methods renders this difficulty particularly acute in mathematics education. How do researchers decide which dimensions of observed behavior to attend to and which to ignore? In most study designs the theoretical frameworks, research questions, observation protocols, etc. explicitly funnel the complexity of student behavior into interpretable streams of data. In studies using grounded theory methods, researchers cast a wide net in initial observation and allow trends to emerge along more natural contours in the data. In all cases, though, we contend that researcher questions, interests, and prior theory play a necessary role in helping distinguish signal from noise. There are two possible pitfalls within this process, each of which is exemplified in our three episodes: 1) researchers filter as noise some aspect of student behavior that is in some way essential to understanding the emergent phenomenon or 2) researchers' framing and theory impose structures on student behavior that are not native to it.

Episodes 1 and 3 exemplify the first issue. The studies purported to be about indirect argumentation and example use, respectively, which implicitly framed the observed behavior as instances of content-general phenomena. The research questions themselves may warrant a researcher's choice to filter the mathematical content of tasks as noise, or to characterize the observed behavior in content-general language. This creates the illusion that the research subjects reasoned about "examples" and "non-examples" rather than transversal configurations or series. This is one instance of how mathematics educators use the language of meta-theory to discuss student behavior. Mathematics educators have rightly called upon mathematical meta-theory to explicate the normative mathematical processes into which we intend to apprentice students. Such theory provides useful categories, terms, and structures for modeling student behavior, but we must carefully distinguish researcher models from observed phenomenon. We find that describing student behavior using meta-theory and assessing whether their behavior is mathematically normative (both of which are appropriate) can subtly lead researchers to impose the structures of meta-theory upon student behavior itself. This suggests how the first issue cited in the last paragraph can often lead to the second. This is probably nowhere more likely or prevalent than in logic (Dawkins, 2014), which is why Episode 2 serves as a cautionary tale.

Proving involves drawing inferences and, somewhat controversially, logic can be used as a meta-theory for describing human inference. The relationship between formalized logic and reasoning has been widely disputed (e.g. Oaksford & Chater, 2002; Toulmin, 1958). It is beyond the scope of the current discussion to elaborate on this debate and its relevance to mathematics education research on proving, but we find Piaget's use of logic an insightful case. Piaget was fond of using formal mathematics as a descriptive language for children's reasoning (e.g. Piaget, 1950). Even though he clearly argued that he was recasting logic to reflect student reasoning (rather than the other way round), reviewers of Piaget's work often interpreted his models of student reasoning as beholden to the structure of formal logic in problematic ways.

Episode 2 demonstrates how content-general models such as logic may be applied to a broad range of students' proving activity, but may also be misleading or dishonest to the underlying reasoning process. We maintain that the two syllogisms we used to model Kirk's arguments are, on some level, representations that express some aspect of his reasoning process. However, each one likely hides other aspects of that process as well. These descriptive models reduce "implication" to mere links between claims with the effect that it fails to distinguish what may have been distinct types of inferences. The logical frame also imposes structure such as directionality that further analysis suggests was not native to Kirk's reasoning (Dawkins, 2012). We perceive that several of the connections Kirk drew between the given claims were distinct in meaning. As such, using logic to model these inferences unintentionally imposes foreign structure upon them. Oren's reasoning also provides evidence for the non-trivial influence of researcher models on data analysis. Oren's reasoning in that interview was far easier to analyze because it was more consistent with a hypothetico-deductive frame of inference. This is to say that modeling student reasoning is easier when the data fits the model on a structural level.

Many researchers avoid using formal logic to model students' argumentation and proving, but this does not circumvent the danger that by applying content-general models mathematics educators will recast student behavior after the image of their analytical lens. Toulmin (1958), dissatisfied with the implicit assumptions entailed in using formal logic as a modeling tool, set forth an alternative scheme for modeling argumentation that has been increasingly popular in mathematics education research. However, this scheme does not alleviate the burden upon researchers to attend to the interpretive process, because the same argument can be modeled in different ways using Toulmin schemes and there is some debate about which dimensions of his framework must be used in mathematics education research (e.g. Inglis, Mejia-Ramos, & Simpson, 2007). How and when do content-general frames such as formal logic or Toulmin schemes obscure the role of mathematical meaning in proving? Researchers should apply these tools with some caution because they can focus analysis on the "signal" of warrants, claims, and data leaving particular mathematical claims as background or "noise." How can mathematics educators adapt these frames or couple them with other tools to integrate mathematical meaning in the analyses of the emergence of mathematical proving? Researchers must be cautious applying content-general models to student reasoning lest the resulting characterizations reflect *researcher's questions* more than *students' mathematical behavior*. Furthermore, if a key goal of proof-oriented instruction is for students to experience proving as a means of developing mathematical understanding, our research lenses for mathematical proving must accommodate the particular mathematical understandings that we intend students to develop.

Future directions

While the primary goal of this theoretical paper was to sensitize the mathematics education research community to the role of mathematical meaning in research on proving, we also see viable avenues for future research to directly address the issues discussed here. There already exist many studies that approach proving phenomena in a contextual way, but often such studies are classified as studies of real analysis learning, geometry learning, etc. One promising research approach is to document student's apprenticeship into mathematical proving across content domains to document characterize content-independent proof skills if and when they emerge. Empirical study is required to determine how and when students develop a sense of mathematical proving as a unified practice with universal techniques and governing principles. Other studies might instead compare students' proving in various mathematical contexts to learn when and how proving knowledge and know-how are situated within a mathematical domain (e.g. Mejia-Ramos, Weber, & Fuller, 2015). Perhaps our highest recommendation is that researchers attend to the co-emergence of proving competencies and conceptual understanding of key mathematical content. We prioritize this because we view it most hopeful for facilitating the integration of proving as a *means* of mathematical learning across the curriculum.

CLEARING THE WAY FOR STEM MAJORS IN INTRODUCTORY CALCULUS

Rebecca Dibbs
Texas A&M-Commerce

Jennifer Patterson
Texas A&M-Commerce

One of the reasons for the exodus in STEM majors is the introductory calculus curriculum. Although there is evidence that curricula like CLEAR calculus support students' adopting a more growth-orientated mindset, it is unclear how this curriculum promotes mindset changes. The purpose of this case study was to investigate which features of CLEAR Calculus students notice and attribution to their success. After administering the Patterns of Adaptive Learning Scale to assess students' initial mindset in one section of calculus, four students were selected for interviews. At the end of the semester, students were re-administered the PALS and all students who took an additional mathematics class were given the survey at the end of their next course. Students cited that the labs CLEAR Calculus curriculum challenge them in ways that facilitate deeper comprehensive learning than that of prior courses, and the positive changes in approaches to mathematics continued in the next course. Students did not notice the formative assessments as part of the course, but the actions taken by the instructor as part of the course was taken as evidence as instructor caring by the students.

Keywords: Calculus, formative assessment, mindsets

Prospective STEM majors who declare a non-STEM major are most likely to do so after introductory calculus (Bressoud, Rasmussen, Carlson, & Mesa, 2014); students cite their lack of a perceived relationship with their instructor and the inability to seek help as primary reasons for switching (Ellis & Rasmussen, 2014). One possible solution is the use of formative assessments such as exit tickets; such assignments show promise in helping students to perceive their instructor as more approachable and caring about their success (Black & Wiliam 1998, 2009; Dibbs, 2014).

However, the number formative assessments completed are a far stronger predictor of students' success than their weight in the course grade would indicate (Author 1, 2015). One possible explanation for this effect was that students who completed more post-labs had different mindsets about learning mathematics than those that did not. It has been noticed that mindsets play a significant role in the overall success of calculus students. Dweck (2006) defines mindset in two different ways: fixed mindset and growth mindset. Students classified under the fixed mindset, if not immediately successful in introductory calculus often leave the STEM field. However, growth mindset students can persist and succeed, even after failures as severe as failing a course (Dweck, 2007).

We examined how CLEAR Calculus supports positive mindset changes in students through a case study of four students enrolled in an introductory calculus class taught using CLEAR Calculus. This research will be guided by the question: What are the features of CLEAR Calculus that students notice and value? By understanding what makes this curriculum effective, an interested practitioner who is not implementing CLEAR Calculus can learn what components to add to their classes if they would like to see a positive increase in their students' mindsets. We argue CLEAR Calculus supports positive changes in students' mindsets because the labs make a challenge and conceptual understanding central components of the course; although students did not notice the formative assessments, the actions were taken by the instructor as the result of formative assessments helped create a positive perception of their relationship with the instructor.

Theoretical Perspective and Methods

Every week followed the same general schedule. On Monday, there was a new section of material introduced and students were given a prelab. The prelab asked students to complete the Unknown Value of the approximation framework (Figure 1) and to identify a quantity that could be used to approximate the unknown value. Students were asked to complete the prelab before class on Tuesday; the prelab was graded on completion at the beginning of class. During class on Tuesday, students worked in groups of three or four on their assigned lab context. After class, students completed a post-lab using the online course management software. Each post-lab asked students to summarize what their groups did, evaluate how well they understood the material, perform a computation similar to the ones expected on the lab, and identify which portions of the lab they still needed help on. This information was summarized and sent to the instructors that night and used to launch a classroom discussion on Wednesday. The remainder of the week was spent on concepts from the textbook. For the derivatives and definite integral labs, the next week would be a repeat of the first; all of the other labs proceeded directly to the regrouping described next. On the third week, students would be placed in new groups, where they were responsible for teaching their context to their new group members; this type of presentation is called a Jigsaw presentation because each student is responsible for one piece of a larger idea. After this Jigsaw presentation, students were expected to write up their individual answers to the 20 parts of the approximation framework. Each lab had one formative prelab and two or three post labs associate with the activity.

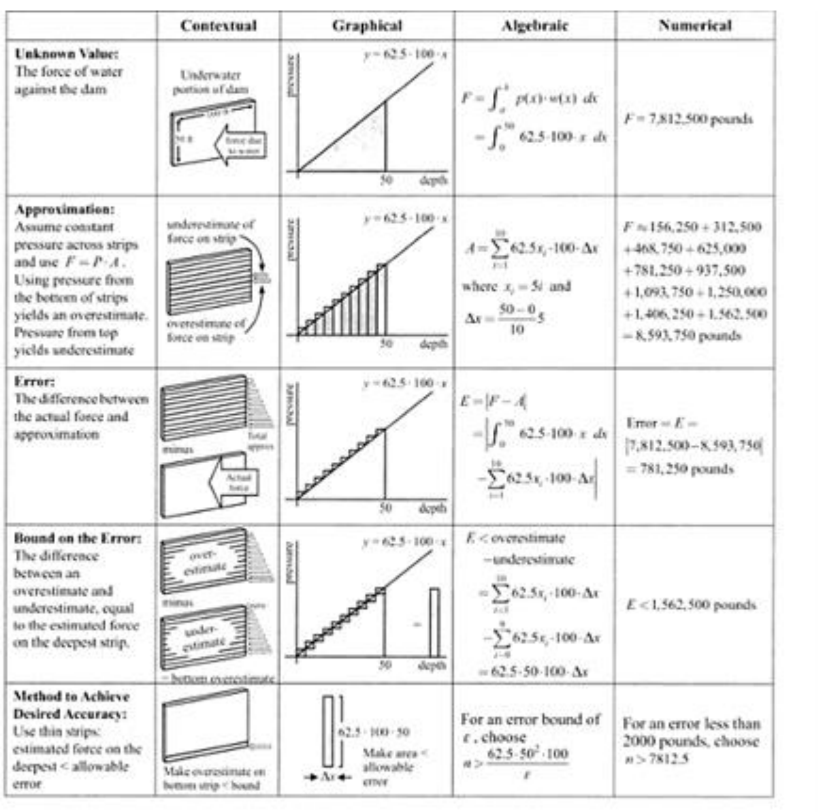

Figure 1: Approximation framework (Oehrtman, 2008)

The approximation framework is built upon developing systematic reasoning about conceptually accessible approximations and error analyses but mirroring the rigorous structure of formal limit definitions and arguments (Oehrtman, 2008, 2009). This study focused on the three multi-week labs developing the most central topics in the course: limits, derivatives, and definite integrals. Each approximation lab consists of 20 questions designed to help students understand their context in terms of approximating a limit. For each calculus concept, students are asked to identify the unknown value that cannot be solved with algebra, an algebraic technique for approximating the unknown, quantify the error, bound the error, and describe how an approximation can be computed to any desired accuracy. Students are asked to represent these five components of the approximation framework contextually (words and pictures), graphically, algebraically, and numerically. The figure above illustrates the 20 components of the approximation framework for one context of the definite integral lab, where students have been asked to compute the water pressure on a dam (Figure 1). Each lab had three or four different contexts; one of which was more challenging and intended for students that had seen calculus before.

The theoretical perspective for this case study (Patton, 2002) was Dweck's (2006) mindsets (Figure 2). Participants attended a midsized rural regional research university in the South, and were recruited from an introductory calculus course taught using CLEAR Calculus labs. These labs are built upon developing systematic reasoning about conceptually accessible approximations and error analyses but mirroring the rigorous structure of formal limit definitions and arguments (Oehrtman, 2008, 2009).

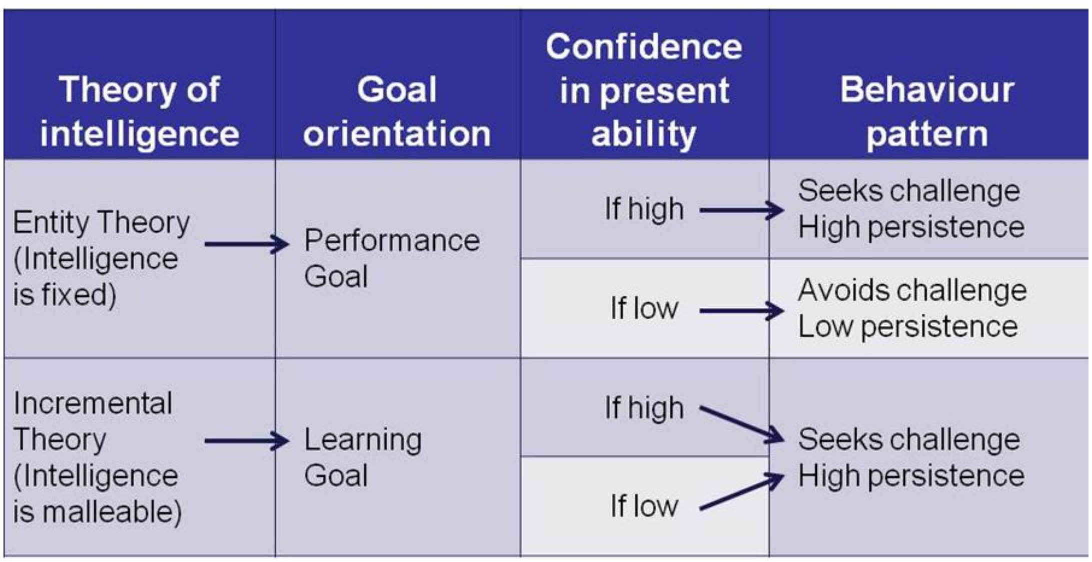

Figure 2. Summary of Dweck's mindset theory

Students in the course who consented to participate in the research (10/12 students in the course) took the Patterns of Adaptive Learning Scale (PALS) during the second week of the semester. Eight of the participants were male, and two were female. All students were math minors, math majors, or double majoring in math and another STEM field. Three participants were upperclassmen, and the rest were freshmen. Six had been exposed to calculus topics before this course. Four participants participated in semi-structured interviews (Patton, 2002) to obtain a sample with maximum variation according to their mindset (Table 1). Author 1, who instructed the course kept a journal of observations of each class and of students' frequency and reasons for office hour visits throughout the semester. Author 2 observed the class and consulted with the instructor of the course for triangulation of the interview data.

Table 1
Interview participants

Pseudonym	Year	Major	Mindset	Final Grade
Ian	Junior	Math	Strong Growth	C
Roland	Freshmen	Biology	Weak Growth	A
Penelope	Sophomore	Biology	Weak Fixed	B
Steven	Freshmen	Math	Strong Fixed	A
Quentin	Freshmen	Engineering	Weak Fixed	D

Participants were interviewed in a semi-structured interview at the end of the semester. The interview questions in the core script are listed below, though each participant had somewhat different probing questions. Interviews lasted approximately 20 minutes. After each interview, the authors discussed initial impressions that were recorded in research journals.

- Tell me what kind of student you've been in previous math classes
- Tell me what this class is like.
- If I had never seen one of the labs, tell me about them. What are they like? What do you do in them?
- Why do you think you do labs?
- Have labs changed you? How?
- What do you do for calculus when you're not in class?
- What will you remember about this class?
- What should I have asked you but didn't?
- Do you think your experience in this class will make you approach your next class differently?
- What have you learned in the class?
- What are the features of the class that stood out to you?
- Have you changed as a student as a result of this class?
- A lot of people mentioned instructor caring?
- What made you decide caring was a thing?
- Would you recommend this class to another student?

After transcribing the interviews, Dibbs and Patterson coded the transcripts separately using the coding scheme developed from the literature and theoretical perspective (Table 3). The interrater agreement on the separate coding was 80%. After reconciling the codes where the researchers differed, a one page summary of each participants' analysis was typed up and given to the participants as a member check. These member checks led to the challenge code to be broken into two separate codes. After the interview analysis was completed, the second PALS survey was scored, and the PALS results were analyzed using Mann-Whitney due to the small sample size.

To if this behavior persisted in future mathematics classes, particularly those that were more traditionally taught, we observed Ian, Steven, and Quentin (who chose to repeat calculus in the one section of CLEAR calculus offered) in their next mathematics classes. Penelope and Roland were not required to take additional mathematics courses. Ian, Quentin, and Steven also took the PALS at the end of their next semester and had brief, informal interviews with Author 1 during the next two semesters. These interviews were coded using the same coding scheme given in Figure 3. To if this behavior persisted in future mathematics classes, particularly those that were more traditionally taught, we observed Ian, Steven, and Quentin (who chose to repeat calculus in the one section of CLEAR calculus offered) in their next mathematics classes. Penelope and Roland were not required to take additional mathematics courses. Ian, Quentin and Steven also took the PALS at the end of their next semester, and had brief, informal interviews with Author 1 during the next two semesters. These interviews were coded using the same coding scheme given in Figure 3.

Table 3
Standards of Evidence

Code	Definition	Standard of Evidence	Example
Challenge is a feature	Students' perception of the class as having difficult problems as the course of the course and seeing this as a positive thing	• Direct statements made by students that (challenging/real life/difficult problems are important in class • Direct statements made by students indicating this is a good thing • Tone of students' response indicated bullet point #2	"This class us challenging, but that is the point" -Penelope
Things that are challenging	What parts of the class students fins to take the most time outside of class/require the most work	• Direct statements or complaints about the things that are the most difficult	"Labs…they've been the most difficult challenges so far. Even more difficult than the test" -Penelope
How labs changed me	Students' perceptions of the work habits and beliefs that participating in this curriculum changed them this semester &/or in the future	• Direct statements made by students about homework or study habits that changed as a result of the class • Direct statements made by students about any beliefs that changed as a result of this class • Evaluative statements about whether this belief will persist into the next class	"Taught me to think through the problems more carefully…to figure out what is wanted" -Roland "I'll think more in depth about [future mathematics courses]" -Ian
Student noticing	Features of CLEAR Calculus labs and course design students recognize as different from other mathematics classes	• Direct statements made by students about the parts of the course that were different from previous math courses	"The main difference between this class and [my last calculus class] is that there are these weekly labs" -Quentin
Perceived course goals	Student's beliefs about the purpose for the components of CLEAR calculus they have not experienced in prior courses	• Direct statements made by students about what they believed the goals of the features they noticed about CLEAR calculus were	"So that we can get almost real world experience so we can retain what we learn" -Steven

Findings

There were four major themes in the interview data: students do not notice the post-labs, students attribute all post-lab based instruction to instructor caring, there was an increase, though not a statistically significant one, in growth mindset tendencies, and participants' challenged in introductory calculus became more growth mindset oriented in the next course.

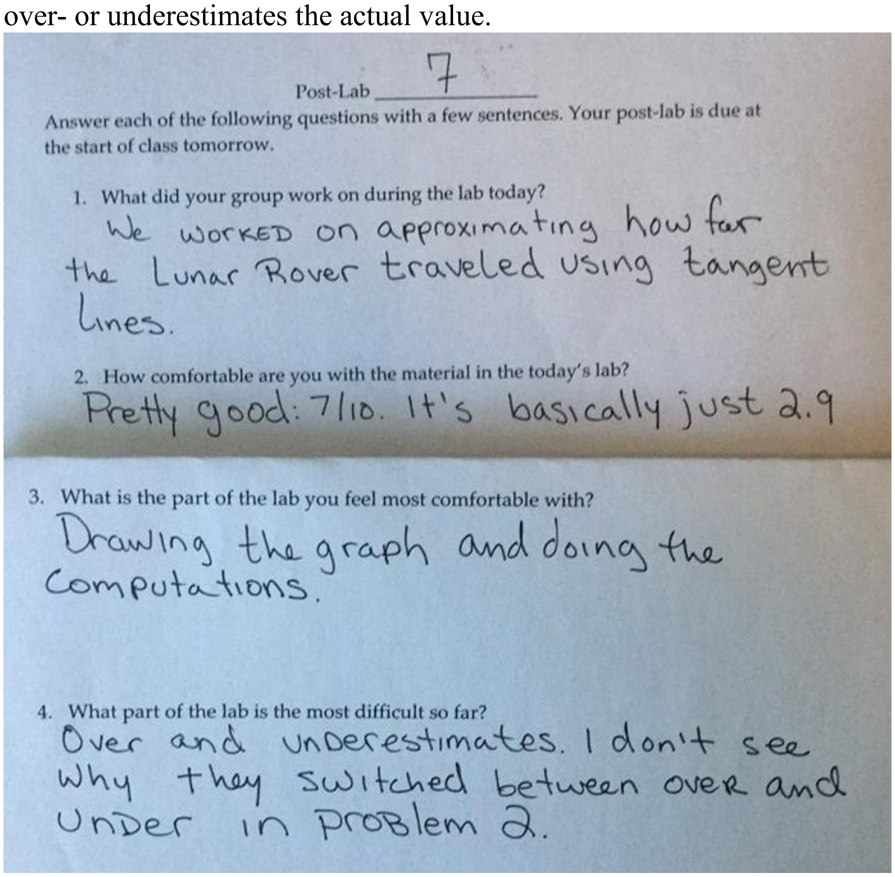
The interview participants all agreed that the labs were the central component of the course. Steven, like the other interview participants, saw the labs as central to the class, challenging, but useful:

> [This class] is harder and easier than you'd expect. As long as you can keep up with your work, you can keep your grades up… [Labs] are great because I'm not necessarily testing as well as I do on my labs. This is my first class with a hard lab so that it was new for me. They're [the labs] kind of like complicated word problems… [I think we do labs] probably so that we can get almost real world experience so we retain what we learn.

The main difference between CLEAR calculus and prior experience with calculus classes was the weekly labs, as Ian explained in his interview:

> Why do we do labs? I think it's to see how the math will be used in real world situations…The labs, probably [are what I will remember about this course]. I've taken calculus before and we didn't do any labs. This is much different than any math class I've ever taken.

As a part of the CLEAR Calculus curriculum, students completed a post-lab in the form of formative assessment after each lab. On this assignment, summarized what their group accomplished, their confidence in the material, the part in which they excelled the most in the lab, and the part(s) of the lab where they struggled. Figure 3 below gives an example of a typical student post-lab. Here, the student is comfortable with the basics of linear approximation, but is not noticing that the first problem is approximating an input value and the second is approximating an output value, which changed whether the computed value over- or underestimates the actual value.



Post-Lab 7

Answer each of the following questions with a few sentences. Your post-lab is due at the start of class tomorrow.

1. What did your group work on during the lab today?

We worked on approximating how far the Lunar Rover traveled using tangent lines.

2. How comfortable are you with the material in the today's lab?

Pretty good: 7/10. It's basically just 2.9

3. What is the part of the lab you feel most comfortable with?

Drawing the graph and doing the Computations.

4. What part of the lab is the most difficult so far?

Over and underestimates. I don't see why they switched between over and under in problem 2.

Figure 3. Typical student post-lab

The post-labs are a significant reflection piece of CLEAR Calculus labs that students rarely appeared to notice. These labs provided the instructor with the knowledge of the areas of the content that students have mastered and the areas that students have struggled. But students did not perceive the post-labs, a brief assignment at the end of class, to be the source of this knowledge. When students finished the in-class lab early, they were usually able to finish the post-lab in the last 5 minutes of class. In the interviews, none of the participants brought up post-labs until the interviewer did. Roland was the only student that mentioned post-labs at all and he only did so in a way that summarized the lab process, "…we do a pre-lab, a lab, and then a post-lab. Overall, I don't really like labs."

Students display a hurried approach to post-labs. They seem to try to finish the post-lab before they leave class on lab day so as to not leave it to the rest of the week to be forgotten. The following was a common episode at the end of every lab. One to three students said something similar at the end of each lab about the post lab starting in the third week of classes:

> Quentin smiled as he left Lab 6 today. "Here is my post-lab," he told me as he put the paper in the folder, "This week, at least, I didn't forget to do it." –Author 1 fieldnotes, Week 6 (Tuesday)

In class, post-labs were only mentioned explicitly by students as something they were glad that they did not forget to complete them. Combined with the students neglecting to mention the post-labs during the interviews, this suggests students approached post-labs as a low-priority afterthought.

Students are not making the connection that the instructor uses the post-labs to alter the course of the content presented in class in any way. When asked, no student in the interview could identify the post lab as something other than a part of the lab. The assignment students most frequently asked to be able to turn in late (late work was not accepted in the course) were post-labs, because they often forgot to complete them. This indicates students did not notice the post-labs as an important component of the lab.

Although students did not see the informal reflections they did on the post-lab as central to the course or important to their learning, students did see the higher stakes test corrections and reflections to be hugely important to their understanding of the material. Students are allowed to correct their tests to receive a token amount of points added to their original test grade; however, in order to receive any credit, the corrected test must be wholly correct and each problem must include at least a one sentence reflection on the error in the original test solution. When talking about correcting the test problems that he got wrong during the test, Steven saw this as an opportunity to learn:

> ....Which is great because I'm not necessarily testing as well as I do on my labs…I try to figure out what's going on again and again and watch YouTube. I like something my grandpa said, 'You're your own best teacher. So you only learn things if you want to learn them. So I'll go back and try to figure out exactly what was going on to see if I can correct it.

While students do not notice the post-labs, they all believe that there was value in the labs and that their instructor probably cared about their learning. However, the actions that were seen by the students as evidence of instructor caring were based upon the reflections in the post-labs, and so the unacknowledged post-labs did help to create a perception of a positive relationship between students and instructor.

Students all saw labs as the most important and memorable part of the course. In three of the four interviews, students made statements comparing the relative importance of labs and tests. While students' lab grades were 15% of their course grade, the same as one test, students saw the labs as being a much bigger part of the course. Although Steven felt that the labs were less difficult than the test, the other three interview participants who did not earn A's in the course disagreed with this sentiment:

> What I'll remember most is probably doing all the labs. I'm taking chemistry as well, and we have a lab every week. So I'm used to doing the lab. I'm used to doing lab assignments, but like the lab assignments she gives us in this class are more challenging because you have a more complex pre-lab. Like lab assignments in chemistry, you don't have to do a whole write up usually. She makes us like write paragraph answers to one-word answers. I guess that way we're answering it more in depth. So we get a better understanding of it. I guess I'll remember the labs the most. They've been the most difficult challenges so far. Even more difficult than the test.
> –Penelope

Participants believed that the labs were valuable, even though the labs were difficult and frustrating. When asked about what he will remember about the labs, Steven responded,

> Probably [I will remember] all the labs, in a little of both [a good way and a bad way]. I'll remember because they were so hard. But it's also nice when you understand one and you get it done. It's a nice feeling of accomplishment. I'll be a little more scared to take Calculus II, but that might be a good thing too.

Since Steven was generally successful at the labs (he actually earned the highest grade in the course) he enjoyed the challenge of the labs and did not necessarily have an experience that would challenge his strongly fixed mindset.

Quentin, who also had a strongly fixed mindset, did not get the same sense of accomplishment from the labs; he actually failed the class because he only turned in two of the 14 labs and only one post-lab. "I don't turn in anything that isn't fit to be seen," he explained, "and my labs are not good enough. I care too much to turn in bad work." When he was asked about not doing the post-labs, which are graded on completion, Quentin's justification was that the other people who did post-labs were asking his questions already: "I don't really need to do them. All my questions get answered on Thursday [when labs are discussed in class], so I don't add anything by doing a post-lab." Overall, the labs were seen as a positive thing, and even though Quentin did not feel post-labs were something he needed to do personally, he did feel that he benefitted from the discussion based on everyone else's post labs later in the week.

After the semester ended, the pre- and post- PALS surveys were analyzed using the Mann-Whitney U test since there were only 10 students who completed the survey. The Mann-Whitney U test was not significant ($p = 0.15$), but the small sample size makes it difficult to rule out mindset changes in general. Although we did not see significant mindset changes, all of the interview participants made actions during class throughout the semester and statements in their interview that suggested that there were qualitative, if not quantitative shifts towards a growth mindset.

In the first month of the course, before the first test, participants' behavior indicated an unwillingness to seek help or admit they did not understand. Two-thirds of the labs and homework were turned in a pattern of completely correct solutions or blank problems. When students were asked if they needed help during the labs and recitation by the instructor or teaching assistant, students responded in the negative or that they 'didn't get it' and could not elaborate (Dibbs fieldnotes, weeks 1-4). During lectures, wait times of over a minute were required before students would participate in class. Only one of the ten students-Ian- visited office hours before the first test. However, on the final question of the post-lab, seven participants did note specific topics in the lab or on the homework that they did not understand on at least three of the four post-labs during the first unit.

During the derivatives unit, students began to be more confident and more willing to seek assistance when they ran into trouble. Students' reported confidence on post-labs improved; 8

out of 10 students reported feeling confident they understood the material, and seven consistently earned passing grades on the labs. Six students, including all three male interview participants, began attending office hours or the optional Friday recitation on at least a weekly basis. The average wait time per question dropped to 20 seconds, and the total number of hours the class spent in the math lab increased from two to 10. For the seven students that eventually passed the course, there was a marked reduction of blank responses; students were more willing to give partial responses and admit they had gaps in their knowledge (Dibbs field notes, Weeks 5-10).

Students were interviewed in the final unit. By the end of the semester, students sought help when needed: in the math lab, on YouTube, from a classmate, via email, in office hours. Roland described his out of class work as a process for seeking help:

> [Outside of class I] do the [optional] problems that she assigns me to do. Try to do them or get someone to help me when I can't understand them. I watch a lot of YouTube videos. I find the book [Stewart 6th Edition] hard to – hard to understand things from the actual book so I usually have to use other things for the harder problems. Usually, I'll do all the ones I can do, and save the ones I can't do for later. I'll use additional resources or get help from the TA.

There were only three comments on the post labs on this unit, all of them asking for help with sigma notation. After midterms, students visited the office at least every other week.

Overall, even though there was not a statistically significant shift in students' mindset, their behaviors and interview statements indicate that participants have at least adopted some more growth-oriented learning strategies. However, grades were still seen as a primary motivator for these students since the average goal orientation sub-score on the PALS was almost a full point below the average response on any of the other sub-score of the PALS results, so in essence students learned to emulate a growth mindset because such characteristics were required to satisfy their performance goals which were more aligned with their actual mindset.

In the next course, two of the three participants became more growth oriented. Steven, who easily earned an A in the second-semester calculus course and the introduction to proof course, actually became more fixed, but Steven is unlikely to experience a change in his mindset until he begins to struggle with the material. Ian's mindset became slightly more growth oriented after second-semester calculus, but his growth score is so high that there is a real chance of a ceiling effect. Quentin became much more growth-oriented after successfully repeating introductory calculus with the CLEAR calculus curriculum; by the end of the semester, his PALS score had become significantly more growth. Figure 4 shows the changes in participants' scores over time; a score of 140 marks the boundary between a more fixed mindset and a more growth mindset.

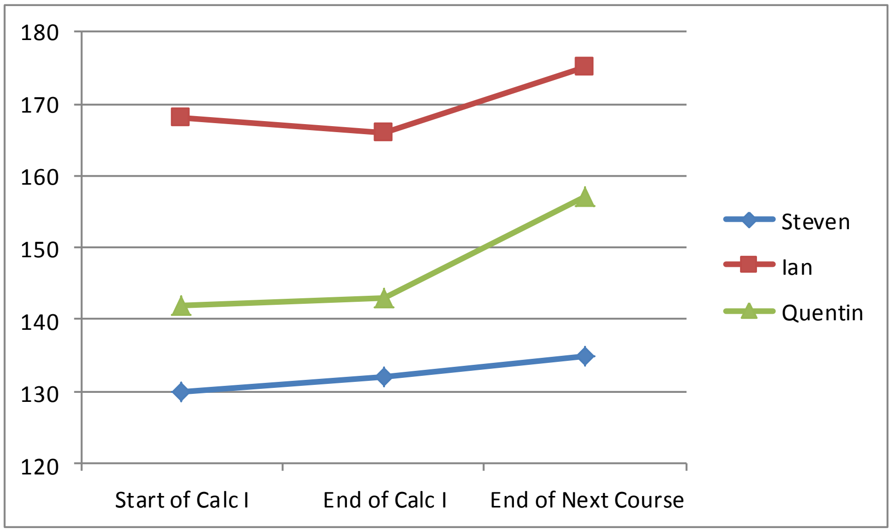


Figure 4. Participants' mindset scores over two semesters

Discussion

The feature of CLEAR Calculus that students notice and value the most are the labs. The post-labs, which were valued most by the instructor were worth a nominal percentage of students' final grades and were neither noticed nor valued by participants. However, students did believe that the instructor cared about them and became increasingly willing to seek help throughout the semester.

There were two components of the course that led students to believe that this course was different and that their instructor cared about them. The first and most important were the labs; the prominence and difficulty of the labs convinced students that this introductory calculus was different from their prior high school or college courses. Without some even causing disequilibration, students are unlikely to make any changes to their learning patterns and make the successful transition to college (Craig, Graesser, Sullins & Gholson, 2004; Zaretskii, 2009). The labs, with the decreasing amount of scaffolding throughout the semester, provided a challenge to their idea of their role as a student, but the test corrections gave students the perception of a margin for error in the course that there was room to struggle without risking their grades. The second component course the students noticed was the test corrections. Test corrections, which could raise students' final grade by a maximum of 2.5% at an institution with no +/- grades did not actually make a difference in the final grade of any student enrolled in the course, but the perception of a safety margin was of central importance to the students. Steven, Penelope, and Roland were especially focused on maintaining their high grades in the course and maintained that the test corrections were very important.

Although the more formative (1% of final grade) post-labs were not noticed by participants, this is likely a combination of the students' strong performance goals and their general success of these participants in the course. The participants that earned A's and B's in the course mastered the limit concepts in the labs around the eighth lab and had few questions on their post-labs after that; for them, the post-labs had limited utility for months be the time they were interviewed. The only participant that mentioned these assignments in any depth was Quentin, who never did post-labs because he felt all of his questions were already answered. Quentin did choose to repeat calculus with the same instructor rather than change majors after failing the course. Given the importance of a perception of their instructor caring about their success is for Persisters (Ellis & Rasmussen, 2014), Quentin's belief that his instructor intuited and answered his questions likely helped him to continue with his intended major. Given that low stakes reflection assignments like these post-labs scale well onto free online platforms with semi-automated feedback like the Just in Time Teaching software (Marrs, Blake & Garvin, 2003; Urban-Lurain et al., 2013), these types of assignments are likely to be the most efficient way to create a perception of instructor caring with some positive effect on student persistence in their STEM major after introductory calculus.

Although there were no significant gains in students' mindsets, we believe that this area is worthier further exploration. The sample size in this study was small and the p-value was relatively low. We also did not collect baseline data from traditional calculus courses or other entry-level mathematics courses. Since students tend to adopt a more fixed mindset in times of stress, like transitioning to college (Murphy & Thomas, 2008), it is worth investigating whether maintaining students' mindsets through their first semester or college is better than a typical curriculum. Regardless, post-class reflections do appear to help students build positive perceptions of their instructor for minimal additional grading.

What do students attend to when first graphing $y = 3$ in R^3?

Allison Dorko
Oregon State University

I interviewed 11 differential calculus students as they graphed for the first time in R^3. This paper considers how students generalise as they graph $y = 3$. Some students drew a line, while others drew a plane. In creating their graphs, students attended to equidistance, parallelism, specific (x, y), (y, z), (x, y, z) tuples, and the role of x and z. Students' use of these ideas was often generalised from thinking about the graphs of $y = b$ equations in R^2. A key finding is that the students who thought the graph was a plane always attended to the z variable as free. I discuss this specific result using Harel and Tall's expansive, reconstructive, and disjunctive generalisations framework. I propose that the expansive and reconstructive categories provide a powerful way to explain and understand the two main ways students generalise from R^2 to R^3, and why multivariable topics are difficult for learners.

Key words: multivariable functions, graphing, generalisation

Introduction

Most real-world uses of mathematics involve reasoning about situations with many variables. Being able to reason about multivariable ideas is so important that the Mathematical Association of America recently recommended that high school mathematics curricula include multivariable topics (Shaughnessy, 2011). This recommendation came as the result of the *Curriculum Renewal Across the First Two Years* report (Ganter & Haver, 2011), which examined the mathematical needs of biology, chemistry, economics, engineering, physics, and other STEM disciplines. Hence research about how students understand multivariable topics has the potential to affect learning outcomes for a large group of students of a variety of ages and in variety of STEM fields.

Because multivariable topics share many similarities with their single variable counterparts, many researchers studying student learning of multivariable topics focus on how students generalise from the single- to multivariable context (e.g., Dorko & Weber, 2013; Fisher, 2008; Jones & Dorko, 2015; Kabael, 2011; Martinez-Planell, Trigueros, & McGee, 2015; Yerushalmy, 1997). This research tells us not only how students generalise specific ideas, but also allows us to take a broad, cross-context look at how students transition from the single- to multivariable setting. The goal of this paper is to contribute to both knowledge of specific multivariable topics and knowledge about students' single- to-multivariable transition. I focus on the following questions:

(1) What do students attend to as they first think about graphing $y = 3$ in R^3?
(2) How do students generalise as they first think about graphing $y = 3$ in R^3, and how are these ways of generalising similar to or different from students' generalisations of other multivariable topics?

Theoretical Perspective

I take an actor-oriented transfer perspective in which generalisation is "the influence of a learner's prior activities on his or her activity in novel situations" (Ellis, 2007, p. 225). The actor-oriented perspective privileges what students see as similar across situations, even if their perceived similarities are not normatively correct (Lobato, 2003; Ellis, 2007). The idea is that a student may do something in a multivariable setting that is not normatively correct (e.g., draw $y = 3$ in R^3 as a line instead of a plane), but in doing so the student is making sense of a situation based on past knowledge and experience (e.g., $y = 3$ in R^2 is a line). Hence the student's work counts as a generalisation, even if she has drawn an incorrect graph.

Under the actor-oriented umbrella, I use Harel and Tall's (1991) expansive, reconstructive, and disjunctive generalisation categories to describe the particular ways students generalise (Table 1). This framework categorises generalisation in terms of how students use existing schemas or develop new ones as they move from one context to another.

Table 1. Harel and Tall's generalization framework (Harel & Tall, 1991, p. 1)

Type	Definition
Expansive	• Expansive generalisation occurs when the subject expands the applicability range of an existing schema without reconstructing it. • Earlier schemas are included directly as special cases in the final schema.
Reconstructive	• Reconstructive generalisation occurs when the subject reconstructs an existing schema in order to widen its applicability range. • Reconstructive generalisation differs from expansive in that the existing schema is changed and enriched before being encompassed in the more general schema.
Disjunctive	• Disjunctive generalisation occurs when, on moving from a familiar context to a new one, the subject constructs a new, disjoint schema to deal with the new context and adds it to the array of schemas available.

These categories fit into the actor-oriented focus on what students see as similar by providing language for instances when students perceive similarity (expansive, reconstructive) and when they do not (disjunctive). In the next section, I identify examples of these three types of generalisation in existing research about students' understanding of multivariable functions' graphs.

Background Literature

Thinking about functions and graphs in three dimensions requires students to coordinate three quantities, as well as shift from thinking of y as a dependent variable to considering z as dependent on x and y. Evidence from a variety of contexts indicates that this is a difficult generalisation for students to make. For instance, some students give the domain of a function $f(x, y)$ as x and the range as y (Dorko & Weber, 2013). Others may offer an (x, y ,z)-tuple as an element of the domain or range (Kabael, 2011). These responses indicate that students have not conceptualised y as independent.

Students' difficulties with multivariable graphing tasks also provide evidence that coordinating three quantities is hard, particularly when a function has a free variable. For instance, Martinez-Planell and Gaisman (2013) described how some students graph $f(x, y) = x^2$ as a parabola instead of a parabolic surface. Additionally, students may draw $f(x, y) = x^2 + y^2$ as a cylinder or a sphere because they are accustomed to $x^2 + y^2$ representing a circle in R^2 (Martinez-Planell & Gaisman, 2013). I characterise drawing $f(x, y) = x^2$ as a parabola as an expansive generalisation because the students seem to apply the idea that x^2 is a parabola to the multivariable context. In contrast, I believe the cylindrical- and spherical-shaped graphs represent reconstructive or disjunctive generalising because students have attended to z. Martinez-Planell and Gaisman (2013) write only that "upon seeing the expression '$x^2 + y^2$', some students think of 'circle' and end up interpreting the graph as a cylinder or a sphere" (p.671) so it is impossible to know if students change how they think of $x^2 + y^2$ (reconstructive) or if they think something like '$x^2 + y^2$ is a circle in R^2 but it is a sphere in R^3' (disjunctive). The latter would represent a disjunctive generalisation because the student has developed different, context-dependent meanings for the symbols $x^2 + y^2$.

In addition to coordinating three quantities, students must also develop a schema for representing points in space. Students sometimes struggle with conceptualising $f(x, y)$ as and output or the height of the graph at a particular (x, y)-tuple (Martinez-Planell & Trigueros, 2013), which may explain Kabael's (2011) finding that students have difficulty projecting a graph to the xy plane to determine its domain and range. Students also have trouble determining the intersection of a surface with fundamental planes (a plane of the form $x = a$, $y = b$, $z = c$ for a constant c). Trigueros and Martinez-Planell (2010) found that students who had taken multivariable calculus knew that these were planes, but weaker students had trouble placing such planes in a set of manipulatives and drawing the planes on a 2D image of a multivariable graph. Stronger students could place the planes, but had difficulty determining the intersection of such planes with a multivariable surface. My research, by focusing on a particular fundamental plane, may provide instructional implications that help students overcome these issues. In particular, my focus on what students attend to when they first graph in R^3 may lend insight into how students build a schema for R^3.

Martinez-Planell and Trigueros' research has been in the context of developing a set of activities to help students learn how to graph multivariable functions. They concluded that students' difficulties with multivariable graphing could due to familiar symbols such as x^2 in $f(x, y) = x^2$ and $x^2 + y^2$ in $f(x, y) = x^2 + y^2$. They subsequently altered the activity sets to avoid familiar notations, so it is unknown if students are able to use such notations productively. My work builds on this research by paying explicit attention to how students' conceptions of single-variable functions' graphs interact with their conceptions of graphs of multivariable functions. Findings from other studies about various multivariable topics indicate that students can often successfully leverage their single-variable knowledge to make sense of multivariable topics (e.g., Dorko & Weber, 2013; Jones & Dorko, 2015; Kabael, 2011; Yerushalmy, 1997), and I wanted to study whether this was also the case when students graph in three dimensions.

Data Collection and Analysis

I interviewed 11 differential calculus students about multivariable functions so that I could observe the initial sense making of students who had not yet received instruction regarding these functions. I thought this would let me observe students' generalisations in real time. Additionally, given the actor-oriented perspective, I wanted to focus on students' reasoning and how that was being constructed. This paper focuses on data from two tasks. The first task directed students to graph $y = 2$ in R^2 which was the intent. The second task directed students to graph $y = 3$ on R^3 axes. After students read the task, I showed them an image of xyz axes and explained that the xy plane was flat with the z-axis perpendicular to it. I used a tabletop (xy plane) and a pen (z-axis) to show students what these axes looked like in 3D[1]. I asked follow-up questions such as "why did you draw a [line, plane] here?"

[1] It is important to note that such a demonstration does not guarantee that students understood how such a coordinate system works; in fact, researchers have found that students often must

I chose to focus on these problems because of reported difficulty students experience with multivariable functions' graphs, and also because fundamental planes can help students complete graphing and other tasks in calculus. That is, thinking of some $f(x, y)$ equation for $x = c$ or $y = c$ results in a cross-section that can then be used to help visualise the function's shape. Parts of fundamental planes also often form the boundaries of solids for multiple integration. These examples provide two good reasons to explore how students might think about equations of the form $y = c$ in R^3. Finally, Gaisman and Martinez-Planell (2011) point out that graphs of fundamental planes are the first R^3 graph students meet in the widely-used Stewart (2006) text. Hence this seemed an appropriate task for students graphing in R^3 for the first time.

I recorded the interviews with audio, video, and LiveScribe technology. I transcribed the interviews and used the transcripts in data analysis. I used the constant comparative method (Strauss & Corbin, 1998) for data analysis, reading the transcripts to identify students' answers to the task (that is, what did they draw for graphs?) and then re-reading to identify how students arrived at their answers.

I observed that some students had drawn $y = 3$ in R^3 as a line, others had drawn it as a plane, and two drew a line but then thought the graph might be a plane. I hence coded students' work as belonging to one of two categories: plane or line. Students' reasoning involved words/phrases like parallel, equidistant, "all x points," "z can be any value," "x can be any value," "I don't think that x and z really have like any effect", all values of x and z, variables as "not mattering," x and z being "any value," and "no matter what x or z is." I also observed students considering about specific points, such as "if you say $x = 2$ and $z = 2$, it's going to be 3." I noticed that these utterances fit into three broader, non-mutually-exclusive categories: reasoning using equidistance and parallelism, reasoning about x and z, and considering specific (x, y), (y, z), and (x, y, z) tuples.

Finally, I looked for patterns in how students had thought about the graphs, and whether their graphs were planes or lines. That is, I looked specifically to see if there were something common to all of the students who drew the graph as a plane, and all the students who drew the graph as a line. I noticed that the difference between the graphs seemed related to whether or not the students explicitly attended to z as a free variable.

Results

Of the 11 students, three drew $y = 3$ in R^3 as a line and 8 drew a plane. Figure 1 groups students' work first by answer, then how they had arrived at that answer. For instance, four of 11 students drew a plane by thinking about x and z as free variables. One student thought about parallelism and drew a line, and one student thought about parallelism and equidistance and drew a plane. The plane and line categories are mutually exclusive. The subcategories are not. The (n/11) parentheses next to each subcategory in the diagram represents the main way students reasoned. In some cases, students reasoned in multiple was (e.g., S3 both thought about particular coordinate points and free variables, but is in the coordinate point category because, in my opinion, this played a bigger role in her reasoning than did the idea of free variables).

---

develop a schema for R^3 through specific actions like plotting (x, y, z)-tuples and working with fundamental planes (Martinez-Planell, & Trigueros, 2012; Trigueros & Martínez-Planell, 2010).

I present the results by giving examples of students in each category (parallelism, *x* and *z* as not changing, tuples, and free variables), focusing on what they attended to and how they generalised.

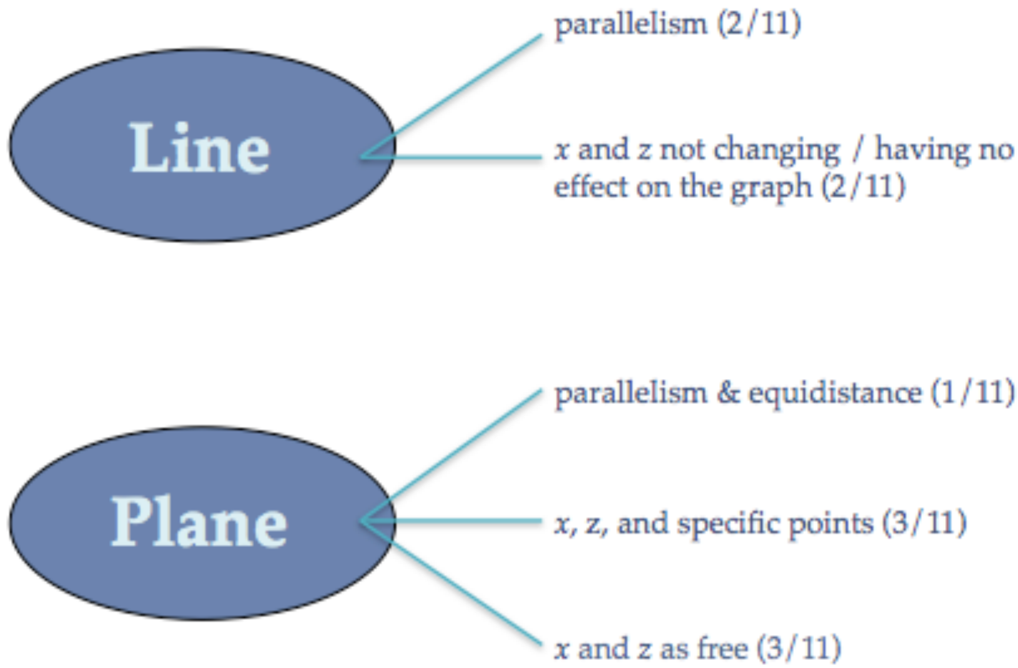

Figure 1. Results

Attending to and generalising parallelism

S6, S9, and S8 both generalised parallelism, but S6 and S9 drew lines while S8 drew a plane:

S6 So $y = 3$. So on an *xy* graph [draws R^2 axes] at 3, would be going this way. So on the *y*, following the *x*. So [switches to R^3 axes] this would be on the *y*, this is the 3 point on the *y*, and it's following the *x* axis [Figure 2].

S9 So if this is, if this is *y* is equal to 3, then I'm wondering if it will just go parallel with the *x* axis…but just at the *y* is equal to 3 point… just kind of like looking here [$y = 2$] it's like parallel to the *x* axis at whatever *y* point because it's just that straight line… I'd assume just for all *x* points that you know *y* would equal to 3. [I think the graph is a line] just cuz … your *y* is only 3. It's not like interacting with, with anything else.

S8 $y = 3$ would be something like this, where this distance right here between each, between *y* and each of these axes would be 3, I think. I'm thinking that because if you take like this thing, and that would be everything except for *y* [shades *xz* plane]... I'm thinking of this plane in relation to *y* and having *y* be every distance that is 3 away from that plane... it would be an entire plane... it has to be parallel to *x*, and this has to be parallel to *z*, so it would be this plane right here that is 3 away from the plane that *x* and *z* creates... like for the last question when *y* is equal to 2, that is every value that is 2 away from $y = 0$, right? So I'm thinking that like $y = 0$ would be the same as this [xz plane; Figure 3]. So it's 3, it's 3 in the positive [y] direction it's going to be parallel to x in the same way that this line right here [draws $y = 2$ in R^2] is parallel …to the x axis.

S6 began by drawing R^2 axes and graphing $y = 3$, describing the line as "following the x." He then drew R^3 axes and said "this is the 3 point on the y, and it's following the x axis." I infer his use of the word 'following' as attending to the parallelism between the x axis and $y = 3$. Moreover, S6 generalised what $y = 3$ in R^3 would look like by thinking about what it looked like in R^2, then drawing the same picture in a new orientation on the R^3 axes (Figure 2). This is an expansive generalisation because S6 expanded his existing schema to a new context without reconstructing it. In particular, he generalised that $y = 3$ in R^3 would be parallel to the x axis, just like in R^2, and he generalised that it would be a line. S9 made a similar generalisation, explicitly generalising between tasks when he said "I'm wondering if it will just go parallel with the x axis…but just at the y is equal to 3 point… just kind of like looking here [$y = 2$] it's like parallel to the x axis at whatever y point". This is an expansive generalisation because he applied his schema for $y = b$ equations as parallel to the x axis to the new R^3 context.

S8 also generalised parallelism. His reference to the R^2 task, "it's going to be parallel to x in the same way that this line right here [draws $y = 2$ in R^2] is parallel …to the x axis" is evidence that saw the two contexts as similar and generalised between them. In contrast to S6, however, S8 generalised by taking properties he knew to be true in R^2 (equidistance; parallelism) and reconstructed them for R^3. He first noted that $y = 3$ would be parallel to the x and z axes. He then shaded the xz plane and described $y = 3$ as always being "3 away from that plane." I take his reference to $y = 2$ as "every value that is 2 away from the x axis" as evidence that he generalised the equidistance property from R^2 to R^3. Because he talked about $y = 3$ as being three away from the xy plane, I consider this a reconstructive generalisation. S8 had to modify his equidistance and parallelism schema from the equidistance and parallelism of two lines to the equidistance and parallelism from two planes. There is evidence that he engaged in modifying these ideas in his statement "this distance right here between each, between y and each of these axes would be 3, I think." S8 first thought about equidistance and parallelism between $y = 3$ and *axes*. He then thought about where $y = 0$ would be in R^3, and having "y be every distance that is 3 away from that plane... it would be an entire plane... it has to be parallel to x, and this has to be parallel to z". That is, S8 modified his equidistance and parallelism schema to thinking about the equidistance and parallelism between two planes.

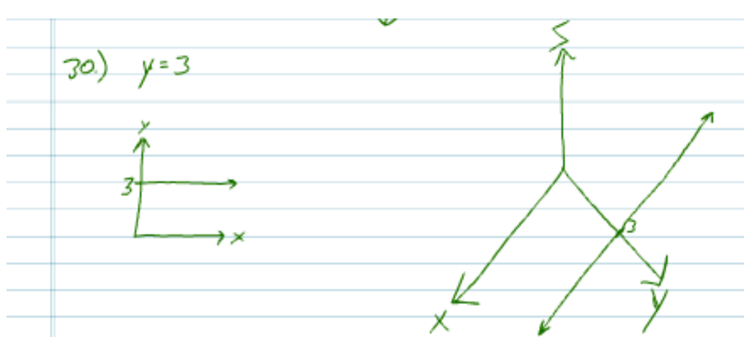

Figure 2. S6's graph of $y = 3$

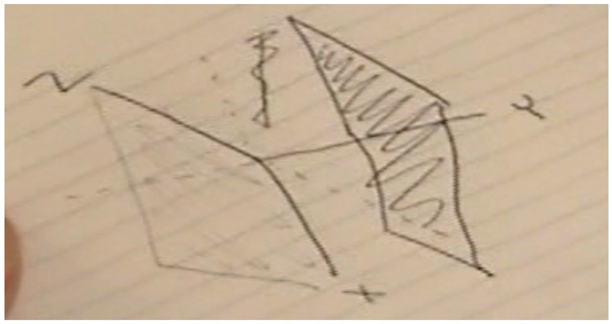

Figure 3. S8's graph of $y = 3$

I believe that although both students generalised parallelism, S6 drew a line because expansive generalisation did not force him to attend to z. Expansive generalisations, however, do not always result in non-normatively correct answers. The next section provides an example of how S3 and S7 engaged in expansive generalisations that supported their drawing planes. I say more about normatively correct and non-normatively correct expansive generalisations in the discussion section.

Attending to and generalising *x* and *z* as not changing

S1 and S11 drew lines for $y = 3$ in R^3, reasoning that x and z did not effect the graph. This was generalised from how they thought about $y = 2$:

S1 [$y = 2$] So, x and y, and at this point y will equal 2, and the graph would just go through 2 all the way, for all values of x.

S1 [$y = 3$] So the z direction, the z can't change and the x can't change… z is the vertical here… I guess I would just use this line for y always equal to 3.

S11 [$y = 2$] So this would be x and this is $y = 2$, and since it's just 2 all around, and it would go that way too [draws $y = 2$ for the negative x values]. Because usually like with the, it's just kind of giving you like a number I guess, so like no matter like what number like input, there's not really like, there's no x, so whatever number it is it doesn't matter, that the output is always going to be 2.

S11 [$y = 3$] It stays on like that like xy plane because there's no like z and there's no x… no matter like what the other ones are, it's just going to be that one number, which is like a straight line across the thing… I don't think that x and z really have like any effect to $y = 3$.

S1 talked about y equaling two "for all values of x" in the R^2 task but said "x can't change" in the R^3 task. From an observer-oriented perspective, we might have expected her to say that y equaled three for all x in R^3. Her statement that x could not change hence seems like the opposite. I wonder if from an actor-oriented perspective, both phrases 'for all x' and 'x can't change' mean the same thing to S1. This seems reasonable given that S11 did the same thing when she said "no matter what the input" and "there's no x" in the same sentence. I infer that S1 generalised that x did not affect the graph of $y = 2$ in R^2, and that x and z would not affect the graph of $y = 3$ in R^3.

S11 also generalised the idea of x having no effect to the idea of x and z having no effect. The evidence for this is that she used the same phrases in both problems: "no matter like what number the input…there's no x… the output is always going to be 2" to "there's no like z and no x… no matter like what the other ones are". I consider both students to have engaged in expansive generalisation because they applied the idea that a variable was not present in the equation, and hence did not matter, to the new context.

Attending to and generalising coordinate tuples

S7 and S3 and graphed $y = 3$ as a plane. Both thought about particular coordinate points, though S7 thought about a three-tuple and S3 thought about (x, y) and (y, z) pairs:

S7 So here's 3, we've got x, or the y, but then it's also going to be for all the z values, since z evaluated at any point will be $y = 3$. So I guess it would come out to be a plane… I kind of just thought since x evaluated[2] at any point on the graph equals 3, since the function is basically saying all, it's saying $y = 3$ at all points on the graph, any point you evaluate, so if you say $z = 2$ and $x = 2$, it's going to be 3.

S3 [$y = 2$] Whatever you plug in for x, at all, ever [makes dashes along the x-axis], y is just going to equal 2. So it's a horizontal line.

[$y = 3$] No matter what x or z is, y is always going to equal 3… I want to draw a line like this [indicates a line following the gridline for $y = 3$ on the xy plane] and a line like that [indicates a gridline parallel to the z axis and going through (0, 3, 0); Figure 4]. So what it's saying here is if x were 1, y equals 3 [Figure 5], or if $x = 2$, $y = 3$. And here too if z were 1, y is always going to equal 3 here [Figure 6]... I guess I drew a plane... [a plane makes sense] when it is drawn out like that.

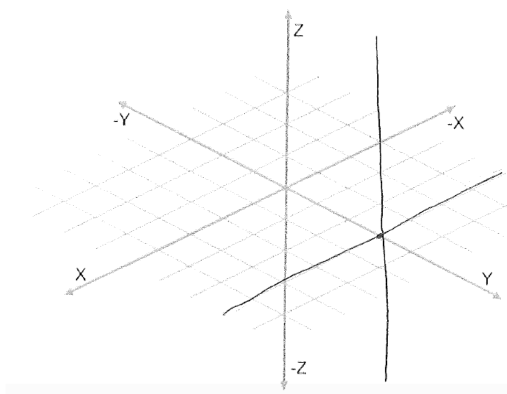

Figure 4. S3's plane

---

[2] I believe that S7 meant to say 'y evaluated at 3', particularly because she followed this phrase with 'it's saying $y = 3$ at all points on the graph' and later used the example of $x = 2$. Consequently, I have analysed this excerpt assuming that she did indeed mean to say y.

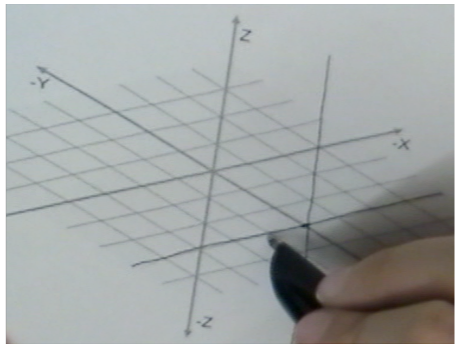

Figure 5. S3 considering (x, y) = (1, 3)

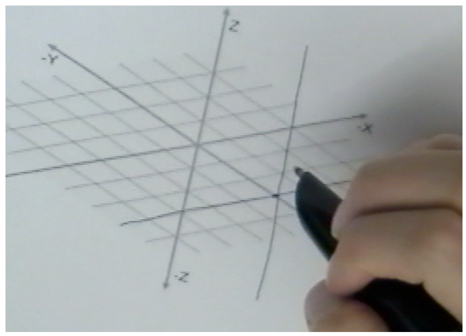

Figure 6. S3 considering (y, z) = (1, 3)

Both S7 and S3 generalised that if a coordinate point satisfies a particular condition (in this case, y = 3), it lies on the graph. S7 identified this condition ("it's saying y = 3 at all points on the graph") and then explained that this meant (2, 3, 2) was on the graph because y equaled 3 in that tuple. S3 identified the condition that "y is always going to equal 3," and used this to draw two perpendicular lines that intersected at (0, 3, 0). She then considered the points *(x, y)* = (1, 3), *(x, y)* = (2, 3), and *(y, z)* = (1, 3) and said "I guess I drew a plane". I interpret the phrase "I guess" as an in-the-moment realisation that the graph was a plane, afforded by considering particular points. I emphasise that S3's gestures (Figures 5 and 6) seemed to play a role in her thinking. Moving the pen from (0, 3, 0) to (1, 3, 0) and then to (2, 3, 0), and then from (0, 3, 0) to (0, 3, 1) seemed to help her see that the graph was a plane. S3 did not gesture toward particular points, but like S3, she said "I guess" the graph is a plane, and explained that she thought it was so because any point in which y = 3, such as (2, 3, 2), would be on the graph.

For both students, considering specific points was an expansive generalisation of the scheme 'If a coordinate point satisfies a particular condition (in this case, y = 3), it lies on the graph'. This is expansive because the students implemented a scheme that they likely had from experience with R^2 graphs, and they did not have to modify the scheme for R^3.

S3's particular points contain examples of both expansive and reconstructive generalisation. She considered two variables at a time, which I infer she generalised from being accustomed to considering *(x, y)*-tuples in R^2. Because she did not consider an *(x, y, z)*-tuple (which would be a reconstruction), I considered this an expansive generalisation. S3's use of a *(z, y)*-tuple, however, is a reconstructive generalisation because she expanded the notion of using *(x, y)*-tuples to using tuples of other variables.

S3 also generalised the notion of a free variable. I detail this generalisation in the next section, along with examples of other students who made similar generalisations.

Attending to and generalising free variables

Three students determined that the graph was a plane by focusing on x and z as able to take on any value. These students differ from the students who thought of x and z as "not changing" because the students here thought of x and z as free, and this afforded their graphing planes.

For example, in the $y = 3$ task, S3 said, "no matter what x or z is, y is always going to equal 3." I interpreted these statements as generalising the idea of a free variable because it seemed similar to her comment in the R^2 task that "whatever you plug in for x… y is just going to equal 2." S3's generalisation of the notion of a free variable seemed to be of the reconstructive variety because she realised that both x and z were free. S12 also appeared to engage in reconstructive generalisations:

S12 So maybe, maybe it would be like this [draws and shades plane]. Well this would kind of just be like just a flat sheet of paper on the $y = 3$, because all x values are 3, and then I guess you assume that all z values, since it's only, the only variable in the equation is $y = 3$, then it would have to be $y = 3$ for all x and z values. It's kind of just like a, I think it's supposed to be like a flat sheet kind of, like a piece of paper, and it's on $y = 3$, so it's supposed to encompass all the x values for negative and positive, and all the z values for z, positive z and negative z. They're all on $y = 3$... Well, I just thought like since $y = 2$ it should be like this, so if it's $y = 3$ it's like that, like all x values are $y = 3$. And z is going this way, so it must be, since there's no z in the equation, then it must be covering all this area.

I believe that the fact that S12 talked about x and then talked about z provides evidence that he engaged in reconstructive generalisations. S12 said "all the x values are 3" (from which I interpreted him as meaning 'for all the x values, y equals 3') followed by "I guess you assume that all z values since… the only variable in the equation is $y = 3$, then it would have to be $y = 3$ for all x and z values." He seemed to generalise that $y = b$ in R^2 would mean $y = b$ for all x, and hence $y = b$ in R^2 would mean $y = b$ for all x and z. The reconstruction is $y = b$ for all z. I take the phrase "I guess" here to indicate changing something in his schema.

Discussion

I observed students engage in expansive and reconstructive generalisations, but not in disjunctive generalisations. The particular generalisations are summarised in Table 2. This table also shows what students attend to when they first think about first graphing $y = 3$ in R^3: they attend to parallelism, equidistance, particular coordinate points, and free variables.

Table 2. Summary of generalisations

Student(s)	Generalisation	Type
S6	$y = 3$ is a line in R^3 just like it is in R^2	Expansive
S6, S8, S9	$y = 3$ in R^3 is parallel to the x axis	Expansive
S8	$y = 3$ in R^3 is parallel to the x axis and the z axis	Reconstructive
S8	$y = 3$ in R^3 is equidistant from the xy plane, just like $y = 2$ in R^2 is equidistant from the x axis	Reconstructive
S1, S11	x has no effect on $y = 2$ in R^2, so x and z have no effect on $y = 3$ in R^3	Expansive
S3, S12	Notion of a free variable: x is free in $y = 2$ in R^2; x and z are free in $y = 3$ in R^3	Reconstructive

S3, S7	If a coordinate point satisfies a particular condition (in this case, $y = 3$), it lies on the graph	Expansive
S3	A coordinate point has two elements	Expansive
S3	The elements of a coordinate point need not always be *(x, y)*	Reconstructive

Trigueros and Martinez-Planell (2010) and Kabael (2011) found students' difficulties with multivariable functions are often related to impoverished schemas for three-space. Our findings lend insight into how students begin to develop an R^3 schema. One way students construct an R^3 schema seems to be treating it like R^2. S5, who drew $y = 3$ in R^2 and then copied that image to the R^3 axes, provides an example of this, as do the students who draw $f(x,y) = x^2$ as a parabola (Martinez-Planell & Gaisman, 2013). Students seem to treat R^3 like R^2 in other function topics as well. Dorko and Weber's (2013) observation of students who gave the domain and range of $f(x, y)$ as x and y (respectively) provides a good example of this. Such treatment of R^3 may be a temporary stage for students. For instance, Yerushalmy's (1997) seventh-graders, engaged in their first multivariable graphing task and not shown R^3 axes like the students in this study, initially drew two graphs, one of independent quantity 1 vs. dependent quantity and one of independent quantity 2 vs. dependent quantity. The students struggled with, but eventually found, a way to draw a single graph. In this study, S3 also considered quantities two at a time. More research is needed to see if S3, S5, the student from Martinez-Planell and Trigueros' (2013) study, and others initially treat R^3 like R^2 but move out of this stage like Yerushalmy's students did.

Instructional Implications

My findings indicate that instructors can help students graph correctly by teaching them to attend to z. Instructors could begin by proposing that students think of a graph as the set of all points that satisfy a particular relationship. This might lead to teaching students to consider specific (x, y, z)-tuples and whether or not those tuples satisfy the given relationship. An instructor could ask a student to give a particular tuple that was on the graph and explain why that particular point is part of the graph, or could ask a student "is (1,3,7) on the graph? Why or why not?"

Instructors should also emphasise that variables vary. I say this because some of the students in this study (S1, S11) thought of x in $y = 2$ (in R^2) as not changing, which led them to conclude that for $y = 3$, x and z 'did not matter'. If we remind students that variables vary, they might consider how z varies in $y = 3$. One way we could reinforce this might be to write free variables as the variable times 0. For instance, perhaps writing $f(x, y) = x^2$ as $f(x, y) = x^2 + 0y$ would help students attend to y as free.

Finally, I suggest instructors use the ideas of equidistance and parallelism to help students think about fundamental planes. This was a powerful strategy for S8, and equidistance and parallelism are ideas that should be familiar to students.

Theoretical contributions

I wish to offer three comments about the expansive, reconstructive, and disjunctive generalisation categories. These are (1) reconstructive generalisations as first requiring expansive generalisation; (2) the idea of reconstruction as explanatory for why multivariable calculus topics are so difficult for students; and (3) expansive and reconstructive generalisations may be normatively correct or non-normatively correct, but in either case the Harel and Tall's (1991) framework helps us see what students are attending to.

I believe that any reconstructive generalisation involves first an expansive generalisation in which the student tries to apply an existing schema to a new context, followed by a reconstruction of the schema to account for differences between the two contexts. The theoretical support for this is the definition of reconstructive generalisation as “ocurr[ing] when the subject reconstructs an existing schema in order to widen its applicability range” (Harel & Tall, 1991, p.1) and expansive generalisation as “occur[ing] when the subject expands the applicability range of an existing schema without reconstructing it” (Harel & Tall, 1991, p.1). That is, if a student is going to reconstruct a schema, she must first see it as potentially applicable to the context. Hence she expands it to the context, then reconstructs as needed. One might envision Harel and Tall’s categories like shown in Figure 7, in which expansive generalisation can occur in its own right, and as part of reconstructive generalisation.

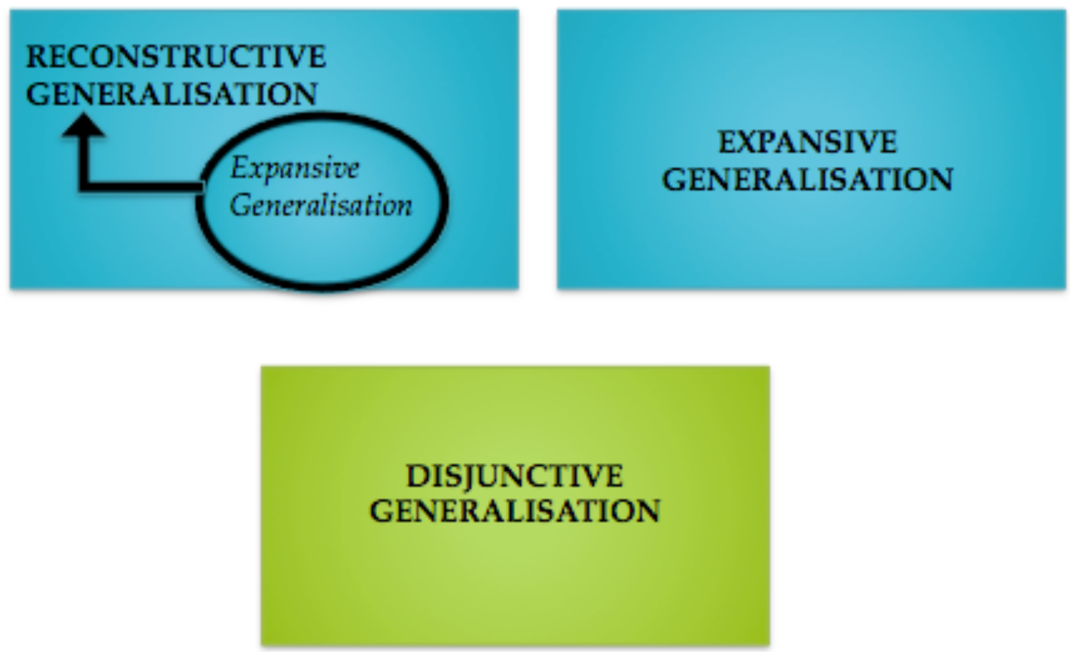

Figure 7. Proposed reconceptualisation of Harel and Tall’s framework

S8’s thinking provides an example for empirical support for expansive generalisation as a necessary condition for reconstructive generalisation. S8 explained his plane as three units away from the *xz* plane, “like for the last question when y is equal to 2, that is every value that is two units away from $y = 0$, right? So I'm thinking that like $y = 0$ would be the same as this [*xz* plane; Figure 3]”. He expanded the idea of y = b as equidistant from $y = 0$ to R^3, reconceptualising $y = 0$ from a line in R^2 to the *xz* plane in R^3. The reconstruction could not have occurred in absence of the expansion. Hence I believe that reconstructive generalisation first involves expansive generalisation.

Secondly, I believe that thinking about expansive and reconstructive generalisation provides explanatory power for why students often struggle with multivariable topics. Understanding that multivariable functions depend on multiple quantities, that domain is a set of *(x,y)*-tuples instead of a set of numbers, that derivatives in R^3 depending on direction, and so on depends on students reconceptualising ideas. Moreover, students need to *realise* that they have to reconstruct their ideas. Expansive generalisation does not always allow for this (e.g., S6). Perhaps students who struggle with multivariable topics tend to engage primarily in expansive generalisation when they need to engage in reconstructive generalisation. More research is needed to determine if this is the case.

Lastly, although I believe many multivariable calculus topics require students to reconstruct their schemas for function and graphing, expansive generalisations may still be productive. They may be productive *for students* when students are able to expand overarching notions such as points being on a graph as long as they satisfy a particular relationship (e.g., S3) or the notion of function as input-output (Dorko & Weber, 2013; Kabael, 2011). These examples illustrate that a reconstructive generalisation is not necessarily better or more sophisticated than an expansive one.

Categorising generalisations as expansive can be productive *for researchers* because doing so highlights what students are attending to. For example, we see from Table 2 that S6 attended to the shape of the graph of $y = 2$ in R^2, and that S3 and S7 attended to specific points and the broader idea that if a point satisfies a particular relationship, it is on the graph. S6's generalisation was non-normatively correct, while S3 and S7 both gave correct responses. However, in both cases, these expansive generalisations lend insight toward what students attended to. Similarly, the reconstructive category allows us to identify what facets of ideas students reconstruct. In summary, the expansive and reconstructive categories provide a powerful way to explain and understand the two main ways students generalise from R^2 to R^3.

Gender, switching, and student perceptions of Calculus I

We analyze survey data to explore how students' reported perceptions of their Calculus I experiences relate to their gender and persistence in calculus. We draw from student free-responses from several universities involved in a comprehensive US national study of Calculus I. We use social cognitive career theory to help inform a thematic analysis on the data. Our analyses indicate that there are significant differences in affective statements among four student groups determined by gender and persistence. Teacher behavior and teaching practices are highly correlated with affective statements, and thus may be very influential in the quality of students' Calculus I experiences.

Keywords: Calculus, gender, persistence, affect, thematic analysis, mixed methods

Stemming from national need to increase persistence in Science, Technology, Engineering, and Mathematics (STEM), Ellis, Fosdick, and Rasmussen conducted a study focused on student persistence in calculus and investigated factors which may impact the likelihood of a student switching out of a STEM major (2016). They identified a striking relationship between gender, switching, and mathematical confidence. Specifically, females were significantly more likely to decrease their intentions to take Calculus II after taking Calculus I. When given a list of potential reasons for not continuing, female students cited that they, "do not believe [they] understand the ideas of Calculus I well enough to take Calculus II," with significantly greater frequency than their male counterparts. However, there did not exist significant differences in the number of A's and B's between men and women. These results highlight the role that calculus is playing in students' decisions to leave their STEM pursuits, and may help to explain the larger issue of the STEM Gender Gap (Eagan, Lozano, Hurtado, & Case, 2013; Seymour & Hewitt, 1997). This work motivated us to delve more deeply into student reports of their experiences in Calculus I. Specifically, we examine the relationships between students' description of their experience in Calculus I, their gender, and their decisions to persist in calculus.

Educators have long been interested in identifying factors that may contribute to the disparity in gender representation in STEM (Fennema & Sherman, 1976 & 1978; Griffith, 2010; Good, Rattan, & Dweck, 2012; Ellis, Fosdick, & Rasmussen, 2015). While there is consistent evidence against gender-based differences in mathematical ability (Fennema & Sherman, 1978; Islam, & Al-Ghassani, 2015; Lindberg, Hyde, & Peterson, 2010), there are clear distinctions between men and women in their persistence in STEM fields (Cunnigham, Hover, & Sparks, 2015; Eagan et al., 2013), and their self-reports of success in these fields (Griffith, 2010; Good, Rattan, & Dweck, 2012). To better understand these differences, we draw on social cognitive career theory (Lent, Brown, & Hackett, 1994), with an emphasis on self-efficacy and affect (Phillip, 2007). Social cognitive career theory is a theoretical framework that maps a student's career/academic choice and integrates demographics as a key component impacting the learning experience through psychosocial processes that contribute to the development of career-related self-efficacy and outcome expectations. Lent, Brown, and Hackett (1994) hypothesize that gender (as well as race and ethnicity) differences in career interest, career goals, and actions arise largely through differential access to opportunities, supports, and socialization processes, rather than due to ability. More recently, researchers have begun to articulate factors related to persistence and the representation of females and other minorities in STEM majors (Ellis, Fosdick, & Rasmussen, 2016; Fennema & Sherman, 1976; Graham, Frederick, Byars-Winston, Hunter, & Handelsman, 2013; Griffith, 2010; Wolniak, Mayhew, & Engberg, 2012). Griffith found that certain environmental factors (such as the representation of females and minorities in graduate programs) can increase STEM participation and success by minorities (2010). Good, Rattan, and Dweck (2012) found that a sense of belonging was related to student persistence in math and that women who exhibited a fixed intelligence mindset coupled with gender stereotyping in the classroom experienced reduced sense of belonging (2012). Gender differences in confidence have also been identified as a possible factor to explain why women discontinue pursuing mathematics at a higher rate than men (Ellis, Fosdick, & Rasmussen, 2016; Fennema & Sherman, 1978).

Our research contributes to this literature by offering an inductive, qualitative analysis of student statements pertaining to their experiences in Calculus I. We draw on students' responses to an open-ended survey question from the *Characteristics of Successful Programs in College Calculus (CSPCC)* project. In this report we address the following research question: *How do student characterizations of their experience in Calculus I relate to student gender and persistence in calculus?*

Methods

This work is embedded within a larger project aimed at investigating college calculus at a national level – the CSPCC project. The first phase of this work involved a survey of "mainstream" Calculus I students from a stratified random sample of colleges and universities. Two surveys were sent to students at the beginning and the end of the fall term. On the beginning-of-term survey, students were asked questions related to their demographics, previous mathematical experiences, affect towards mathematics, and career plans. On the end-of-term survey, students were asked questions related to their experience in Calculus I, affect towards mathematics, and career plans, as well as the open-ended question: "Is there anything else you want to tell us about your experience in Calculus I?" We analyze students' responses to this question in this report. The surveys provide us with information to distinguish students based on gender and whether they continued in calculus. Continuation to Calculus II is a proxy of whether students will persist in STEM majors because it is required of most STEM majors. Students who indicated an intention to take Calculus II at the beginning-of-the-term survey and still reported this intention at the end-of-the-term survey were coded as *Persisters*. Students who first intended on taking Calculus II but reported differently on the end-of-the-term survey were coded as *Switchers.* Students were divided into four student groups, Male Persisters, Female Persisters, Male Switchers, and Female Switchers, based on reported gender and intention to take Calculus II.

In order to answer our research question, we sought to identify themes in the data and determine how those differ among the four student groups. There were 2,266 students who responded to the beginning-of-term and end-of-term surveys and were part of the analysis conducted by Ellis, Fosdick, and Rasmussen (2016). Of these students, there were 522 students who provided a response to the open-ended question. As shown in Table 1, the subset of 522 students was composed of more male Persisters than in the original data set (51.3% compared to 45.6%), less female Persisters (30.7% compared to 34.7%), slightly more male Persisters and slightly fewer female Switchers. Further, this subset of students reported slightly lower standardized test scores, the same level of Instructor Quality, and slightly higher levels of Student-Centered Practices as compared to the larger data set. *Instructor Quality* and *Student-Centered Practices* were variables ranging from 1-6, based on student reports of sixteen instructional practices and behaviors (see Tables S3 and S4 for detailed information on the derivation of these variables). Instructor Quality characterizes the level of conventional quality teaching, including availability outside of office hours, listening to questions, and encouraging students mathematically. Low values on this scale indicate low perceived instructional quality, and high values correspond to high instructional quality. Student-Centered Practices characterizes the frequency of classroom practices such as whole-class discussion, students giving presentations, and group work. Low values coincide with reported traditional, instructor-centered instructional practices, and high values correspond to more innovative, student-centered teaching.

Table 1. Comparison of larger data set to data set with open-ended responses

	Larger data set *(n=2588)*	Open-ended responses *(n=522)*
Number of Institutions	142	102
Number of Instructors	80	70
Student Group		
1 – Male Persister	1181 (45.6%)	268 (51.3%)
2 – Female Persister	897 (34.7%)	160 (30.7%)
3 – Male Switcher	203 (7.8%)	43 (8.2%)
4 – Female Switcher	307 (11.9%)	51 (9.8%)
Standardized Test average (percentile)	86.37	84.80
Instructor Quality	4.61	4.61
Student-Centered Practices	3.29	3.35

To characterize the ways these students discussed their experiences in Calculus I, and to relate these characterizations to student gender and persistence, we employed thematic analysis (Braun & Clarke, 2006). Social cognitive career theory guided this work, which emphasizes the role of demographics, self-efficacy, and learning experiences in a person's career decisions (Lent, Brown, & Hackett, 1994). During the thematic analysis we familiarized ourselves with the student responses, blind to the gender and persistence of the students, though aware of the literature related to the STEM gender gap and, more specifically, aware of the relationship in this data set between gender, reported mathematical confidence, and persistence in calculus. We took an inductive approach, deriving themes from the data, but we brought to bear our knowledge of the literature in organizing these themes. The two authors each coded subsets of 50 student responses to develop and refine codes. The final codes, reported in Table 2, were finalized after multiple iterations of comparing codes and once 85% reliability was consistently achieved between researchers. One researcher then coded all responses, with a small percentage of questionable responses coded by both researchers. We weighted the codes on a scale of -1 to 1 to indicate a negative, neutral, or positive connotation. We coded each student response with as many codes as appropriate. We did not repeat codes within a student comment unless the same code carried different weights (positive, negative, or neutral) in the same student response. For instance, "*I was pretty nervous about calculus because I was never strong at math … but so far it is going well*" was coded twice for affect since this comment includes affective statements with different weights. The student communicated negative feelings about self with regards to mathematical ability, but made a positive statement about the calculus course. The NA code was only used if the entire student response was not relevant directly to the student's Calculus I experience. Responses were regarded as not relevant if the student stated that they had no other comments about the course or if the statement was too vague to apply to the calculus course.

To frame this work we draw on literature surrounding self-efficacy and affect. We define and understand affect according to Phillip's summary of research done on mathematical belief and affect from the years 1992 to 2007. By consolidating definitions from research, Phillip defines affect as "a disposition or tendency or an emotion or feeling attached to an idea or object. Affect is comprised of emotions, attitudes, and beliefs" (Phillip, 2007, p. 259). In our examination of students' open-ended responses about Calculus I, we analyse students' reported affect. Based on Phillip's definition, nearly all student responses could be viewed as affective statements. Thus, we narrowed our use of the "Affect" code to only capture statements about a student's emotions, attitudes, or beliefs towards the calculus course, oneself as a learner, or mathematics in general. For instance, "*This professor is pretty good at explaining the concepts*," is an example of a response that was coded as being about the teacher but not as a report of the student's affect. By contrast, "*I feel that I am loving math because my professor loves to teach it. She makes class so much fun and she believes in us*," is an example of a response that was coded with both the "Teacher" and "Affect" codes. The former comment is merely an evaluation of the teacher, while the latter comment discusses the teacher as well as the student's attitude towards math.

Table 2. Codes, code descriptions, and examples.

Code	Includes statements about…
Affect	Student's emotions, attitudes, and beliefs about (a) the calculus course, (b) mathematics, (c) themselves as learners. *For the first time in my life I really struggled in a math class.*
Assignments and assessments	Assignments, and both formative and summative assessments. *The exams tended to be stressful/time consuming.*
Pacing	The pacing of the course in general and of class sessions. *The length of class … didn't really allow for … anything rather than the 'spewing' of material*
Preparation	Preparation coming into the course and preparation going into the next course. *Taking calculus in high school helped me succeed in this class!*
TA	The TA and his/her aspects such as communication, availability, helpfulness, etc. *The help desk hours with the T.A. were great.*
Teacher	The teacher and his/her aspects such as communication, availability, helpfulness, etc. *I thoroughly enjoyed my professors teaching style and presentation of material.*
Teaching	Specific teaching practices and teacher-controlled aspects of class room environment. *My instructor …had no passion for learning and lectured instead of taught.*
Other	Other reasons and resources that may have impacted the student's

	success *Without the math tutoring lab there is no way I would do well in this class or even pass.*
Not applicable	Anything irrelevant to the calculus course. *If a teacher truly loves the subject, students can tell and learn to love it too.*

Once the responses were coded, we investigated patterns within this data, drawing on descriptive and correlational analysis. These analyses provide a rich understanding of the overall aspects of student's Calculus I experience that they find important, and that may be related to their decisions to persist (or not) through the calculus sequence, and eventually their STEM career decisions. After identifying relationships between students' comments and their gender and/or persistence we took a deeper look into the qualitative nature of the comments that emerged as related to career decisions.

Results

To understand the relationships between students' responses, their gender, and their calculus persistence, we provide an overview of the distribution of the codes among the four categories of students in Figure 1. Of the 522 original student responses, 68 were coded as not applicable and were filtered out, leaving 454 relevant comments. Half of these comments came from Male Persisters, 9% from Male Switchers, 32% from Female Persisters, and 10% from Female Switchers. Among all students, the most frequent responses were related to Affect, the Teacher, Assignments and Assessments, and Preparation. However, the frequency of these responses within each student group varies; for instance, 37% of Male Persisters' responses were coded as Affect while 63% of Male Switchers' responses were coded this way. There are statistically significant differences among the distribution of the responses related to Affect, the Teacher, and Preparation.

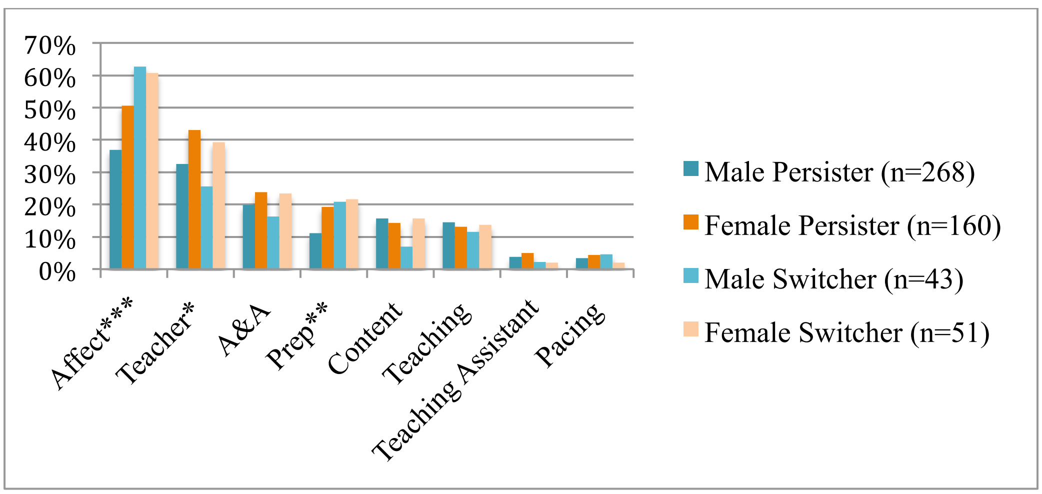

Figure 1. Prevalence of codes among four student groups

The most significant differences are in affective comments, where around 60% of both male and female Switchers' comments were coded as Affect, while these percentages are significantly lower for male and female Persisters. Much research has been done on mathematical affect and its role in student persistence (Ellis, Fosdick, & Rasmussen, 2016; Fennema & Sherman, 1978; Good, Rattan, & Dweck, 2012), with clear links identified between students' affect and their career decisions. To better understand the nature of students' affective statements, we conduct two secondary analyses: first, we compare the weight distribution of Affect statements across the four groups of students. As shown in Figure 2, the majority of male and female Persisters' Affect statements were positive, while male Switchers' Affect comments were nearly evenly split between positive, negative, and naturally, and the majority of female Switchers' Affect statements were negative. These findings harken back to decades of research on mathematical self-efficacy and gender. Bandura (1986) defined self-efficacy as "people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances" (Bandura, 1986, p. 391). In a meta-analysis of research on mathematical self-efficacy and gender, Pajares (2005) concludes that women consistently have lower mathematical self-efficacy compared to men at all ages. This literature may help explain the differences in the weights of Affect statements among the four student groups. Men's stronger mathematical self-efficacy may explain why the males, even those who choose to leave their STEM pursuits after Calculus I, tend to report more positive affective statements. Comparing the proportion of comments coded with positive Affect, the male Switchers in our data set report positive affect much more frequently than do female Switchers. Although our Affect code is not identical to self-efficacy as defined by Bandura, the two are certainly related. Thus, the gender disparity in mathematical self-efficacy may help explain the gender differences in the weight distribution of responses coded with Affect.

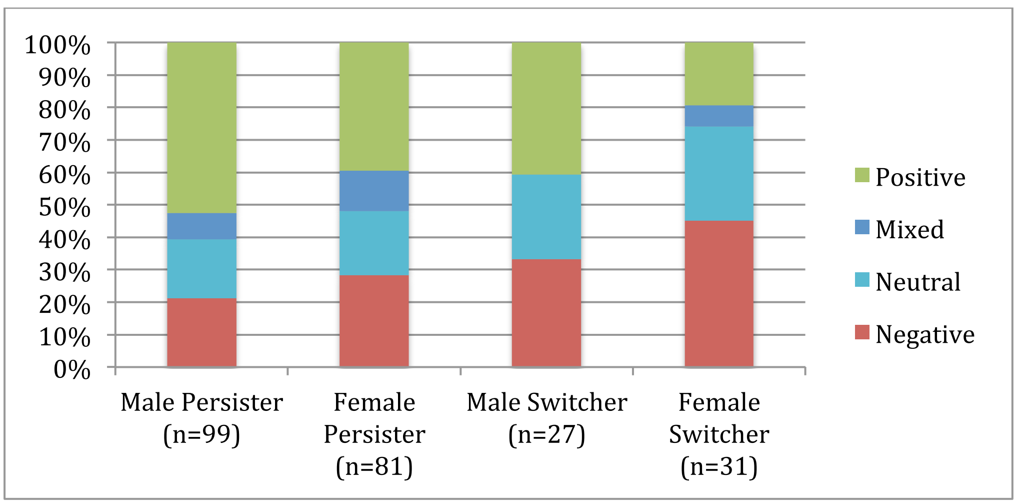

Figure 2. Weight distribution of Affect code

The second ancillary analysis we conduct to further understand the relationships between gender, STEM persistence, and students' calculus experience is a correlational analysis among the codes to understand what codes are most associated with Affect statements. As shown in Table 3, Affect statements are significantly correlated with Teacher statements [$r = 0.601$, $n = 85$, $p < .001$] and Teaching statements, [$r = 0.819$, $n = 31$, $p < .001$]. Thus, it seems that of the many aspects of the calculus learning experience, the instructors' behaviour and teaching approach can have the most impact on the students' emotions, attitudes, and beliefs about mathematics, the calculus course, and themselves as learners.

Table 3. Correlations between Affect code and other codes

	Aff	AA	C	P	Pr	TA	Teaching	Teacher	O
Pearson Correlation	1	.038	.284	-.232	-.090	-.577	.819**	.601**	-.092
Sig. (2-tailed)		.794	.115	.547	.557	.423	.000	.000	.640
N	238	49	32	9	45	4	31	85	28

This analysis indicates that the overlap between the codes Teacher and Teaching with Affect are especially important. Thus, we investigate these overlaps more deeply – first with Teacher and then with Teaching. We initially do this qualitatively and look into the nature of the comments in these overlaps. At this point in the analysis, the number of student responses under examination is small and so our findings cannot be taken as representative of a pattern in the larger data set. The purpose of this analysis is to understand the specifics aspects of the teacher or teaching that were related to students' affect. We then look at the prevalence of these overlaps between the four groups of students (again, here the numbers are quite small and thus cannot be representative of larger trends), and revisit the analysis conducted by Ellis, Fosdick, and Rasmussen (2016) to compare the trends in our smaller sample of data to the trends in the data set of 2,266 students.

Affect and Teacher

There were 85 student responses coded with both Affect and Teacher. Through thematic analysis, we refined the analysis further to uncover two subthemes related to affect and the teacher that were most prevalent in this data set: comments related to the teacher's approachability, and comments related to the teachers' communication. Comments in the approachability subtheme included comments about how the teacher's (lack of) approachability made students feel about themselves as learners, calculus, or mathematics in general. Comments in the communication subtheme included comments about how the teacher's communication, including both potential language barriers and their general communication style, made students feel about themselves as learners, calculus, or mathematics in general.

Table 4. Prevalence of Teacher and Affect subthemes among four student groups.

	Approachability	Communication
Male Persisters *(n=27)*	4	7
Male Switchers *(n=7)*	2	2
Female Persisters *(n=33)*	11	8
Female Switchers *(n=14)*	5	0

Ellis, Fosdick, and Rasmussen (2016) constructed an aggregate variable, called *Instructor Quality,* from end-of-term survey questions related to various aspects of the quality of the instructor, including questions related to approachability and communication. Here we extend their analysis to shed light on how instructor quality may be related to student gender and/ or persistence. As shown in Table 5, Persisters report significantly higher Instructor Quality than Switchers [$F(1, 4111) = 64.981$, $p < .001$], but there were not significant differences in reports of Instructor Quality between men and women. However, when we compare across the four groups it appears that the difference between female Persisters and Switchers is larger than that between male Persisters and Switchers.

Table 5. Comparison of means of Instructor Quality among student groups.

	Switcher Code***		Gender		Combined Student Groups***			
	Persisters	Switchers	Male	Female	Male Persister	Female Persister	Male Switcher	Female Switcher
Mean	4.66	4.33	4.66	4.64	4.69	4.72	4.47	4.36

Affect and Teaching

There were 31 student responses coded with both Affect and Teaching. These responses addressed the instructional approach, the technology used in the class, and the connection between material taught in class and material assessed.

Table 6. Prevalence of Teaching and Affect among four student groups.

	Teaching and Affect
Male Persisters	13
Male Switchers	3
Female Persisters	12
Female Switchers	3

Ellis, Fosdick, and Rasmussen (2016) constructed an aggregate variable, called *Student-Centered Instruction,* from end-of-term survey questions related to various aspects of the format of the instruction, including questions related to the level of student-centered instruction such as group work and whole class discussion versus lecture. Here, again, we extend their analysis to shed light on how instructional approach may be related to student gender and/ or persistence. As shown in Table 5, Persisters report slightly significantly higher Student-Centered Instruction than Switchers [F(1, 4117) = 3.702, p = .054], significantly higher report by men than women [F(1, 2682) = 3.918, p = .048]. However, when we compare across the four groups these differences diminish, though it does show that female Persisters report slightly lower levels of Student-Centered Instruction than the other student groups.

Table 7. Comparison of means of Student-Centered Instruction among student groups.

Discussion

This work was motivated by work that clearly linked gender to persistence in calculus, with a lack of confidence in mathematical ability as a major contributing factor for women's decisions to leave calculus but not for men's. In this report, we further investigated aspects of male and female Calculus I students' reports of their experience in calculus to try to better understand the link between gender and persistence in calculus. Our analyses identified a number of aspects of the Calculus I experience as related to gender and persistence.

After coding 454 relevant student responses, we found that the differences in distribution among the four coding groups were statistically significant for responses coded with Affect, Teacher, and Preparation. In particular, the proportion of affective statements made by male and female Switchers was significantly greater than the proportion for Persisters. This indicates that students who did not continue to Calculus II more frequently made statements expressing their emotions, attitudes, or beliefs about the calculus course, math, or themselves as learners than did those who persisted with their intention to pursue a STEM major. It is possible that the students who left the calculus sequence made affective statements more often than Persisters because they may have had more impactful experiences that they felt should be reported.

There were also differences among the student groups in the distribution of weight of the Affect code. As would be expected, Persisters largely made affective statements which held positive connotation. The female Switchers' affective responses were primarily negative in connotation, which also would be expected. However, the weight distribution among the male Switchers' Affect comments was very even between positive, negative, and neutral statements. This disparity in the proportion of negative affective statements made among male and female Switchers may be explained in part by the literature surrounding mathematical self-efficacy. The literature indicates that women consistently have lower self-efficacy than men, where women tend to judge that they have less mathematical capability than do men. This could be linked to the pattern in our data set, that among students who no longer pursue a STEM major, men tend to make positive statements about the course, mathematics, or themselves much more often than do women. Self-efficacy related to STEM careers plays a large role in actually pursuing that career, which may explain the underrepresentation of women in STEM fields.

Student responses that were coded with Teacher or with Teaching were significantly correlated with responses coded with Affect. Thus, teachers' behaviors and practices may be a very impactful factor in shaping students' affect towards mathematics, the calculus course, and themselves as learners. We found that in a small subset of student responses coded with both Teacher and Affect, female students made proportionally more comments about teacher approachability than about teacher communication. Although this data set was too small to be representative of the entire body of student responses, it prompted us to extend the analyses of Ellis, Fosdick, and Rasmussen (2016) to explore differences among the four student groups in various aspects of teaching. Two aggregate variables we examined from this past study were Instructor Quality, which relates to our Teacher code, and Student-Centered-Instruction, which is relevant to our Teaching code.

When examining these two variables, we were working with a data set of 2,266 students who provided responses to the beginning and end-of-term survey. As would be expected, Persisters reported significantly higher Instructor Quality than did Switchers. No significant gender differences were seen with regards to this variable. When considering differences among the four student groups, there is a greater difference between female Persisters and Switchers than between male Persisters and Switchers, and female Switchers have the lowest number for

Instructor Quality among the four groups. This may indicate that female Switchers are having encounters with their teachers that are not as positive as for other students. This may be linked to our finding that the women in a small sample reported teacher approachability more often than men. Perhaps female Switchers are having more negative experiences with their calculus teacher, which may dissuade them from continuing to Calculus II. Again, the smaller difference between male Persisters and Switchers may indicate that men generally have better math self-efficacy and thus make similar reports regardless of switching.

There are statistically significant differences in Student-Centered Instruction, with Persisters reporting a higher score than Switchers, and with men reporting higher Student-Centered Instruction than women. The differences decrease across the four student groups, although female Persisters report a somewhat lower level of Student-Centered Instruction. It is expected that Persisters would report beneficial teaching practices more often than Switchers. Women do not report student-centered teaching practices as often as men, which may play a role in deterring women from taking more STEM courses. Although the differences are small among the student groups, it is interesting that female Persisters reported the lowest levels of Student-Centered Instruction. Perhaps a lack of student-centered practices is not enough to prevent some women from taking Calculus II. Yet, it is still possible that these students may switch out of STEM major later on in their educational career. These small differences may be influential over the course of time, and could be factors that contribute to the shortage of women in STEM careers. The Teacher and Teaching codes were highly correlated to Affect, and affect and self-efficacy are very influential factors in a student's pursuit of STEM and eventual career choice. Thus, teachers may help with student retention in STEM fields by striving to better their communication and perceived approachability and by shifting teaching practices to be more student-centered. These actions may improve student affect towards mathematics and STEM in general, and may also reduce the disparity in gender representation in STEM.

Learning to think, talk, and act like an instructor: A framework for novice tertiary instructor teaching preparation programs

Jessica Ellis
Colorado State University

In this report I present a framework to characterize novice tertiary instructor teaching preparation programs. This framework was developed through case study analyses of four graduate student teaching assistant professional development (GTA PD) programs at institutions identified as having more successful calculus programs compared to other institutions. The components of the framework are the structure of the program, the departmental and institutional culture and context that the program is situated within, and the types of knowledge and practices emphasized in the program. In this report I characterize one of the programs involved in the development of the framework as an example of how it is used. In addition to characterizing existing programs, this framework can be used to evaluate programs and aid in the development of new novice tertiary instructor teaching preparation programs.

Keywords: Graduate student teaching assistant, professional development, pedagogies of practice, mathematical knowledge for teaching, framework

Theoretically driven research centered on the teaching preparation of tertiary instructors pales in comparison to the research related to the professional development of K-12 teachers. While there are aspects of K-12 professional development (PD) programs that can be highly relevant and informative to the tertiary level, there are also many ways in which tertiary-level teaching preparation should be examined as its own field. In this paper, I articulate ways that K-12 PD literature can inform tertiary level teaching preparation and the components that are more idiosyncratic to the tertiary context. I then introduce a theoretical framework that draws on K-12 PD literature and responds to the particular needs at the tertiary level, and use this framework to characterize two novice instructor teaching preparation programs as an example of its use as a way to characterize programs as well as to compare programs.

The National Science Board (NSB) uses the term professional development to refer both to teacher preparations (i.e. the teaching of pre-service teachers, prospective teachers, and teacher candidates) and to the development of practicing teachers (i.e. in-service teachers and practicing teachers) (National Science Board 2012). Novice tertiary instructors, especially graduate students, have commonalities with both categories of teachers: the training they receive for these roles is typically the first training to teach they will have received, however often they receive a large portion of this training while they are teaching. For many practicing tertiary instructors, any professional development related to teaching they may have received as graduate students or post-doctoral fellow is likely to be their only formal training as mathematics educators, rather than as mathematics researchers, and can help enculturate graduate students into academia (Austin 2002). Thus, the literature on professional development programs designed both for pre-service and in-service teachers at the K-12 level is relevant to tertiary teaching preparation. While there is extensive research into the professional development of teachers at the K-12 level, there is substantially less literature focusing on tertiary instructor teaching preparation, especially research that is theoretically driven. A large portion of the studies focused on tertiary instructor teaching preparation report on the success of existing programs or needs (often unmet) of novice instructors (e.g. Hauk et al. 2009; Kung and Speer 2009; Speer, Gutmann, and Murphy 2005). However, the body of research that connects aspects of these programs to identify commonalities and key features to consider when creating a new program is lacking.

Ten years ago, Speer and her colleagues (2005) initiated the conversation among mathematics education researchers interested in novice tertiary instructor teaching preparation, calling attention to what we could learn from K-12 PD, and identified a number of research directions to pursue. Some of these directions have been pursued directly by Speer and others since this call, and as a result there are more productive models of novice tertiary instructor teaching preparation programs in existence. In this paper, I develop a theoretically driven model that connects such productive programs. This framework may be used to better understand (and make improvements to) existing programs as well as to influence the development of a new program geared at preparing novice tertiary instructors.

Background

As part of a large, national study focused on identifying elements present in successful calculus programs, *Characteristics of Successful Programs in College Calculus (CSPCC),* (Bressoud, Mesa, and Rasmussen 2015), I studied the novice instructor teaching preparation programs at four institutions with successful calculus programs where graduate students and post-doctoral fellows were involved in the teaching of calculus. Through analyses of survey data, the project team identified institutions that were more successful than comparable institutions, where success was viewed as a combination of retaining students' positive dispositions towards mathematics, retaining students' intentions to take Calculus II, and having a reasonable pass rate. We then conducted case studies (Stake 1995) at these institutions to learn what they were doing in calculus that may be contributing to students' success, and how this success could be translated to other institutions. Robust novice instructor teaching preparation programs were one such element, and were then studied in depth in the national sample and at the case study institutions (Author). It is important to emphasize that the novice instructor teaching preparation programs themselves were not identified as successful; rather, these programs existed at institutions (a) whose calculus programs were identified as successful, and (b) where novice instructors were responsible for a considerable amount of calculus instruction.

Methods

Analyses of the case study data at the selected institutions led to development of the framework for novice instructor teaching preparation programs that I introduce in this paper. While I primarily attended to the ways in which these institutions prepared graduate students in their roles as instructors, these programs can be informative for preparing other novice tertiary instructors, such as post-doctoral fellows, lecturers, and new tenure-track faculty. As part of the CSPCC study, an abundance of data was collected surrounding each of four PhD-granting institution's novice tertiary instructor teaching preparation programs. At each institution, the data set includes the collection of all documents related to the novice instructor teaching preparation programs (e.g. handbooks for graduate students and post-doctoral fellows, observation protocol for observations, etc.), observations of the training when possible, observations of instructor meetings, observations of novice instructors teaching and leading recitation sections, and interviews with novice instructors, administrators, teaching preparation program facilitators, and students. The purpose of this data collection was to gain an in depth understanding of the ways that novice instructors (predominantly graduate student teaching assistants) were prepared and supported for their roles in the calculus programs at each of the institutions selected as having a more successful calculus program. The goal of this data collection was not to evaluate the novice instructor teaching preparation, but rather to understand the relationship between the novice instructor teaching preparation and the success of the calculus program at each institution.

I analyzed the data with an eye towards understanding the components of the teaching preparation program at each institution, and to understand how this related to the success of the calculus program. To do so, I conducted inductive thematic analysis of the case study data. Thematic analysis involves "identifying, analyzing and reporting patterns (themes) within data. It minimally organizes and describes your data set in (rich) detail. However, frequently it goes further than this, and interprets various aspects of the research topic" (Braun and Clarke 2006, p.79). Inductive thematic analysis is a bottom-up approach, where the themes are data-driven, though may also be informed by research literature. This process involves first becoming familiar with the data, then generating initial codes, searching for themes, reviewing these themes, defining and naming these themes, and lastly producing the report. The themes that were developed through this process both emerged from the data set and were influenced by the literature. For each theme, I used multiple components from each data set to complement and triangulate the information obtained through the interviews, specifically to fact check information and to add details when needed.

After identifying the main themes related to the novice instructor teaching preparation programs, I revisited the data to identify the ways that these themes were related to one another and how they were related to the success of the calculus programs. Together, the themes developed through the inductive thematic analysis and the relationships between them comprise the framework for novice tertiary teaching preparation.

Components of framework

The central dimension of the framework is the *structure* of a program; when it occurs, for how long, who participates, what is discussed, and how. The structure of a program includes objective information about the formal and informal structural components of the novice instructor teaching preparation programs program. This includes the five components identified by Belnap and Allred (2009): (a) timing, (b) frequency, (c) duration, (d) topics covered, and (e) overall design. The structure of a teaching preparation program is the aspect that is typically used to characterize a program, much like the specifications of a house (number of bedrooms and bathrooms, square footage, architectural design, etc.) are typically used to characterize it. However, like these specifications are shaped and constrained by the environment in which one builds a house (including the lot size, zoning laws, and builder and/or designers' preferences), the structure of a teaching preparation program is constrained, determined, and enabled by the environment within which it is situated: the institution and the department. The *institutional and departmental context* and *culture* together comprise the environment within which the teaching preparation program exists. The institutional and departmental context guides the needs and capabilities of a teaching preparation program. For instance, the responsibilities of novice instructors are determined by (a) the number of graduate students, post-docs, and other novice instructors in the department in relation to the number of other faculty and in relation to the number of undergraduates served by the department, (b) the types of classrooms available (large lecture halls versus small classrooms), and other components of the context of the institution and department. The institutional and departmental culture shapes how the department responds to these needs and capabilities. For instance, whether graduate students serve as discussion section/recitation leaders or course instructors will be shaped by (a) the institution and departments' views on class size, (b) their orientation toward optimal learning environments, (c) their aspirations for undergraduate instruction, and other components of the culture of the institution and department.

Within the structure of the program, different *knowledge* and *practices* are emphasized and in different ways. Once a structure has been developed, various knowledge and practices can be emphasized and fostered in different ways. As part of becoming an instructor, one develops knowledge and practices surrounding instruction. Thus, the tertiary teaching preparation programs emphasize different types of knowledge and practices depending on the community within than institution.

To characterize the types of knowledge needed to teach I draw on the classic distinction by Shulman (1986), who differentiated between pedagogical knowledge (PK), content knowledge (CK), and pedagogical content knowledge (PCK). Pedagogical content knowledge is distinct from a blend of basic pedagogical knowledge and basic content knowledge and was introduced by Shulman in response to the wide-held belief that content knowledge alone was sufficient to teach. PCK is the particular form of content knowledge related to the aspects of content knowledge "most germane to its teachability", including ways of representing content so that it is understandable to others (Shulman 1986, p. 9).

Each of the three types of knowledge can be emphasized to varying degrees though a teaching preparation program. To illustrate the level of emphasis I use shading in the visual representation of the framework. No shading illustrates that this type of knowledge was not emphasized at all during the program. Light shading represents that this type of knowledge was emphasized to a small degree, but developing this type of knowledge was not the main focus of the teaching preparation program. Dark shading represents that developing this type of knowledge was the main focus of the preparation program. For instance, consider teaching preparation programs aimed at mathematics graduate student teaching assistants (GTAs) that does not provide any opportunities for participants to increase their content knowledge related to the area they are going to be teaching, is heavily focused on developing basic pedagogical knowledge, such as how to write on the board clearly, how to organize a lecture, and how to prepare a syllabus and an exam, talks briefly about common students misunderstandings in calculus and how to present ideas to help students grapple with these misunderstandings. Such a program would be characterized with no shading for content knowledge, dark shading for pedagogical knowledge, and light shading for pedagogical knowledge, as shown in Figure 1.

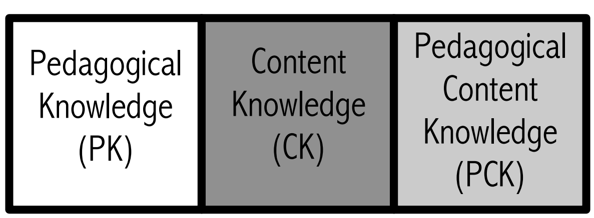

Fig. 1 Shading of three types of knowledge to represent three levels of emphasis of each type of knowledge through the teaching preparation program

To characterize the practices graduate students can legitimately and peripherally engage in as they learn how to be tertiary instructors, I draw on Grossman et al.s' (2009) *pedagogies of practice.* Grossman and her colleagues (2009) identified three concepts for describing ways to teach practices in professional education: representations of practice, decompositions of practice, and approximations of practice. *Representations of practice* comprise different ways practice can be represented for novices. In teacher education, one may represent the practices of teaching through written case studies, Video cases, photographs of the classroom, narratives, lesson plans, technological reproductions, among many others. The authors note that "the nature of the representation determines to a large extent the visibility of certain facets of practice" (p. 2066) and thus different representations of the same practices have different affordances for the learner. *Decompositions of practice* break down a complex practice into its multiple parts, which has affordances as well as limitations. By decomposing a practice, it may remove the practice from the actual context within which it is situated (for an elaboration on this point see Putnam and Borko 2004) however it also enables the novice to focus on specific aspects of a practice without the complications of the actual context. *Approximations of practice* are activities that allow novices to engage in legitimate practices of a community in a peripheral way, meaning that they are "more or less proximal to the practices of a profession." (p. 2058) These approximations may take the learner directly to the practice, as is done during student teaching, or bring the practice to the learner through various representations, such as Video cases or role-playing.

Teaching preparation programs provide many examples of representations, decompositions, and approximations of the practices of teaching with varying levels of authenticity. For instance, by watching Videocases, novice teachers are able to "enter" the classroom, observe student behavior and imagine how they would react as the teacher, without the actual responsibility of being in the classroom. This approximation of teaching has a low level of authenticity because real teachers do not have the opportunity to pause or rewind classroom activity in order to decide how to react or how to interpret the situation. Practice teaching is an example of an approximation of teaching with much higher authenticity. During practice teaching, novice teachers have limited responsibility in the classroom, but are able to experience it in real time and in a much more authentic way than by watching a video. Grossman and her colleagues (2009) highlight the benefits of representations, decompositions, and approximations of practice with varying levels of authenticity, which "quiet the background noise so that they can tune in to one facet of practice at a time" (p. 2083). As novices participate in the practices of a community (through approximations of practice, representations of practice, and/or decompositions of practice) they do not just develop the skills of the community, but also develop (to varying degrees) a shared knowledge base and shared dispositions.

A teaching preparation program can involve each pedagogy of practice to a varying degree. To illustrate the level of involvement of each pedagogy of practice I use shading in the visual representation of the framework. No shading illustrates that the teaching preparation program did not involve this type of pedagogy of practice. Light shading represents that this pedagogy of practice was involved in the program to a small degree, but was not the main feature of the teaching preparation program. Dark shading represents that this type of pedagogy of practice was the main feature of the teaching preparation program. For instance, consider a teaching preparation program held the week before graduate students teach for the first time that involves a short session where graduate students prepare a five-minute lecture and present it to other graduate students, video presentations about how to foster whole class discussion and group work and a lecture presentation about how to organize notes well and write on the board clearly. Such a program would be characterized with light shading for approximations of practice, dark shading for representations of practice, and light shading for decompositions of practice, as shown in Figure 2.

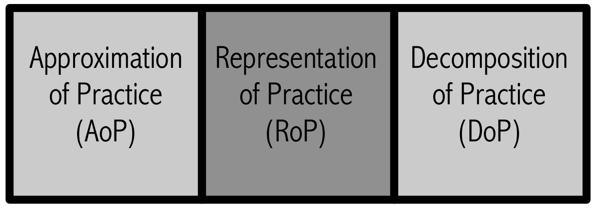

Fig. 2 Shading of three pedagogies of practice to represent three levels of involvement of each through the teaching preparation program

These components are summarized in Table 1. Figure 3 illustrates the relationships between them, and provides a visualize representation of the framework for novice tertiary teaching preparation.

Table 1 Dimensions of the tertiary teaching preparation programs

Dimension	Description
Institutional and Departmental Context	Objective information about the institution and department that is relevant to Calculus 1 instruction and the graduate student professional development program. This includes details about the current state of the institution, department, calculus program, and novice instructor teaching preparation program, and the history of each of these elements.
Institutional and Departmental Culture	Objective and/or subjective information about the views, beliefs, objectives, goals, and aspirations of the institution and department that are relevant to Calculus 1 instruction and the graduate student professional development program. This includes the views, beliefs, objectives, goals, and aspirations of (a) the institution regarding undergraduate education, (b) the department regarding Calculus 1 instruction, (c) the department regarding novice instructors' roles in Calculus 1 instruction, and (d) the department regarding novice instructor preparation for their role in Calculus 1 instruction. These views, beliefs, objectives, goals, and aspirations may or may not be explicitly stated. The priorities surrounding the Calculus I program and/or the novice instructor preparation program and the department's general orientation to teaching both fall somewhere in between the institutional and department culture and context.
Structure	Objective information about the formal and informal structural components of the novice instructor teaching preparation programs program. This includes the five components identified by Belnap and Allred (2009): (a) timing, (b) frequency, (c) duration, (d) topics covered, and (e) overall design.
Development of knowledge	Objective and subjective information about the types of knowledge emphasized through the structure of the program. This includes the three main types of knowledge identified by Schulman (1986): (a) pedagogical knowledge (PK), (b) content knowledge (CK), and (c) pedagogical content knowledge (PCK).
Development of practices	Objective and subjective information about the pedagogies of practice that are involved in the structure of the program. This includes the three pedagogies of

practice identified by Grossman et al. (2009): (a) representations of practice, (b) decompositions of practice, and (c) approximations of practice.

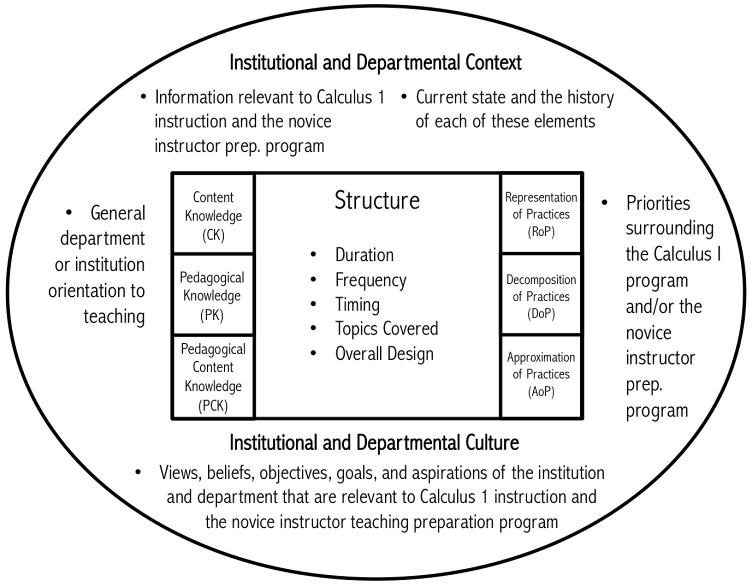

Fig. 3 Framework of instructor teaching preparation programs

Two Examples

Here I use the framework to visually represent two models of novice instructor teaching preparation program models that were observed through the case studies at institutions with successful calculus programs and where novice instructors (including graduate students, post-doctoral fellows, an undergraduate students) were heavily involved in Calculus I instruction. I call these two models the Apprenticeship Model and the Coordinated Innovation Model. These examples serve to illustrate how the framework can be used to characterize programs as well as to aid in comparison of programs.

The Apprenticeship Model. *The Apprenticeship Model* of novice instructor teaching preparation was enacted at a small university with approximately 5,000 undergraduate students, where fall enrollment in Calculus 1 is around 270 and class sizes are around 45. Graduate students, both Master's and Doctoral students, are involved in the teaching of Calculus I as teaching assistants, tutors, and course instructors. Post-docs are not involved in the teaching of Calculus I at this university.

The primary guiding philosophy behind the Apprenticeship model is the desire to transition graduate students into the role of instructor, both as part of their immediate role as GTAs and as their (potential) future role as undergraduate mathematics instructors. Embedded within this philosophy is the belief that people learning a new profession (who will develop a professional identity surrounding it) must participate in the practices of the profession with growing responsibility. This belief is in line with a perspective in which learning is viewed as the process of engaging a novice in the practices of the profession with legitimate but peripheral participation (Lave and Wenger 1991). The term "peripheral" indicates that the practices novices are involved in are less central versions of the authentic practices, or are central practices with limited responsibility. As one clinical psychology professor involved in the Grossman et al. (2009) study said when describing how clinical psychologists are prepared, "if you're learning to paddle, you wouldn't practice kayaking down the rapids. You would paddle on a smooth lake to learn your strokes" (p. 2026). The main components of the Apprenticeship model are:

- A three-unit class, inspired by Lesson Study (Lewis, Perry, and Hurd 2009), that takes place during the semester before the graduate student is placed as a course instructor.
- A mentor instructor for whom the mentee acts as a teaching assistant in the class they will be teaching during the semester before the graduate student is placed as a course instructor.
- Weekly course meetings once the graduate student is placed as a course instructor.
- Observations and feedback once the graduate student is placed as a course instructor.

Graduate students are required to participate in a number of teaching development activities, both prior to teaching and while they teach. All new GTAs must attend a one-day seminar led by the mathematics department, with some of this time spent doing practice teaching presentations. During the seminar faculty conduct workshops on topics including pedagogical basics, such as how to write well on the board, as well as more advanced pedagogical topics, such as how to implement cooperative learning. Additionally, all first-year GTAs are assigned a faculty mentor during the orientation session.

As shown in Figure 4, the framework representation of the Apprenticeship Model gives a clear overview of the structure and encompassing environment of the novice instructor teaching preparation program.

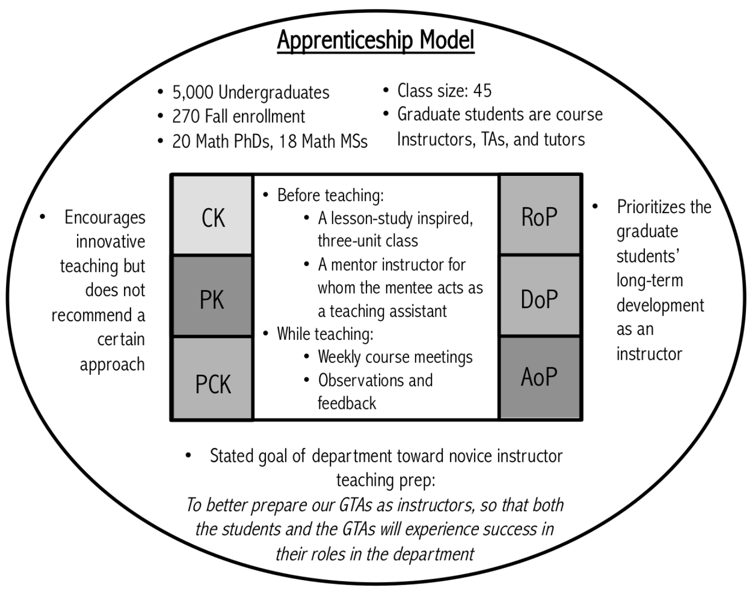

Fig. 4 Apprenticeship model

The main structural components of the program are a lesson-study (Lewis, Perry, and Hurd 2009) inspired course and mentoring that occur before the GTA is placed as an instructor, and ongoing meetings and observations once the GTA is placed as an instructor. The shading provides a visual representation for the level of emphasis of the knowledge and the level of authenticity of the practices involved in the programs. Within this structure, pedagogical knowledge is emphasized more deeply than PCK or content knowledge, though PCK is emphasized through both the lesson-study inspired course and the mentoring. Content knowledge is potentially emphasized through the mentoring, although it is not a primary focus. During the lesson-study course, novice instructors participate in a number of pedagogies of practice to varying degrees of authenticity. Through the lesson-study-like iterations of developing, presenting, and refining lessons, graduate students engage in approximations of the practice of teaching to increasing degrees of authenticity. The practice of teaching is decomposed into planning, presenting, and refining through the lesson-study course. Through both the lesson-study course and the mentoring, graduate students have multiple opportunities for teaching to be represented, by other graduate students, their mentor instructor, and by reading and watching cases. This program is situated within a small department that prioritized graduate students' long-term development as instructors and encourages innovative teaching but does not require a certain pedagogical approach.

Coordinated Innovation Model. *The Coordinated Innovation Model* of novice instructor teaching preparation was enacted at a large university with around 25,000 undergraduate students, where fall enrollment in Calculus I is around 2,000 and class sizes are around 30. Novice GTAs teach the majority of these sections. The remaining instructors are experienced GTAs, post-docs, and occasionally faculty. All courses are coordinated by a team of three permanent faculty, and all Calculus 1 courses are taught using an Inquiry Based Learning (IBL) inspired instructional method, which emphasizes student discovery, group work, and conceptual understanding (see http://www.inquirybasedlearning.org/ for more information.

The primary guiding philosophy behind the Coordinated Innovation Model is the

that Calculus I should be taught in an innovative and student-centered way, in small, highly coordinated classes. This innovation addresses the approach to the content, which is conceptually oriented and application driven, as well as the pedagogical approach, which includes group work and whole class discussions surrounding students' mathematical activity (rather than the teacher's). The coordination of these classes ensures that students have similar experiences. Further, this coordination helps to support the secondary guiding philosophy: that graduate students can be prepared and supported to successfully implement innovative instruction. This model is also motivated by a third, underlying philosophy: that graduate students can be, as Seymour (2005) termed it, "partners in innovation" and that graduate students who are effectively prepared to implement innovative instruction will likely carry these innovative practices into their future roles as undergraduate mathematics instructors. The main components of the Coordinated Innovation Model are:

- An intensive four-day training seminar that takes place the week before GTAs are placed as course instructors.
- Weekly course meetings once the GTA is placed as a course instructor.
- Observations and feedback once the GTA is placed as a course instructor.

The Coordinated Innovation model prepares and supports GTAs to teach coordinated sections of Calculus I with a conceptually oriented and student centered approach. The main component of this novice instructor teaching preparation program is a five-day seminar that takes place the week before the semester begins. It provides multiple opportunities for graduate students to present a prepared lesson and get feedback, and a series of presentations aimed to introduce graduate students to the department's approach to calculus, to explain the rationale for the approach, and to share evidence of its success. Many of the materials are reused year after year, with small additions or changes based on facilitators' experiences and feedback from the GTAs. All first-time GTAs participate in the seminar. After the third day of the seminar, the GTA supervisors make course assignments based on availability and graduate student participation in the seminar, specifically their performance in their practice lessons. Most graduate students are placed as course instructors for Calculus I, while some are placed as instructors for precalculus, Calculus II, or are assigned to be tutors in the calculus tutoring center.

Part of the support that graduate students receive once placed in the role of course instructor comes through the coordination of the course. This coordination encompasses common homework, quizzes, exams, and schedule. Because there are many aspects of teaching that are new to graduate students, having these aspects of the course coordinated by an expert instructor allows them to focus their energy on other aspects of instruction. This can be especially helpful when implementing more innovative instruction.

Part of the coordination that is especially helpful for supporting novice instructors is weekly meetings. These meetings involve all instructors for Calculus I and the course Coordinator. These meetings serve as a place to address class management issues including use of group work or how to address specific content, and function not only as an opportunity to cover the logistics of the week, but also as a venue for discussions about student thinking and difficulties.

An experienced graduate student or faculty member observes all GTAs (new and experienced) at least once each term. The observers give feedback to the graduate student. If issues were noted, these are communicated to the GTA, along with concrete ways to address these concerns. In these cases, additional observations are done. As shown in Figure 5, the framework representation of the Coordinated Innovation Model gives a clear overview of the structure and encompassing environment of the novice instructor teaching preparation program.

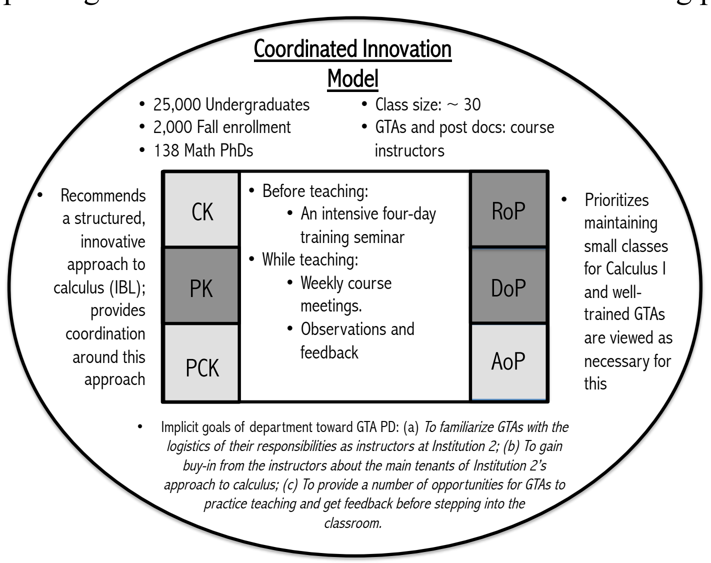

Fig. 5 Apprenticeship model

The main structural components of the program are an intensive four-day seminar that takes place the week before graduate students are places as course instructors, and ongoing meetings and observations once the GTA is placed as an instructor. The shading provides a visual representation for the level of emphasis of the knowledge and the level of involvement of the pedagogies of practices in the programs. Within this structure, pedagogical knowledge is emphasized more deeply than both PCK or content knowledge. The majority of the focus is on preparing graduate students to enact a specific pedagogical approach, and helping them understand why this approach is taken. During the summer seminar, there is some discussion surrounding student thinking related to difficult topics, and this may also occur through out the year during meetings – especially during exam time. During the summer seminar, teaching is decomposed into lecture, asking questions, discussions, and group work. Novice GTAs discuss each aspect with experts, and then have opportunities to practice teaching these practice, decomposed into a practice lecture and a practice student-centered activity, where GTAs are expected to engage their students in group work and discussion. Both the practice lecture and the practice student-centered activity are fairly inauthentic as the audience members are fellow graduate students. Thus, these activities serve both as an opportunity for the GTAs to approximate the practices (in an inauthentic environment) as well as watch many of their peers represent the practices for them, while also benefitting from the feedback given to their peers. This program is situated within a large department that has a team dedicated to the calculus program and the preparation of the graduate students who enable the calculus program. In this program, innovative, student-centered instruction is prioritized, and is able to be enacted on a large scale due to the high levels of coordination within the calculus instruction.

Comparison

By representing the Apprenticeship Model and the Coordinated Innovation Model using the framework, a number of similarities and differences become salient. One major similarity between the two programs is that they rely on substantial resources from their surrounding environment (department and institution). The Apprenticeship Model relies on the department supporting graduate students for a semester before they are placed in the classroom, as well as on mentor instructors in the department. The Department Chair at the institution where this model was enacted is a proponent of supporting graduate students in their long term development as instructors, and believes that one semester of support is worth it to almost guarantee quality graduate instructors for their remaining semesters. The Coordinated Innovation Model relies on the institution to secure small classes for the large numbers of Calculus I students, and relies on the department to bring in large numbers of graduate students to support the abundance of Calculus I sections.

While there are clear differences in the structure of the programs within both models, the visual representation of the framework highlights the more subtle differences in the emphases and goals of these programs. The Apprenticeship Model focuses on developing graduate students as instructors, not just in their current roles as GTAs but as future mathematics faculty. Influenced by this goal, the structure of this program emphasizes both pedagogical knowledge as well as pedagogical content knowledge, to support graduate students in beginning to think like instructors. Throughout the program, graduate students participate in an array of pedagogies of practice, and with increasing authenticity. This supports the graduate students in developing a professional identity related to being an instructor, and the ongoing meetings and observations are geared towards helping the graduate students internalize their role as instructor. In contrast, the Coordinated Innovation Model focuses on preparing their GTAs to successfully implement a specific type of Calculus I instruction, rather than supporting them as long-term instructors. Certainly, graduate students will benefit as instructors in the long-term by being well-prepared to teach Calculus I in a specific way, but this is not the focus of the preparation, rather a side benefit. Influenced by this goal, the structure of this program strongly emphasizes pedagogical knowledge related to teaching using the IBL approach. Throughout the program, this approach is decomposed and represented to novice instructors, and they get some practice in approximating this practice. This supports the graduate students to implement IBL instruction, and the ongoing meeting and observations are geared towards solving problems, answering questions, and improving instruction related to the IBL approach.

Both models are influenced and constrained by their surrounding environments, and thus it would not make sense to pick up the Coordinated Innovation Model and use it in place of the Apprenticeship Model or vice versa. However, if an institution were looking to develop a new novice instructor preparation program, and their goals of this preparation were in line with those related to the Apprenticeship Model, but the institutional characteristics were more in line with the institution that enacted the Coordinated Innovation Model, this institution could identify aspects of each model that may work within their constraints and help them achieve their goals.

Conclusion

While the framework representation does not give the rich detail of the program on its own, it provides information useful in comparing across models, and can be used to ask and answer questions regarding the evaluation or implementation of an individual model. The framework can also be used to evaluate a program or to help with the creation or improvement of a teaching preparation program. To aid in the evaluation of a program, a mathematics department may determine that their GTAs and post-doctoral fellows seem to know very little about how their students may think about mathematics, their difficulties, and how to explain problems so that they will better understand them. They could use this framework to describe their current program and identify that they are not, in fact, spending time during the teaching preparation discussing PCK. To aid in the development of a program, this framework can help direct attention to important components to consider, as well as provide a visual representation of the many important components of a novice instructor preparation program. In many mathematics departments, a more robust novice teacher preparation program is developed based on the initiative of one or two motivated individuals – the change agents. Often, these change agents are not necessarily mathematics education experts, or may have good ideas about what the novice instructors need at their institution but do not know how to go about setting up a new program. The framework introduced here provides an organized and systematic way to think about the components of a tertiary teaching preparation program.

The primary intention of this framework is to characterize existing novice instructor teaching preparation programs situated within a mathematics department at a tertiary institution. Often such programs are mainly intended for graduate students works as teaching assistants or classroom instructors, but such programs may also be used to support post-doctoral fellows, instructors, visiting faculty, and junior faculty in their teaching. The framework draws on theoretical underpinnings from the K-12 education literature, some of which are specific to mathematics and some of which are not. Thus, a number of questions arise about the relevance of this framework in thinking about teaching preparation programs outside of tertiary mathematics departments.

For instance, one may wonder about how the ideas presented here can help one think about a graduate student teaching assistant training program in a Philosophy Department. There are a number of ways that this framework can be leveraged in this context, however there are also a number of reasons why it is specific to mathematics. Mathematics is a unique content area in that it is taught throughout K-12 education, rather than primarily (or exclusively) at the tertiary level, such as with Philosophy. This results in students coming in with a wide range of previous experiences in mathematics, which adds complexity to the teaching of tertiary mathematics, especially in the first or second years of study (such as with Calculus). Mathematics graduate students, who are often tasked with teaching lower level courses rather than upper level tertiary courses, then must be prepared not just to teach the content, but also to identify student (mis)understanding in the moment and bridge this understanding with the understanding needed in their class.

Mathematics is also largely a service department, and first and second year tertiary mathematics courses are widely required service courses. Thus, mathematics graduate students are tasked with teaching a course that a large percentage of the students may not be particularly interested in taking. Further, first and second year mathematics courses have been identified as greatly contributing to students losing interest in pursuing STEM fields – thus the instructors of these course should also be aware of the role their teaching may play in students' career goals. While the same may be true to some extant in introductory Philosophy courses, it is to a much lesser degree. Thus, there are aspects of this framework that may be applicable when thinking about the development of a novice instructor preparation program for non-mathematics departments, but there are also important contextual differences that must be considered.

There are also aspects of this framework that may be applicable to the teaching preparation of a specific subset of K-12 teachers: alternatively places teachers in high-need schools. Teach for America is the most widely known of these programs, but others include New York City's Teaching Fellows Program, Teach Kentucky, and the Mississippi Teacher Corps programs (Heilig and Jez 2010). Teach for America (TFA) is a non-profit organization that recruits recent graduates from elite colleges to teach in low-income schools for two years. TFA teachers often do not have an education background and thus do not participate in the extensive teaching preparation that teachers receive over four-years (or more) in undergraduate credentialing programs. Instead, TFA teachers participate in a five-week summer program between graduating from college and beginning their teaching assignments. This training often includes a brief stint of student teaching, short lessons on pedagogy, content, and classroom management. In addition to the summer training, TFA teachers must continue coursework in local colleges to pursue full teaching credentials while they teach. Research into the efficacy of TFA teachers is mixed, with some indicating that students taught by non-TFA teachers outperform students taught by TFA teachers on reading and mathematics (Darling-Hammond, Holtzman, Gatlin, and Heilig 2005), though there are large differences between first-year TFA teachers and second-year teachers (Boyd, Grossman, Lankford, Loeb, and Wyckoff 2006).

TFA teachers, and other alternatively-certified teachers, share a number of commonalities with mathematics graduate student teaching assistants: they are often strong with respect to their content knowledge, receive relatively little pedagogical preparation compared to other teachers, are younger than most other teachers, are not as interested in a long-term career in teaching as other teachers, teach students who are mathematically weaker than they were as students, and are often thought of as not as effective as traditional teachers (Boyd, Grossman, Lankford, Loeb, and Wyckoff 2006; Heilig and Jez 2010). However, both GTAs and TFA teachers are cost effective as teachers and serve a need. Thus, thinking about how to best prepare TFA teachers within the confines of the public school system is similar to thinking about the preparation of GTAs within the confines of tertiary mathematics departments, and as such the framework presented here can contribute to both situations.

In this paper, I have provided two examples of how this framework can be used to characterize existing programs. In addition to being used in this way, the framework can also be used to help develop a novice teaching preparation program and to evaluate an existing program. The framework can be used to help develop a new program by narrowing down specifics aspects of the desired program. The individuals tasked with creating a new novice instructor teaching preparation program should think about what types of knowledge their novice instructors need to develop, and what types of activities they want novice teachers to engage in during the teaching preparation. This will result in their own shading of the types of knowledge and the types of pedagogies of practice desired in the teaching preparation program. This information can be used then to help organize the program develops and bring ideas together, or the program developers could compare what they are hoping to develop to characterizations of existing programs to "find a match." The institutional and department culture and context will help the program developers determine how applicable and adaptable existing programs would be to their department.

The framework can also aid in the evaluation of existing programs. Those familiar with the needs a novice instructors could identify types of knowledge their novice instructors need to develop, and what types of activities they believe the novice teachers need to engage in to develop this knowledge. This could be then contrasted with a characterization of their existing program using the framework, which would illuminate discrepancies between the needs of novice instructors and the existing program. If changes are then implemented, a post-implementation of the program could then be characterized using the framework and compared to the original characterization to identify how the changes were in line with the needs of the novice instructors.

Due to recent increased attention to tertiary mathematics instruction, coupled with continued reports of the role of poor teaching in introductory mathematics courses in the leaking STEM-Pipeline, many tertiary mathematics departments are focusing more attention on the teaching preparation of instructors who teach introductory courses. The framework presented here aims to aid these improvement efforts by providing organization to the abundance of considerations related to teaching preparation.

Student responses to instruction in rational trigonometry

James D. Fanning

University of Massachusetts Dartmouth

In this paper I discuss an investigation on students' responses to lessons in Wildberger's (2005a) rational trigonometry. First I detail background information on students' struggles with trigonometry and its roots in the history of trigonometry. After detailing what rational trigonometry is and what other mathematicians think of it I describe a pre-interview, intervention, post interview experiment. In this study two students go through clinical interviews pertaining to solving triangles before and after instruction in rational trigonometry. The findings of this study show potential benefits of students studying rational trigonometry but also highlight potential detriments to the material.

Key words: [Rational Trigonometry, Undergraduate Mathematics, Interviews]

Introduction

Students struggle with trigonometry. This struggle is a contributing factor to students not pursuing studies in the STEM fields. Students struggle with trigonometry at many points during their mathematical studies. While many pedagogical changes to trigonometry instruction have been tried (Bressoud, 2010; Kendal & Stacey, 1996; Weber, 2005) little has been done looking at replacing or augmenting trigonometry instruction with a mathematical alternative.

Rational trigonometry is a system for studying triangles using different units to measure length and the separation between two lines instead of using distance and angle (Barker, 2008; Campell 2007, Franklin, 2006; Henle, 2007; Wildberger, 2005a, 2005b). The use of a different unit necessitates different formulas than traditional trigonometry. Wildberger (2005a, 2005b) claims that rational trigonometry is simpler to learn, understand, and use than its traditional counterpart. He believes this based on the formulas for rational trigonometry lacking the sine, cosine, tangent or other transcendental functions. Little if any research has been conducted looking into educational benefits of rational trigonometry.

To investigate his claims, I conducted task-based interviews before and after lessons in rational trigonometry to explore the following: How do mathematics majors approaches to solving problems pertaining to triangles change after studying rational trigonometry?

Traditional Trigonometry

Trigonometry as we know and teach it causes many difficulties for students. Previous research on students' difficulties with trigonometry include studies using quantitative methods (Brown, 2005), teaching experiments (Moore, 2009, 2013; Weber, 2005, 2008), and theoretical pieces (Bressoud, 2010; Gilsdorf, Moore, 2012; Wildberger, 2005a, 2005b, 2007).

What is Trigonometry?

This is a question that is rarely answered explicitly in mathematics texts (Wildberger, 2005a). One method to defining words is the etymological approach. "Tri" being the prefix for three, "gon" referring to a polygon (e.g. pentagon, hexagon etc.) and "metry" referring to measure. Putting these together yields trigonometry as the study of the measure of three sided polygons.

A second way to define a word is to look at its use throughout history. The predecessor of the sine function was developed in the second century BCE (Bressoud, 2010). This was a relationship between central angles and chords of a circle (Bressoud, 2010; Gilsdorf, 2006).

Using these techniques for triangles started in the 11th century CE and was formalized as sine and cosine in the 16th century (Bressoud, 2010). Introducing students to the trigonometric functions through the use of triangles began in the 19th century (Bressoud, 2010).

A third approach to defining trigonometry is to see how the word is currently used in the literature. Looking at texts yields the following list of topics: triangles, trigonometric functions, trigonometric identities, trigonometric equations, trigonometric graphs, imaginary numbers, polar coordinates, De Moivre's theorem, McClaurin Series, integral substitutions, waves, Fourier Analysis and more (Hirsch, Fey, Hart, Schoen, & Watkins, 2009a, 2009b; Larson & Edwards 2014, Liebeck, 2005). This would lead us to defining trigonometry as the study of anything pertaining to angles, triangles, or the functions sine, cosine, and tangent.

Based on these three perspectives, trigonometry is the study of everything pertaining to the functions, which resulted from applying the study of circles, to the study of triangles. For this study I am going to focus on the mathematics of triangles.

Student difficulties with trigonometry. Many difficulties pertaining to trigonometry are well documented (e.g., Akkoc, 2008; Blackett & Tall, 1991; Bressoud, 2010; Brown, 2005; Marchi, 2012; Moore, 2009, 2012, 2013; Weber, 2005, 2008, Wildberger, 2005b). Most of the documented difficulties can be sorted into two categories: 1) difficulties pertaining to the concept of angle (Akkoc, 2008; Bressoud, 2010; Moore, 2009, 2012, 2013; Wildberger, 2005b), and 2) difficulties pertaining to the sine, cosine, and tangent functions (Bressoud, 2010; Brown, 2005; Marchi, 2012; Moore, 2012; Weber, 2005, 2008; Wildberger, 2005b).

Student difficulties with angles. Akkoc (2008) claims that student difficulties with angles stem from gaps in their teachers' understanding of angles. Moore (2012) attributes this difficulty to the current common approaches to teaching trigonometry. Bressoud (2010) attributes difficulties with angles to incompatibilities between the ratio and the unit circle approaches to understanding trigonometry. These approaches are associated with degrees and radians respectively. Students are then taught that they are interchangeable yet certain problems are to be done in terms of one and other problems in terms of the other without any justification for the decisions made (Akkoc, 2008; Bressoud, 2010). Wildberger (2005b) takes these views to an extreme by claiming that the unit itself is overly complicated and that with the exception of a few values cannot be calculated without a background in calculus.

Student difficulties with trigonometric functions. Moore (2012) attributes flawed understandings of the trigonometric functions on the volume of inconsistent definitions used for them. Brown (2005) found that students compartmentalize two different definitions for sine and cosine. These two definitions for sine and cosine are as the ordinate and abscissa respectively of points on the unit circle and as ratios of side lengths of a right triangle. Some authors have found that the meanings of the trigonometric functions are obscured by the use of the unit circle instead of the use of ratios of side lengths of right triangles (Kendal & Stacey, 1996; Markel, 1982). Markel (1982) argues that the unit circle includes angles above 180° which are unnecessary and does nothing to help students differentiate sine and cosine. Kendal (1996) found that the unit circle approach gave students more opportunities to make mistakes. However, Weber (2005) states that the unit circle was a more effective pedagogical tool than right triangles. He found that students were more likely to recognize sine and cosine as functions if taught using a unit circle approach. Students have problems viewing sine, cosine, and tangent as functions due to their non-algebraic nature and as such are unsure about how to perform algebraic operations with them (Weber, 2005). This could be due to the pedagogy straying away from beginning with the study of circles and chords (Bressoud, 2010; Gilsdorf, 2006) or it may be due to the transcendental nature of the functions (Weber, 2005; Wildberger 2005b).

Need for trigonometry. One debated topic is the importance of studying traditional trigonometry. While the importance of many mathematical topics is debated in the K-16 curriculum the inclusion and exclusion of trigonometry can be seen in multiple scenarios. Multiple groups believe that high school students are not being taught enough trigonometry and that it should be the penultimate high school course instead of calculus (Bressoud, 2012; Markel, 1982). While many college calculus courses expect a prior knowledge of trigonometry many colleges now offer variants of their calculus courses that attend to the same topics with the exception of omitting trigonometry-based problems.

Rational Trigonometry

Rational trigonometry is a reformulation of trigonometry based on replacing the units of distance and angle, with the units of quadrance and spread (Wildberger, 2005a, 2007). Quadrance is distance squared. The spread between lines l_1 and l_2 is the quadrance of $\overline{BC}$ divided by the quadrance of $\overline{AB}$ shown in Figure 1.

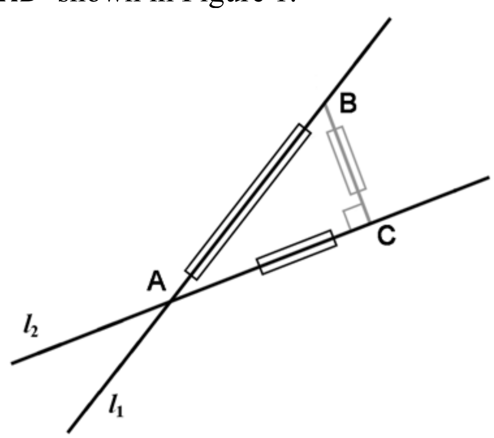

Fig. 1

Replacing the concept of angle with the concept of spread, results with the main formulas in trigonometry needing to be reformulated. The result is that the traditional trigonometry laws are replaced with the laws of rational trigonometry. They are analogous to the tradition trigonometric laws but the trigonometric functions are replaced with algebraic operations shown in Table 1 (Barker, 2008; Franklin, 2006; Henle, 2007; Wildberger, 2005a).

Table 1. Analogous Formulas in Tradition Trigonometry and Rational Trigonometry

Traditional	Rational
$c^2 = a^2 + b^2 - 2ab\cos C$	$(Q_1 + Q_2 - Q_3)^2 = 4Q_1Q_2(1 - S_3)$
$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C}$	$\frac{S_1}{Q_1} = \frac{S_2}{Q_2} = \frac{S_3}{Q_3}$
$A + B + C = 2\pi$	$(S_1 + S_2 + S_3)^2 = 2(S_1^2 + S_2^2 + S_3^2) + 4S_1S_2S_3$

Curricular Change

For something new to be adopted by the mathematics community it needs one of two things. It needs to either be able to do old tasks better than older approaches or it must be able to do new things. In the next three subsections I will discuss arguments supporting Wildberger's (2005a, 2005c, 2007) claim and opposing his claim that Rational Trigonometry is simpler than its traditional counterpart.

Arguments in favor of rational trigonometry. Arguments in favor of rational trigonometry being simpler than traditional trigonometry are that it gets rid of the difficulties caused by the angle and the trigonometric functions by replacing them. With Rational Trigonometry, sine, cosine and tangent are no longer needed to study triangles (Barker, 2008; Franklin, 2006; Henle, 2007; Wildberger, 2005a, 2005b). Wildberger (2005a, 2005b) claims that the most complex operation needed for trigonometry becomes the square root function and that a student who has learned the quadratic formula has the prerequisite skills needed to study rational trigonometry.

Arguments against rational trigonometry. Three arguments have been made against rational trigonometry. One of these is that the units are less intuitive (Campell, 2007; Gilsdorf, 2006). Adding consecutive angles of 30° and 30° yielding 60° is more intuitive than adding two consecutive spreads of 1/4 and 1/4 and getting 3/4 as your result. Another is that many triangle problems would have irrational solutions when solved with rational trigonometry and that the irrational solutions from rational trigonometry are no more useful than the transcendental solutions from traditional trigonometry (Gilsdorf, 2006). A third is the inflexibility of the educational system (Campbell, 2007). Educational sequencing rarely changes and it pushes students to study traditional trigonometry before higher mathematics.

Questions from the arguments. The two sides of this argument bring up some interesting points in comparing the systems. Is the benefit of avoiding trigonometric functions worth a unit that is less visually intuitive? Should simpler be defined in how one uses the material or in how one learns the material? Is there any benefit to rational trigonometry when you have to study traditional trigonometry anyway? While all of these are interesting my research question only addresses aspects of the first two. This study shows a glimpse at students working with quadrance and spread instead of the trigonometric functions. It also lets us see how two students use both trigonometric systems to address the same problems.

Mathematical Research

As stated earlier there are two reasons for the mathematics community to adopt alternative mathematics. The second of these mentioned was that if it does something that has not been done before. There is a small yet existent body of literature in higher mathematics that makes use of rational trigonometry. Authors have applied the concepts of rational trigonometry to geometry (Alkhaldi, 2014; Le & Wildberger, 2013; Vinh, 2006, 2013; Wildberger, 2010), computer programming (Kosheleva, 2008), and robotics (Almeida, 2007).

Factors Influencing Students Pursuing Mathematics

One of the factors that determines students' course taking patterns in college mathematics is their overall confidence with mathematics.

Students who expressed confidence in their mathematical abilities are more likely to take additional mathematics courses (Fennema & Sherman, 1977; Else-Quest, Hyde & Linn, 2010, Oakes, 1990). Those courses tend to be at a higher-level than the ones taken by their less confident peers (Fennema & Sherman, 1977; Else-Quest et al., 2010; Laursen, Hassi, Kogan, Hunter, & Weston, 2011; Stodolsky, Salk, & Glaessner, 1991). Typically, a loss in confidence is caused by performing lower than one's expectations (Ahmed, van der Werf, Kuyper & Minnaert, 2013). Improving students' performance in trigonometry would help their confidence and positively influence their future studies.

Students' Problem Solving Strategies.

Students tend to use the strategies and techniques they are most recently familiar with when approaching problems (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Owen & Sweller, 1985). This explains why students might solve a quadratic by formula instead of factoring or use the law of aines when solving a right triangle. This phenomenon is stronger in weaker students who are less likely to stray from the patterns established in examples (Chi et al., 1989). Situation and context also influence how students attempt to solve problems (Moore, 2012). A student is most likely going to use the formulas they think an instructor or exam wants them to use.

As it pertains to trigonometric problems the strategies are the same in both rational and traditional trigonometry but the techniques are different. For example, consider a problem where a student is given the measurements for two sides of a triangle and the vertex (Note: In this paper I use vertex to refer to the corner points of a triangle to avoid referring to angle as both an object and a unit of measurement) between them and asked for the third side. A strategy would be to use a formula that relates those four quantities. In traditional trigonometry the technique would be to use $c^2 = a^2 + b^2 - 2ab\cos C$ while in rational trigonometry the technique would be to use $(Q_1 + Q_2 - Q_3)^2 = 4Q_1Q_2(1 - S_3)$. Based on the previous paragraph I expected their techniques to change after studying rational trigonometry. Nothing I found in the literature leads me to believe their strategies will or will not change.

Methodology

Decisions need to be made when designing a study. These decisions impact the result of a study. Giving an assessment before an intervention may influence the intervention. Omitting such an assessment limits before and after comparisons in data analysis. Using students who struggle in mathematics increases the chance of benefit but also increases the potential unforeseen issues in intervention design. Using students who do not struggle in mathematics may decrease the potential for benefit but also decreases the likelihood of unforeseen issues in design. Some decisions are not made because of something being definitively better than an alternative but are made because they fit the study that researcher has decided to conduct.

The comparative nature of this study influences many design decisions. Only distances are given and asked for in these tasks. To give or ask for spread or angle would inherently design the questions towards the use of a particular approach. A second outcome of this is the triangles presented in both interviews are geometrically similar. Without similarity is it possible that one interview task was inherently simpler due to the triangles used. A third result is the tasks asking for an altitude, median, and vertex bisector. These three concepts have been studied since antiquity (Heath, 1956) and as such are not dependent upon rational trigonometry for analysis.

Research Design

The inquiry approach for this study is case study design. Case study is the study of a case across a timespan (Hatch, 2002; Yin 2009). Case studies can be exploratory or explanatory in nature (Yin, 2009). For this study the cases are the two participants and the timespan is five days (the pre-interview, three days of lessons, and the post-interview). Combining the need for a before and after and the exploratory affordances of task-based interviews (Confrey, 1981; Maher & Sigley, 2014; Schoenfeld, 2002) leads to the design of pre task based interview, lessons, post task based interview. The first interview is being used to look at strategies and techniques used by participants without a background in rational trigonometry. The lessons are used to create a background in rational trigonometry. The post interview is being used to see how a participant's behavior and/or reasoning when approaching the same task is altered after studying rational trigonometry. Three video lessons on rational trigonometry were given to the participants. I designed these lessons to give familiarity with the units and formulas for rational trigonometry. The first lesson focused on the units of quadrance and spread. Quadrance was described as distance squared and spread was first defined geometrically. After that I detailed arithmetical properties of spread such as the range of spread (0 to 1) and the spread of parallel lines (0) perpendicular lines (1) and showed examples of how to calculate the spread for lines given in both slope-intercept and standard forms. Spread bisection was also shown. The second lesson focused on the formulas $(Q_1 + Q_2 - Q_3)^2 = 4Q_1Q_2(1 - S_3)$ (the cross law) and $\frac{S_1}{Q_1} = \frac{S_2}{Q_2} = \frac{S_3}{Q_3}$ (the spread law). Examples were shown of using the cross law with three given quadrances to get one spread and then use the spread law to find the remaining spreads. The last lesson focused on the triple spread law. The third lesson focused on $(S_1 + S_2 + S_3)^2 = 2(S_1^2 + S_2^2 + S_3^2) + 4S_1S_2S_3$ (the triple spread law). The lesson was an example of using the triple spread formula to find the third spread in a triangle if only two spreads were known. Each lesson was accompanied with a worksheet that acted as practice for the participant, additional data for myself, and verification that they watched the videos.

Participants

Due to the comparative nature of this study, participants with a strong background in mathematics in general, trigonometry in particular, and with no background in rational trigonometry were recruited. To ensure this, mathematics students with a 4.0 in their first year mathematics courses including Euclidian trigonometry were chosen.

Data Collection

Data was collected through a pre-interview, three worksheets and a post-interview.

Interviews. Task based interviews were used to gather information about the participants' approaches to solving problems pertaining to triangles. The two interviews were audio recorded and occurred four days apart. Between the pre and post interviews the participants watched all three lessons and completed all three worksheets. Participants were supplied with pencil, paper, and a selection of traditional trigonometric formulas. During the second interview they were also given the rational trigonometry formulas from the lessons. From the interviews both their spoken word and written work were collected. The three tasks chosen for the interviews were chosen to have no inherent bias towards traditional or rational trigonometry. The first task was to find the length of an altitude of a triangle. This task is commonly shown in the high school curriculum and is often done with and without the use of the sine, cosine, and tangent functions (Keenan & Gantert, 1989; Hirsch, et al., 2009b). The second task was to find the length of a median of a triangle. The last task was to find the length of a vertex bisector. The triangle from the pre-interview is shown in Figure 2.

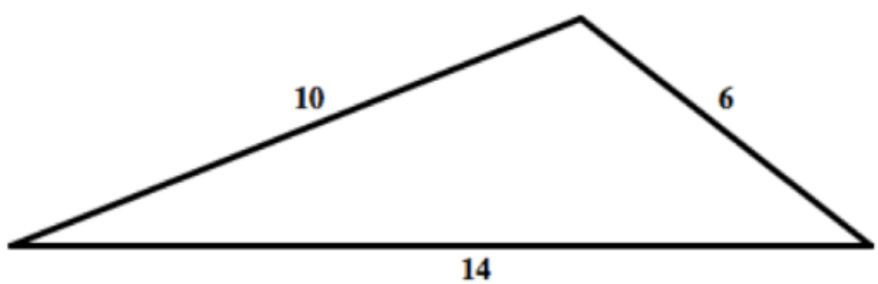

Fig. 2

Worksheets. The primary purpose of the worksheets was to ensure that the participants watched the videos. The work was analyzed with respect to the findings from the interviews for triangulation purposes. All three worksheets were collected at the second interview.

Data Analysis

I began my data analysis by transcribing the interviews. At this point I was already making decisions about what data had the potential to show interesting findings. After this my next step was coding the data. That data was separated and regrouped for organizational purposes (Creswell, 2014; Maxwell, 2013; Saldana, 2009; Seidman, 2012). My coding efforts were focused on the written work and verbal statements given during the interviews. Once this was done I focused on the findings that were most abundant and different between both interviews. The strongest examples are highlighted here.

Findings

After my analysis three themes emerged. These themes were strategies, numerical properties of triangles, and confidence. The strategies used involved the Pythagorean theorem and the relationships represented by the laws of sine and cosine and the spread and cross laws. Numerical properties were that distances must be positive, the triangle inequality, and that the longest sides of a triangle are across from the largest angles / spreads.

Maureen

Maureen is a mathematics major with the goal of becoming a high school mathematics teacher. Her undergraduate course on trigonometry ended four months prior to the study.

Strategies. Maureen started the pre-interview using the Pythagorean theorem in an attempt to find the value of an altitude. After multiple iterations gave her more unknowns than equations or values that did not make sense to her she abandoned this strategy. Her next attempt was to use the law of cosines to find one of the angles. Her goal was to use that angle in the law of sines to find the altitude. Once she found $\cos\theta = \frac{13}{14}$ she abandoned that approach as well. During the second interview Maureen used the cross and spread laws in the manner she intended to use the laws of cosines and sines in the first interview. In this attempt she successfully used both formulas. Though her use of the spread law gave her the quadrance of the altitude she did not turn that value into a length as the question was asking for. When questioned she said that the answer she gave was the length of the altitude.

Numerical properties. During the pre-interview Maureen made ample use of numerical properties of triangles. In particular, she made use of the fact that side lengths cannot be negative and she made use of the triangle inequality. She used these to check her computational results. The triangle inequality was also used to determine ranges for the answers to the interview tasks. Since she did not compute an angle there was no opportunity to observe if she would have used that the longest side is opposite the largest angle. In the post interview there was no use of the triangle inequality. This could have been used to alert her to not having the right answer in the first task. She did however use the property that the largest spread has to be across from the largest side of a triangle.

Confidence. Maureen's confidence in approaching these tasks appeared to increase after the lessons in rational trigonometry. In the first interview she spent a lot of time staring at the tasks without performing any calculations. After a particularly long silence she said:

> As much as I hate to admit that I can not remember how to solve for altitude, I'm just going to spend 20 minutes staring at this, because I'm not liking what I'm getting. I feel very bad saying that and admitting that, but it's not gonna happen.

In the second interview the gaps in work and expressions of frustration lessened. After the interview she gave the following two statements: "That was really really cool the whole quadrance and [spread]" and "if I had more time to practice I think I could have gotten all 3." These statements point towards a higher confidence level using rational trigonometry.

Tom

Tom is a mathematics major aiming towards graduate studies in applied mathematics. He took his trigonometry course approximately three years before the study.

Strategies. In the first interview Tom's strategy was to solve for anything he could find in hopes that he would come up with pieces he needed to solve the tasks. When he found $\cos\theta = \frac{13}{14}$ he used that value in another law of cosines equation in order to solve one of the tasks. In the second interview his strategies were nearly identical. The biggest change between the two interviews was he was using the rational trigonometry formulas instead of the traditional trigonometry formulas.

Numerical relationships. There was no evidence in either interview that Tom used the numerical properties listed above. He submitted answers to all three tasks and he could have but did not find two of them to be impossible due to the triangle inequality. In both interviews he was confident in his strategies (which would have worked) and his computations (which contained errors).

Confidence. Tom showed no notable change in confidence.

Discussion

If nothing else was accomplished this paper serves as another data point for the belief that some difficulties in trigonometry stem from difficulties related to the teaching, learning and use of functions. This aligns with the previous findings of many authors and studies (Bressoud, 2010; Brown, 2005; Marchi, 2012; Moore, 2012; Weber, 2005, 2008; Wildberger, 2005b).

Based on the findings I believe it is safe to say there may be some benefits to students studying rational trigonometry. The strongest evidence for benefits come from Maureen's case. Maureen falls into the category of students who are weaker with their algebraic manipulation of functions, which hindered her mastery of trigonometry (Weber, 2005). She seemed to increase in confidence after studying rational trigonometry and appeared more capable of solving problems when using the rational trigonometry formulas. Tom showed a strong mastery of the algebra of functions and little change in performance using the rational formulas. This may point to potential benefits being more likely for students with a weaker skill set pertaining to functions. Potential weaknesses also need to be mentioned. Maureen did not apply the numerical properties that she showed earlier evidence of using. She also at one point equated quadrance and distance. Quadrance being less intuitive than distance (Campbell, 2007; Gilsdorf, 2006) is likely a contributing factor of this.

I would also like to take this moment to point out a missed opportunity in this study. Since I did not notice it until data analysis I did not ask Maureen why she did not use the triangle inequality. Did she just not think of it? Did she not know how to work with it while using rational trigonometry? Did she know how to work with it but decide it wasn't worth the effort? Did she not feel the need for it? The reasoning for this change may be useful for later lesson design or research.

Future Research

There are many possibilities for future research. While it would be impossible to list them all, the following are the ones that stand out between my experiences with this study and with the mathematics.

Similar Studies

As stated earlier there were decisions with regard to this study that had both pros and cons. Redesigning this study as a longitudinal study or with a larger participant count may allow for more insights. Omitting the pre-interview, inserting lessons on traditional trigonometry before the pre-interview, or picking students with different backgrounds and experiences may also offer different results.

The Esperanto Effect

In the early twentieth century linguists were considering the idea of teaching Esperanto as a second language before teaching a third language to students. The idea being that a less complicated yet similar language would ease the transition from one language to the next. Eaton (1927) brought up multiple studies that supported this idea.

A similar principle could be studied in regards to traditional and rational trigonometry. Students could develop their problem solving strategies with regards to triangles without the burden of the trigonometric functions. Then later on be introduced to traditional trigonometry to see how they respond.

Other Geometric Structures

Lastly students and rational trigonometry can be studied in non-Cartesian / non-Euclidian contexts. Student difficulties in studying geometries outside of the Cartesian plane are not unheard of. Wildberger has published mathematical works applying rational trigonometry to both polar coordinates (Wildberger, 2005a) and hyperbolic geometry (Wildberger, 2009).

Conclusion

Will rational trigonometry ever replace traditional trigonometry in the mathematics curriculum? Most likely not. Very large portions of most curriculums and branches of mathematics are dependent on traditional trigonometry. However it does have potential as supplemental material. To quote Almeida (2007) and his work on robotics "The main role of R[ational] T[rigonometry] in this work was that it forced a different approach than the standard, due to difficulties that had to be resolved, that ended up forcing the paving of a new path of study." (p. 44). Using an alternative system gave him the opportunity to look at a problem differently. The potential gains from this type of opportunity merit further investigation.

Using Student Reasoning to Inform Assessment Development in Linear Algebra

Muhammed Haider, Khalid Bouhjar, Kelly Findley,
Ruby Quea, Brittany Keegan & Christine Andrews-Larson
Florida State University

The primary goal of this study was to design and validate an assessment of student reasoning in undergraduate linear algebra. We worked toward this goal by conducting semi-structured clinical interviews with 8 undergraduate students who were currently enrolled or had previously taken linear algebra. We identified the variety of ways students reasoned about the items in order to determine the extent to which the assessment measured or failed to measure students' reasoning about the intended topics. Students were interviewed using a think-aloud protocol while they completed the assessment, and interview data was analyzed by using the theoretical framing of concept image and concept definition (Tall & Vinner, 1981). In this paper, we describe how students' reasoning on items relating to span and linear independence informed adjustments to our assessment.

Key words: assessment, linear algebra, student reasoning

Students from a variety of science, technology, engineering, and mathematics (STEM) disciplines are required to take linear algebra as part of their undergraduate mathematics coursework. Students typically struggle with the theoretical nature of linear algebra as it is often their first time grappling with abstract mathematical concepts. Carlson (1993) argued that students' mathematical background up to this point is often primarily computational in nature; this often creates a barrier for students to overcome when they reach linear algebra. Linear algebra is a pivotal course that includes the mathematical underpinnings of different STEM fields, but it is filled with challenges for students. According to Wawro (2011), "The content of linear algebra, however, can be highly abstract and formal, in stark contrast to students' previous computationally-oriented coursework. This shift in the nature of the mathematical content being taught can be rather difficult for students to handle smoothly" (p. 2). The abstract concepts of linear algebra are often taught in such a way that students do not find any connections between new linear algebra topics and their previous knowledge of computational mathematics (Carlson 1993).

Researchers have worked to address this issue by developing inquiry-oriented instructional materials that help instructors to bridge students' informal and intuitive ideas with more formal and conventional understandings (Wawro, Rasmussen, Zandieh, & Larson, 2013). Our work aims to move towards documenting the effectiveness of these inquiry-oriented instructional materials in supporting students' conceptual understanding of central topics in an introductory undergraduate linear algebra course. In this study we have designed an assessment that aligns with four focal topics typically covered in an introductory linear algebra course: (1) span and linear independence, (2) systems of linear equations, (3) linear transformations, and (4) eigenvalues and eigenvectors. We aimed to create two questions for each of these four topics in order to develop an 8-item written assessment that could be completed by students in less than one hour. Based on findings from similar studies, we anticipate the results of the assessment to show greater conceptual learning gains from students who learned in inquiry-oriented classrooms along with similar procedural learning gains (Rasmussen & Kwon, 2007).

The central goal of this work is to develop a valid assessment to measure students' conceptual understanding of linear algebra. In order to develop an assessment that is sensitive to students' reasoning in linear algebra, we found it necessary to delve into the various ways that students reasoned about the items on our assessment. In particular we wanted to consider the kinds of reasoning elicited by our items, both to determine whether students interpreted items in ways that we intended and, importantly, to identify aspects of students reasoning to which we need our assessment to be sensitive. Our process of item refinement was informed by the kinds of student reasoning we observed during the interviews. With these ideas in mind, our work was guided by the following research questions:

- What is the nature of student reasoning elicited by the items on our assessment?
- To what extent do the items on our assessment accurately measure student reasoning?

Literature

In this section, we lay out our literature review in two parts. First, we report on the process of assessment development for other undergraduate STEM courses and how others have established validity and reliability. Then, we discuss research on student thinking and common difficulties faced in learning linear algebra concepts, particularly with regard to our four previously mentioned focal topic areas. Examining the research on student thinking in linear algebra is important for contextualizing our work examining student reasoning.

Literature on Assessment Development

Assessments can serve a number of purposes – they can be designed to inform teachers' ongoing instructional decisions (formative assessments), to evaluate students' learning (summative assessments), to establish the effectiveness of an instructional approach or compare multiple instructional approaches, or to inform policy decisions (among other reasons). Our assessment is intended to measure students' conceptual understanding related to the four previously mentioned focal topic areas in introductory undergraduate linear algebra.

The processes used to develop assessments that measure conceptual understanding in multiple STEM topic areas have been well-documented (e.g. Sadaghiani, Miller, Pollock, & Rehn, 2013; Carlson, Oehrtman, & Engelke, 2010; Barniol and Zavala, 2014; Melhuish, 2015). For example, Carlson et al.'s (2010) approach to developing an assessment for Pre-Calculus was by first identifying foundational content areas within the course, creating open-ended questions to comprehensively cover those content areas, interviewing students to determine how students approached each question, refining the questions and converting them to multiple-choice format based on interview data, and finally administering the instrument to multiple samples. In contrast, Barniol and Zavala (2014) followed a simpler process in which they collected their questions from existing instruments and had the content validated by experts.

An important aspect of assessment development relates to the ways in which researchers validate these assessments. Examining how students reason about particular items and using this to inform the work of creating appropriate distractor items for multiple choice questions was an important phase in the process for several researchers (e.g. Hestenes, Wells, & Swackhamer, 1992; Carlson, Oehrtman, & Engelke, 2010; Wilcox & Pollock, 2013; Sadaghiani, Miller, Pollock, & Rehn, 2013). Their interview component helped establish construct validity by giving researchers a glimpse into students' interpretations of the questions and the kinds of reasoning that the items elicited. Appropriate probing and occasional direction from the interviewer also provided insight on student reactions to potential distractor items (Sadaghiani, et al., 2013).

Literature on Student Thinking in Linear Algebra

Broadly, linear algebra can be considered to encompass theory about systems of linear equations and their solution sets as well as theory about vector spaces and mappings between them (Andrews-Larson, 2015). Difficulty in the teaching and learning of linear algebra during students' first year of undergraduate study is well documented (Hillel, 2000; Sierpinski, 2000; Stewart & Thomas, 2009). The literature reveals that students also struggle with formal mathematical language in linear algebra courses (Stewart & Thomas, 2010; Sierpinska, 2000; Carlson, 1993). Additionally, the need to learn and coordinate modes of the description and representation of abstract concepts of linear algebra can function as a source of difficulty for students in their early learning (e.g. Carlson, 1993; Hillel, 2000). For example, Larson & Zandieh (2013) developed a framework that highlights geometric and algebraic interpretations of three views of the matrix equation A**x**=**b** that students need to develop: a linear combinations view, a system of equations view, and a transformation view. While these three views are organized around the mathematics that students need to learn, the framework highlights the ways in which the literal symbols A, **x**, and **b** are coordinated in each view – providing a useful lens for identifying the (sometimes idiosyncratic) ways in which students often blend these views. Flexible, coordinated use of these three views lies at the core of many ideas central to an introductory linear algebra class. For instance, understanding a matrix times a vector as a linear combination of the column vectors of the matrix is importantly related to ideas about span and linear independence (properties of sets of vectors), and understanding a matrix times a vector as a representation of a linear transformation is important for understanding ideas about mapping between vector spaces.

Span and linear independence: The literature has shown that students generally rely on procedural methods for approaching questions about linear dependence and independence, and often do not leverage geometric intuition (Bogomolny, 2007; Aydin, 2014). Furthermore, students have been found to perform better on questions about linear independence that require algebraic interpretation than on questions that require geometric interpretation, and that performance on both kinds of items was largely unrelated to students' performance on questions that require understanding of the formal definition of linear independence (Ertekin, Erhan, Solak, & Yazici, 2010). Stewart & Thomas (2010) laid a similar argument with regard to students' understanding of span. To ameliorate the problem of this disconnect between algebraic and geometric interpretations and their connection to formal definitions, Wawro et. al. (2012) have developed instructional materials intended to support students in developing well-connected understandings of span and linear independence.

Systems of linear equations: There is extensive literature on student thinking in K-12 settings documenting the importance of students' interpretations of the equals sign as they learn to solve single equations in one variable (e.g. Star & Rittle-Johnson, 2007; Li, Ding, Capraro & Capraro 2008). In the previously mentioned set of views of the matrix equation A**x**=**b**, Larson & Zandieh (2013) highlight the flexible set of interpretations for the vector **x** that students need to develop and ways in which students coordinate these views. Zandieh and Andrews-Larson (2015) have subsequently expanded this framework to consider ways in which the augmented matrix [A|**b**] relates to this set of interpretations, and commented on the mischief created by ***x***'s disappearing act. Students often struggle to interpret row-reduced forms of this augmented matrix to make sense of the solution sets of systems in which the number of equations differs from the number of unknowns, or in which the solution is unique; whereas in R^2, students are better able to leverage their geometric intuition to interpret the solution than in higher dimensional settings (Zandieh & Andrews-Larson, 2015).

Linear transformations: Research on students' thinking about linear transformations has identified a variety of metaphors students draw on to reason about how their understandings of functions might relate to linear transformations: input/output correspondence, morphing or mapping of vectors, and thinking in terms of a function 'machine' (Zandieh, Ellis, & Rasmussen, 2012). Bagley, Rasmussen, and Zandieh (2015) identified two productive ways of student reasoning about matrix invertibility: thinking about an inverse as a transformation that undoes another, and conceiving of an inverse as a transformation that, when composed with another, acts as the "do nothing" function – the latter being more closely consistent with typical definitions of invertibility. Others have considered students' thinking about invertibility as it relates to the set of equivalent statements included in the invertible matrix theorem (e.g. Wawro, 2015; Selinski, Rasmussen, Wawro, and Zandieh, 2014).

Eigenvectors and eigenvalues: Sinclair & Tabahgi (2010) have noted the highly geometric ways in which mathematicians talk and gesture as they reason about ideas related to eigenvectors and eigenvalues. In contrast, students often primarily draw on algebraic ways of reasoning about these ideas, and can struggle to make sense of the reasons behind symbolic shifts such as shifting from $A\boldsymbol{x} = \lambda\boldsymbol{x}$ to $(A - \lambda I)\boldsymbol{x} = 0$ (Thomas & Stewart, 2011). It can be challenging for students to coordinate algebraic interpretations with geometric ones (e.g. Stewart & Thomas, 2010; Larson & Zandieh, 2013), and students' ideas about eigenvectors are often not well connected to other conceptual aspects of linear algebra (Lapp, Nyman, & Berry, 2010). In light of the value of these findings, researchers have developed interventions to support students in developing geometrically motivated ways of reasoning about eigenvectors and eigenvalues (Tabaghi & Sinclair, 2013; Zandieh, Wawro, & Rasmussen, 2016).

Theoretical Framing

A theoretical construct that has been useful in many areas of mathematics education for making sense of students' reasoning is the notion of concept image and concept definition (Tall & Vinner, 1981). According to Tall and Vinner (1981), concept image is the "total cognitive structure that is associated with the concepts, which include all the mental pictures and associated properties and process" (p. 152). For a given concept, every individual creates an image or structure in their mind that helps the individual understand and remember that concept. This concept image may or may not be similar to other individuals' images, and these images can be quite different from the formal definition of the concept. Tall and Vinner (1981) use the term "formal concept definition" to refer to the definition that is largely accepted by the mathematical community; they argue that this can be different from an individual's 'personal concept definition,' which may change over the time and with new knowledge as is the case with one's concept image.

The notion of concept image and concept definition has been used as a lens for examining student reasoning at the undergraduate level in a number of content areas, including linear algebra (e.g. Wawro et. al., 2011; Britton & Henderson, 2009). We draw on the notion of concept image and concept definition as an analytic tool for interpreting students' responses to assessment items. For our analysis, we look for alignment between a student's elicited concept image and the formal concept definition as evidence of understanding.

Data

In this study, we conducted semi-structured clinical interviews (Bernard, 1988) with eight university undergraduate students: six males and two females. One of the participants was taking linear algebra at the time of the interview, and the other participants had taken linear algebra within the last two years. The participants' majors covered fields that included mathematics, statistics, education and economics. At the time of the interview, participants had completed an average of four math classes after taking linear algebra.

Each participant was asked to work through eleven assessment questions using a think-aloud interview protocol in which the interviewer asked the student to read each item aloud and think aloud as he or she came to an answer. The interviewer then asked follow-up questions as needed to understand the student's reasoning in arriving at their answer. Each interview lasted for approximately one hour and was audio and video recorded.

We developed the assessment items used in this study by consulting past assessments prepared by five different mathematics faculty members at different institutions. After identifying a set of questions related to each of our four focal topics, three mathematics faculty members from three different institutions were consulted to identify which items these experts felt focused on key ideas and had the potential to assess students' conceptual understanding of these ideas. We modified our assessment according to experts' initial feedback, and the assessment items to be used in interviews were selected after receiving a second round of feedback from these experts.

In this paper, we provide an in-depth analysis of student reasoning on the first two items on our assessment. Figures 1 and 2 below show the wording of these two items as they appeared in the interview.

1. Answer the following questions regarding the set of vectors $V = \left\{ \begin{bmatrix} 1 \\ 2 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 2 \end{bmatrix} \right\}$.

a. Which of the following best describes the <u>span</u> of the set V?
   - i. A point
   - ii. Two points
   - iii. A line
   - iv. Two lines
   - v. A plane
   - vi. Two planes
   - vii. A 3-dimensional space

b. Give an example of one vector in the span of V, and show or explain how you found that vector.

c. Give an example of one vector in R^3 that is not in the span of V and explain how you know it is not in the span of V, OR explain why there is no such vector in R^3.

Figure 1: Assessment item focused on span

The items shown in Figures 1 and 2 focus on span and linear independence, which also entail conceptual connections to linear combinations and dimensionality. These concepts, along with their abstraction and notation, are often new ideas for students taking their first linear algebra course, and their position near the beginning of the course can also make these concepts the first hurdles to complete. They serve as core concepts in linear algebra as they provide foundation for thinking about solution sets to systems of linear equations as well as vector spaces and the mappings between them. In addition, the interview data was particularly rich for these items, possibly because they appeared at the beginning of the interview when students and interviewers were at their "freshest." For these reasons, as well as for the sake of time and space, we will only provide a closer look at students' reasoning on these two items.

2. Consider the set of vectors $\left\{ \begin{bmatrix} 1 \\ -2 \\ 3 \end{bmatrix}, \begin{bmatrix} 4 \\ -1 \\ 0 \end{bmatrix}, \begin{bmatrix} 3 \\ 1 \\ -3 \end{bmatrix}, \begin{bmatrix} 6 \\ -5 \\ 6 \end{bmatrix} \right\}$. To determine whether the set is linearly independent or dependent, a student did the following correct row reduction:

$$\begin{bmatrix} 1 & 4 & 3 & 6 & 0 \\ -2 & -1 & 1 & -5 & 0 \\ 3 & 0 & -3 & 6 & 0 \end{bmatrix} \sim \begin{bmatrix} 1 & 0 & -1 & 2 & 0 \\ 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

a. The set of vectors is (circle one): linearly independent / linearly dependent.

b. Explain what it is about the solution that tells you whether or not the set is linearly independent or dependent.

Figure 2: Assessment item focused on linear dependence/independence

Methods of Analysis

In order to identify the kinds of student reasoning elicited by our assessment items and the extent to which these accurately assessed student understanding, we conducted our analysis in four phases: (I) characterizing individual students' concept images, (II) identifying themes across students, (III) identifying alignment between responses and reasoning. Phases I and II allowed us to identify the kinds of student thinking elicited by our assessment items. Phase III offered insight to the extent to which the items accurately assessed students understanding. Specifically, we looked to see whether the assessment items accurately documented alignment between students' concept images and the formal concept definition. The phases of analysis are described in greater detail below.

Phases

Phase I: Characterizing individual students' concept images: We developed a short description of what our data revealed about each student's concept image by first watching the video and, in some cases, transcribing each student's interview response to the question. We then developed a list of themes that characterized how he/she thought about the concept and collected quotes that exemplified characteristics of the student's thinking.

Phase II: Identifying themes across students in how students reason: We grouped students according to the nature of their concept images. This helped us document themes in how students reason about the items. These groupings of students' concept images were organized in a table to make it easier to identify trends in thinking.

Phase III: Documenting written responses: We identified what students stated their final answer would be (and other answers they offered if they changed their mind) as well as the justification they offered for their answer(s). This was accomplished by drawing on students' written work as well as using audio/video data as needed in cases when the response was given orally but not written on the student pages. Each response was then color-coded to indicate whether a correct response corresponded to correct or incorrect reasoning and whether an incorrect response corresponded to correct or incorrect reasoning. This was used to assess the extent to which the item accurately measured what we intended.

Findings

In this section, we will describe in detail trends observed in students' reasoning on items 1 and 2. We then offer an overview of how we coded alignment between correctness of responses and rationales offered for responses in order to synthesize the extent to which items accurately assessed students' understanding. In the discussion section, we address the ways in which our analysis informed revisions to the assessment.

Students' Reasoning about Item 1: Span

After interviewing students and transcribing their interviews we analyzed the first assessment item to document students' concept image of span. In part a of item 1, which asked students which best described the span of the given set of two (linearly independent) vectors in $\mathbb{R}^3$, four of eight students correctly chose "a plane," and the other four students were split with one each choosing a point, two lines, two planes, and a three-dimensional space. In examining students' justifications for these choices, we identified four themes in students' responses that offer insight into those aspects of students' concept images for span that are elicited by this item: (i) interpreted individual elements with notable effort, (ii) attempted to resolve the number of entries with the number of vectors (related to issue of dimensionality), (iii) reasoned about relationships between elements (related to linear dependence/independence), and (iv) interpreted procedurally.

Three students' responses were coded as entailing effortful interpretation of elements. For example, Barry reasoned "x is at 1, y is at 2, and then z is at 3, so that I would say that's a point." Kody argued "I'm pretty sure each of these represents a plane… could be two lines but I don't think it is because there's three coordinates." While these students selected different choices for what best represented the span of the set given in the question, both quotes highlight the students' focus on interpreting individual elements of the set.

Three students spent time working to resolve the number of entries in each vector (3 entries) and the number of vectors (2 vectors) as they came to their answer. Brenda, who ultimately came to incorrectly conclude the answer was a 3-dimensional space, explained her reasoning, "This [writes R^2] was x and y, and R^3 was x, y, and z. This might be 3-dimensional space, but there are two of them [vectors]." Carissa, who ultimately resolved the issue to correctly conclude the answer was a plane, said "So since there are two it will span just in the second dimension and in the second dimension would be a plane so then it might actually just be a plane."

Four students addressed relationships between elements of the set as they explained their reasoning on this question, in particular focusing on linear independence and dimension. Notably, all four of these students answered the question correctly. Carissa elaborated her earlier comment with the remark, "I think I need three linearly independent vectors to span a third dimension. So I think in this case it doesn't span a third dimension." Another student Lee argued "If they were linearly independent then one is either basically a scalar multiple of the other, so basically the same vector just different magnitude."

One student, Kenneth, described a procedural approach to answering the question. He put the two given vectors into a matrix, row reduced that matrix, and (incorrectly) concluded that the vectors in the row reduced matrix were in the span, and that the row reduced matrix would "span" the given set of vectors V. In explaining his choice that the span was best described as two lines, Kenneth explained, "I don't remember the graph, I don't think we went over the graphing. How to convert like the matrices and the variables to like graphs and stuff. I guess since I have two variables it would get two lines?" The comment about two variables is consistent with his work row reducing a matrix with two columns, and suggests he is drawing on a systems of equations interpretation to respond to the question – but he is unable to effectively use this interpretation to reason about the span of the two vectors given. It is also noteworthy that, while Kenneth's procedure was incorrect, it does correspond to a procedure that would be correct in a different context – for instance if one is given a vector and told to determine if it is in the span of a particular set of vectors, row reducing is a common method for making this determination. We posit that Kenneth was aware of some version of this procedure and attempted to adapt it to this context.

Looking across these themes in student responses as shown above in Table 1, we note that all students who reasoned about relationships between vectors in terms of linear dependence/independence responded to the item correctly. Students who exhibited effortful interpretation of elements gave incorrect responses, which suggests students need to be able to consider relationships among vectors to answer the item correctly.

Student	Response	Reasoning Categories Observed
Barry	Point (two?)	Effortful interpretation of elements (interpreted as points)
Kody	Two Planes	Effortful interpretation of elements (interpreted as planes) Attempting to resolve number of entries with number of vectors
Brenda	3d space	Effortful interpretation of elements; related to Attempting to resolve number of entries with number of vectors
Carissa	Plane	Attempting to resolve number of entries with number of vectors Evidence of reasoning about linear dependence
Lee	Plane	Evidence of reasoning about linear dependence (geometric)
Derrick	Plane	Evidence of reasoning about linear dependence (geometric)
Ronaldo	Plane	Evidence of reasoning about linear dependence (geometric) **ONLY student to draw on definition of span**
Kenneth	Two Lines	**Procedural approach** (row reduce matrix of given vectors; vectors in row reduced matrix are in the span of given set)

Table 1: Student responses to Question 1a and categories of reasoning observed

Students' Reasoning about Item 2: Linear Dependence and Independence

When analyzing the second item, we documented students' reasoning on the topic of linear independence and linear dependence. Seven out of eight students came to the correct conclusion that the vectors were linearly dependent. However, only four students reached this conclusion using sufficient, conceptually correct, generalizable reasoning. Amongst the eight students, five different ways of reasoning about linear dependence and independence were identified. Many of the students reasoned about the problem in more than one of these ways. The five ways of reasoning identified are: (i) dependence as a linear combination or one vector being a multiple of another, (ii) independence as a pivot in each row and/or column in the RREF augmented matrix, (iii) dependence as a row of zeros in the RREF augmented matrix, (iv) dependence as a relationship between variables (e.g. in the equation $x - z + 2t = 0$, x can be thought of as depending on z and t), and (v) dependence as the number of vectors exceeding the dimension space in which the vectors live. Below, we offer examples to illustrate these ways of reasoning. The first four ways of reasoning were used in ways that were sometimes correct and sometimes incorrect.

Three students talked about the concept of dependence as a linear combination (Ronaldo, Lee, Carissa). For example Ronaldo explained, "… so linear dependence also means that there is one of the vectors that can be written as a linear combination of the other ones, so there will have to be a solution to the system and that system has a solution because we don't have anything of the form all zeros…" We argue this aspect of these students' concept image of linear dependence was consistent with the concept definition of linear dependence. In contrast, Kenneth, the one student who arrived at the incorrect conclusion that the set was linearly independent argued that, "If the vectors are dependent that means they are like multiples of each other." While it is true that if one vector in a set is a multiple of another, the set will be linearly dependent, this is not the only way that a set can be linearly dependent as it doesn't include the important possibility that a set can be linearly dependent if one of the vectors is a linear combination of other vectors in the set. Because Kenneth's concept image of linear dependence only aligned partially with the definition of linear dependence, he was unable to answer this item correctly.

Two students argued the set would be linearly independent if there is a pivot in each row and/or column (Derek and Carissa). Carissa gave the explanation "… I think it has to be linearly independent because it has to have a pivot in every row or column I can't remember which one, but either way I don't have that here …" Carissa elaborated when she was asked about how the pivots relate to the linear dependence of the set, saying "we have two pivots so that means … since there is 4 vectors in the third dimension and we only have two [pivots], since we don't have the correct number of pivots they are linearly dependent". This suggests that Carissa was aware that there is a relationship between pivots and linear dependence, her uncertainty about whether the pivots need to be in rows or columns indicates that her understanding of the relationship between pivots and linear dependence is largely procedural and perhaps somewhat tenuous.

Two students reasoned that dependence can be determined by whether the augmented RREF matrix has a row of zeros (Brenda and Kody). Kody for example said "… it's linearly dependent because of that row of zeros … we can't have a row of zeros and have it be independent". While this reasoning was not considered incorrect, it is easy to give examples in which a row of zeros in the augmented RREF matrix does not imply that the corresponding set of vectors is linearly dependent. Therefore, although both students who cited this reasoning arrived at the correct conclusion (that the given set of vectors is linearly dependent), this particular reasoning was classified as conceptually insufficient or incomplete. In fact, the item was ultimately revised to remove the possibility that students could use this justification to argue that the set of vectors was linearly dependent.

Three students used the idea of dependence as a relationship among variables to give justification for the set being linearly dependent (Barry, Brenda and Ronaldo). Barry argued, "... whenever you look at these top two rows this is essentially like $x_1 - x_3 + 2x_4$ and similar to this one $x_2 + x_3 + x_4$ and so there is a kind of some dependency there because you can arrange this equation but you can see like x_1 depends on what x or … these solutions are kind dependent upon each other on x_1, x_3, x_4 and x_2, and x_3 and x_4 so if I am remembering things correctly I am gonna say it is linearly dependent." When the interviewer wanted to know more about what it is that he is saying it is linearly independent he replied “the variables, so I think abstractly it does not necessarily … it does not have to be necessarily x_1, but I am saying x_1 is linearly dependent on x_3 and x_4 but I feel like you could definitely switch around and say x_3 is linearly dependent on x_1, x_4 or x_4 linearly dependent on x_3 and x_1.” While Barry’s reasoning about the variables was correct, when probed by the interviewer, he said he did not know what this revealed about the original set of vectors. Note that Ronaldo’s previous comment shows how he was able to use ideas about linear combinations of vectors to relate the idea of dependence as relationships among variables to the idea of dependence as a property reflecting relationships among a set of vectors.

Finally, one student correctly noted that no computations were needed to solve this question, pointing out that because the number of vectors exceed the dimension space in which the vectors live, the set must necessarily be linearly dependent. Derek stated “It has to be linear dependent before even looking at the row reduction, because it is the 3-dimensional vectors so you know you are in R^3 and if you have 4 vectors in R^3 then you know that it is a linearly dependent, because at most the span of $\square^3$ can be all of R^3 but then only three vectors can do that.” This comment further highlights the interrelated nature of students’ understanding of span with their understanding of linear dependence and independence.

Looking across these ways of reasoning, we see that students who reasoned about linear dependence in terms of linear combinations were the most successful at producing correct and generalizable justifications for their responses. When students reasoned about linear dependence in terms of pivots and variables, there was more variation in evidence that they were able to link this reasoning to what this revealed about the original given set of vectors. This is perhaps unsurprising as these forms of reasoning are organized around representations that are more obscured from the original set of vectors when compared to reasoning organized around linear combinations of vectors.

Summary of Interview Analysis

Table 2 summarizes student responses to each assessment item. The “Correct%” column indicates which percent of students answered the item correctly, and the “Works%” column displays percentage of occurrences for which response and reasoning were aligned. We coded an item as “working properly” if a correct response was accompanied by correct reasoning or if an incorrect response was accompanied by incorrect reasoning. An example of misalignment between response and reasoning would be Barry’s response to item 1b; even though he provided a vector that was in the span of the set, he only picked it because he interpreted span to simply be the set, not as any vector that was a linear combination of the vectors in the set.

Table 2 also provides basic information about which items were changed, which will be addressed in more detail in the Discussion section. All changes were made after the eight interviews were completed with exception to 1a and 5. These items were modified after the first and sixth interview respectively to account for adjustments needed in light of these interviews. The additional distractors in 1a were added as a result of Barry’s response that the two elements of the vector set each represented a point. “Two points” as well as “two lines” and “two planes” were added to make the list of distractors comprehensive for all cases where students might use effortful interpretation of elements. The change in item 5 was made after six interviews because no student was able to correctly answer the question as it stood.

5. “Assume that T is a linear transformation where $T: \mathbb{R}^2 \to \mathbb{R}^2$ first rotates the plane clockwise by 90 degrees about the origin, and then stretches the plane horizontally by a

factor of 2. If A is the standard matrix for *T*, which of the following is true? Justify your choice."

Four answer options were provided, each of which expressed the transformation as the product of two matrices. Students had a difficult time interpreting the transformation resulting from each answer choice. The process was often time-consuming, and students usually started interpreting or computing the product of the two matrices given each answer choice, which offered limited insight into how students reasoned about the composition of two linear transformations. The revision version of the question gives students transformation described as product of two matrices, and asks them to decide which of four geometric descriptions best describes this transformation. While the two students who received the modified version still did not answer the question correctly, they reasoned about the item in ways more aligned with our intent.

Table 2: Alignment between correct reasoning and correct answers

**1: Span; 2: Linear Independence; 3&4: Liner Systems; 5&6: Transformations; 7&8: Invertibility; 9&10: Eigenvalues, Eigenvectors*

***RA: Right Answer; RR: Right Reasoning; WA: Wrong Answer; WR: Wrong Reasoning; Cst: Consistent; UC: Unclear; US: Unsure; IC: Incomplete; DK: Don't Know*

As Table 2 indicates with green shading, we can see that there was consistent alignment between answer and reasoning on many of the items. Some items were more problematic than others with respect to having alignment between responses as reasoning, such as items 1b and 1c. Other items elicited unclear or incomplete reasoning from students, making it difficult to judge whether the question was working properly. More careful future analysis of these items is needed. Item 6 was a more theoretical question that was written in a symbolically abstract way, and as a result, students had a very difficult time reasoning through the question and coming to an answer without some manner of interviewer scaffolding.

We can also begin to say something about the discriminatory power of many of the questions based on the percentage of correct responses. For example, several were answered correctly 50% of the time, while other items were answered correctly closer to 0% or 100%. This informed us about the strength of some of our questions to discriminate between students with strong and weak conceptual understanding. None of the eight students were able to correctly answer item 5, suggesting that this item was doing a poor job measuring any student understanding about transformations.

Discussion

Trends in Student Reasoning

Reflecting on our findings from item 1, we noted a key feature of students' reasoning that distinguished students who answered correctly from those who did not: students whose responses focused on making sense of the individual vectors answered the item incorrectly whereas students who focused on the relationship between vectors (typically framed in terms of linear dependence/independence) answered the item correctly. This finding has potential pedagogical implications, in that it suggests that students need opportunities to develop rich interpretations of vectors and linear combinations of vectors to help them develop ways of thinking about all possible linear combinations of a set of vectors in a coordinated way – the very definition of the span of a set of vectors. Additionally, our findings highlight the ways in which students' understanding of linear dependence and independence is interconnected with their understanding of span.

The trends we noted in students' responses to item one also have implications for assessment development in linear algebra. First, students' responses to item 1 also suggested that, in order to more fully students' understanding of span, we need to find a way to assess students' strategies for resolving differences between the number of vectors in a set and the number of entries in each vector – an idea related to dimensionality. Second, it might also be worth asking questions that target students' understanding of the linear combinations and span separately. Third, we also find it important to consider the relationship between students' understanding of span and linear independence and how we can assess students' recognition of that connection. We've added items to our assessment that aim to capture the first two of these implications; the third remains as an area for future exploration.

For item 2, students expressed a number of ways of reasoning about linear dependence and independence. For example, some students focused on the row of zeros in the RREF as providing justification to claim that the vectors were linearly dependent. Others drew on the presence of a pivot in each row or column of the RREF as the basis for their reasoning. One student also believed linear dependence was solely based on the idea that one vector should be a multiple of another vector. It was difficult to establish whether these students had a clear conceptual understanding of linear dependence of vectors or if they were simply trained to look for certain conditions to answer such questions. The prevalence of these relatively procedural ways of reasoning suggest it would be fruitful to be able to document conceptual connections students have with regard to those procedures.

Assessment Adjustments

We left the first item largely as-is because it had good discriminatory power, and this discriminatory power aligned with a clearly distinguishable aspect of students reasoning (e.g. whether they focus on individual elements in a set of vectors or relationships among elements when reasoning about span). However, we adjusted the second part of item 1 to more fully document students' concept image by requiring that they indicate all vectors among several options are in the span of a given sent of vectors; this accounted for a misalignment between correctness of reasoning and response documented on the second part of item 1 (which was not part of our fine-grained analysis). In addition, we added new item that aims to capture students' reasoning about the relationship between the number of entries in a vector and the space in which that vector lives.

The second item was adjusted so that students were still given a (linearly dependent) set of four vectors in $\mathbb{R}^3$, but these correspond to a row-reduced matrix that does not include a row of zeros. This removes the possibility that students would use the justification that there is a row of zeros to claim the set of vectors is linearly dependent. In fact, this change might increase the discriminatory power of the item, as if students think this is the only way for a set of vectors to be linearly dependent, they will now answer the item incorrectly.

Although, this paper focuses on the items related to span and linear dependence and independence, we also briefly describe the other kinds of modifications made in other items given the findings of the interviews. There were two main reasons for additional adjustments. One of these reasons was lack of discriminatory power (e.g. most students got question 4 correct and most students got question 5 correct) – so these items were removed or omitted. The other reasons were more logistically oriented, e.g. many students spent far more time than intended performing a row reduction on question three, so we elected to provide the row reduced matrix and ask students to interpret the result. We similarly removed item 7 because it had the potential to be computationally cumbersome and we wanted students to be equally likely to do well on the assessment regardless of their access to a calculator.

While this paper shares useful findings about the creation of an assessment to measure students' conceptual understanding of linear algebra, there is still more work to do. Our next step is to administer the revised assessment to several larger samples and conduct item and factor analysis based on this data. While the validation process for our assessment may not yet be complete, we believe this preliminary study reveals important insights into student reasoning that could be helpful to linear algebra instructors and assessment developers.

Example construction in a transition-to-proof classroom

Sarah Hanusch
Texas State University

Accurately constructing examples and counterexamples is an important component of transition-to-proof courses. This study investigates how one instructor of a transition-to-proof course taught students to construct examples, and compares this instruction to the examples constructed by the students.

Keywords: transition-to-proof; undergraduate instruction; example construction

Introduction

Learning to write proofs is a complicated process, and students develop a variety of beliefs about how to construct a proof (Harel & Sowder, 2007). Using examples is a well-established strategy in the proof writing process, and examples can be used for several purposes when developing and proving conjectures (Alcock & Inglis, 2008; Alcock & Weber, 2010; Lockwood, Ellis, & Knuth, 2013). Yet undergraduate students often use examples ineffectively (Iannone, Inglis, Mejia-Ramos, Simpson, & Weber, 2011).

The term example has many meanings in mathematics (Watson & Mason, 2002). Within this study, the term example is limited to a mathematical object which satisfies specific characteristics and illustrates a definition, concept or statement (Moore, 1994). This definition excludes sample proofs, such as demonstrations of the direct proof technique or proofs by induction. Alcock and Weber (2010) claim that this definition of example is "probably the most common intended meaning of the term when it is used by mathematicians and mathematics educators in the context of proof-oriented mathematics" (p. 2).

Research questions. In this study, the following questions are addressed:
1. In what ways do students construct examples effectively and ineffectively on tasks in their transition-to-proof course?
2. How did the instructor teach example construction?
3. What connections are found between the students' construction of examples and the instruction given?

Literature and Theory

Considerable literature is available on the proving abilities of students and mathematicians, and the use examples on proving tasks (Alcock & Weber, 2010; Buchbinder & Zaslavsky, 2011; Dahlberg & Housman, 1997; Iannone et al., 2011; Lockwood, Ellis, Dogan, Williams, & Knuth, 2012; Moore, 1994; Watson & Mason, 2002, 2005; Weber, Porter, & Housman, 2008). However, in the interest of space, much of this literature has been omitted. The review below focuses on the literature concerning the construction of examples, and the role of example in teaching advanced mathematics courses.

Example construction. Antonini (2006) sought to answer how examples are constructed, by conducting clinical interviews with seven mathematicians. From these interviews three distinct techniques emerged: *trial and error*, *transformation*, and *analysis*. *Trial and error* is characterized by constructing objects, and then testing whether the object has the desired characteristics. *Transformation* is characterized by taking a known object which has some of the necessary characteristics, and then performing adjustments until the object has all the required characteristics. *Analysis* is characterized by deducing additional properties of the object, until this list of properties evokes a known example or produces an algorithm for constructing an example.

Antonini (2006) observed that mathematicians often follow a process of starting with *trial and error* and then using *transformation*, if *trial and error* failed. The *analysis* technique was used after failing to construct an example with both the *trial and error* and *transformation* techniques. Antonini (2006) notes that the *analysis* technique is appropriate when it is possible that no example with the given properties exists, since the derivation of properties could lead to a proof by contradiction.

This classification of example constructions was applied to undergraduate students by Iannone et al. (2011), when they asked students to generate examples of a particular type of function and classified the students' construction technique. The students generated examples with a *trial and error* technique on 51 out of 62 constructions, and on the remaining 11 constructions the students used a *transformation* technique where they modified a known example.

Iannone et al. (2011) theorized that the *trial and error* strategy resulted in weaker conceptual gains than the other strategies. However, in a second study Iannone et al. (2011) found that there was no significant differences between the proof productions of students who generated their own examples and those who were provided examples. In fact, Iannone et al. (2011) found that the proof productions of the example reading group was slightly higher than the proof productions of the example generating group, although the difference was not significant.

The teaching and learning of mathematics. One of the primary goals of mathematics education is to develop and implement interventions that change mathematics teaching (Fukawa-Connelly, 2012a). At the undergraduate level, Speer, Smith, and Horvath (2010) criticized that "very little empirical research has yet described and analyzed the practices of teachers of mathematics" (p. 99), even though poor undergraduate mathematics teaching is often cited as a reason students change majors away from science, technology, engineering, and mathematics fields (Seymour & Hewitt, 1997). In fact, Mejia-Ramos and Inglis (2009) conducted a literature of 102 mathematics education research papers concerning undergraduate students' experience reading, writing and understanding proofs, yet none of these papers described the instruction the students received. Although some studies have investigated instruction in proof writing since the publication of these critiques (e.g. Fukawa-Connelly, 2012a, 2012b; Mills, 2014), there is still a need for additional studies in this area.

Instruction can influence the choices that students make and their preferences when solving problems, including proofs. Students need strategic knowledge in order to select appropriate strategies (Weber, 2001), but students typically do not learn these strategies without instruction (Lester, 1994). However, some instructors try to design their courses in order to explicitly teach students strategic knowledge (Weber, 2004, 2005).

Theoretical framework. This study draws on the emergent framework developed by Cobb and Yackel (1996), which links the social perspectives of classroom mathematical practices to the psychological perspectives of mathematical conceptions and activity. This theoretical perspective explains the design choice to look simultaneously at instructional practices and student responses to tasks.

In addition, this study draws on a theory of effective example use on proof-related task (Hanusch, 2015). This theory was developed by utilizing grounded theory, in the style of Glaser and Strauss (1967). When using examples effectively on proof-related tasks, an individual proceeds through four phases: deciding to use an example, establishing the intended purpose of the example, constructing the example, and finally drawing conclusions from the example (see Figure 1). In the first phase the individual decides to use an example, usually either because it was indicated by the task language or because the individual felt they lacked sufficient knowledge about a concept. In the second phase, the individual identifies their intended purpose for using the example, such as to gain improved understanding or to determine the truth of a statement. Then the individual moves into the third phase, constructing the example. Finally, in the fourth phase, the individual draws conclusions from their example, such as determining if they have fulfilled their purpose or if they need additional examples. This study focuses on the third phase of this framework, example construction, but the analysis of the constructions must consider the other phases of the process.

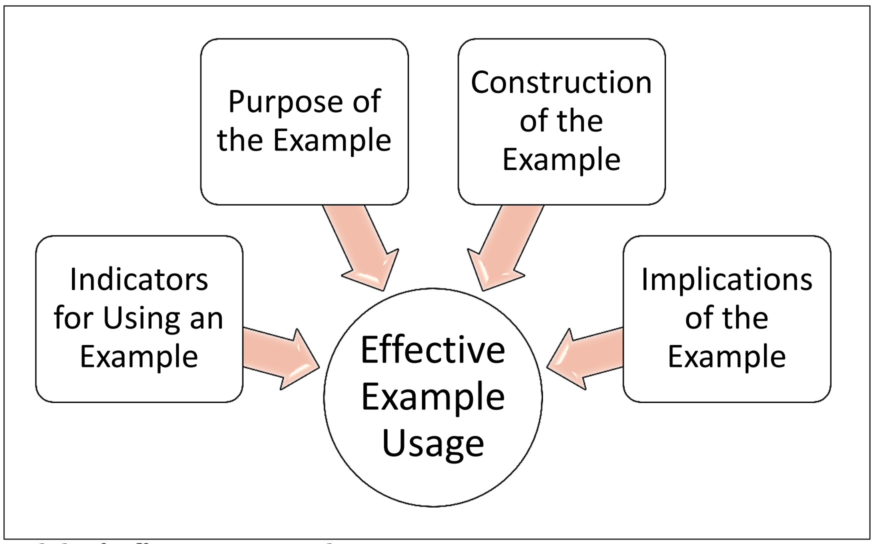

Figure 1. A model of effective example usage.

Method

This study is part of a larger study that focused on all example activity within a single section of a transition-to-proof course at a large university. The participants in this study are the instructor, Dr. S, and the 27 students enrolled in her course during the semester of the study.

Four students were selected for more detailed data collection during the fourth week of the semester using maximal variation sampling (Creswell, 2013). By varying the stu-

Table 1
The characteristics of the sampled students.

Name	Year	Major	GPA	Course Attempt
Amy	Sr.	Mathematics for Secondary Teaching	2.50-2.99	3rd
Carl	Soph.	Mathematics for Secondary Teaching	2.50-2.99	1st
Raul	Jr.	Applied Mathematics and Biochemistry	3.50-4.00	1st
Mike	Sr.	Mathematics and Spanish	3.00-3.49	2nd

dents' levels of academic success (indicated by a self-reported grade point average), mathematical preparation (indicated by self-reported grades in mathematics coursework), and specialization (pure, applied, secondary teaching), the findings have increased transferability (Merriam, 2009). The characteristics of the four students included in the sample are presented in Table 1. These students were purposefully selected because they frequently spoke during class, both by asking the professor questions and presenting their own work on the blackboards.

Data collection. Interviews were conducted with the four selected students, in order to observe each student's process on proof-related tasks while working independently. These interviews occurred three times during the semester: around the seventh week of the semester, the twelfth week of the semester, and the last week of the semester. Unfortunately, Mike was unavailable for the final interview, which explains why he used significantly fewer examples than the other participants.

Each interview with a student had three components: a semi-structured portion addressing proof strategies and goals for the course, a task-based portion where students attempted several proof-related tasks, and a reflection on the tasks. The semi-structured portion asked the students to talk about their impressions of the course, namely what they had learned and what they thought they should be learning. The tasks for the interviews were selected from the textbook, or other studies on undergraduate proof writing (Alcock & Weber, 2010; Dahlberg & Housman, 1997; Iannone et al., 2011). The mathematical content of the questions varied over the three interviews, corresponding to the recent content from the course. Additionally, the tasks asked for different types of products including, constructing examples, constructing counterexamples, making conjectures, validating proofs, and writing proofs. After a student completed all tasks, then the students were asked to reflect on their work. Sometimes the final reflection was omitted due to time constraints.

The classroom was observed daily to observe the examples used by the instructor during lectures and student presentations. The observations are supplemented by three interviews with the instructor during the semester, and a member checking interview the following year. These interviews focused on the motivation for the choices made during class and how those choices influenced the desired instructional goals.

Results

Construction of examples. When considering the construction of examples, two levels of analysis were needed: 1) the accuracy of the example, and 2) the construction technique used. The accuracy was determined by the author by checking that the hypotheses and conclusions were met by each construction, and the accuracy levels for each student can be found in Table 2.

Four categories were used to describe the construction technique: *blind trial and error*,

Table 2
This table summarizes the construction abilities of the students.

Construction	Amy	Carl	Raul	Mike	Total
Accurate Construction	30	16	18	4	68
Inaccurate	1	1	3	1	6
Incomplete	5	2	0	1	8
Authoritarian Source	3	2	2	0	7
Blind Trial and Error	2	1	7	3	13
Informed Trial and Error	14	17	4	1	33
Transformation	17	2	8	2	29

informed trial and error, *transformation* and *authoritarian*. An *authoritarian* example is retrieved from a source, instead of being constructed by the prover. The sources included the textbook, their notes, and the statement of the question. The terms *trial and error* and *transformation* came from the definitions of Antonini (2006). However, the students used two distinct version of the *trial and error* technique: *blind trial and error* where a student selected a potential example with no consideration for the hypotheses and then tests the hypotheses and conclusion, and *informed trial and error* where a student purposefully selected a potential example thinking about the hypotheses. Neither the students nor the professor discussed the *analysis* technique, so this category was not used. Table 2 indicates the frequency of each of these classifications by student.

Only six of the constructions were inaccurate. Four of these occurred during the first interview, when Raul and Mike appeared to misunderstand which conditions must hold for a construction to be an example or a counterexample. During the first interview, Raul wrote the constructions found in Figure 2, while attempting to prove if $a|(b-c)$ and $a|(c-d)$, then $a|(b-d)$. The construction that Raul labeled as a counterexample does not satisfy the hypotheses or the conclusion of the statement, which means it is not a counterexample. The remaining two inaccurate examples were due to the students making errors when verifying the hypotheses.

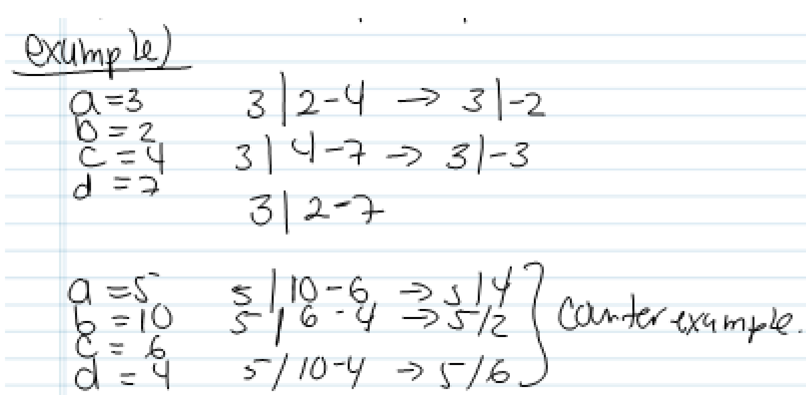

Figure 2. The constructions generated by Raul for if $a|(b-c)$ and $a|(c-d)$, then $a|(b-d)$.

Some of the accurate constructions were not useful for fulfilling the intended purpose. For instance, Mike was seeking a potential counterexample on a divisibility problem and chose $a = 1$ as the value for the divisor, stating that he chose this value because "1 divides

Table 3
The construction techniques used by the students during the interviews

Interview	1	2	3
Authoritarian Source	0	5	2
Blind Trial and Error	9	0	4
Informed Trial and Error	14	6	13
Transformation	1	5	22

everything." Mike did not realize that this choice for a meant that every possible construction would be an example of the statement. Although other students constructed examples that were not useful for their purpose, this was the only instance in which a student stated a fact that would directly indicate the lack of usefulness.

The students transitioned to more advanced construction techniques later in the semester, see Table 3. During the first interview, Mike was the only student to utilize the *transformation* construction technique, and he only did so once. By the final interview, the students were using the *transformation* technique more frequently than *trial and error*. For instance, when constructing an example of a fine function, Amy, Raul and Carl all began by modifying the graph of $\sin x$ so its zeros coincided with the integers satisfying the definition of a fine function. Raul made two additional transformations of the sine function to construct examples of fine functions, see Figure 3.

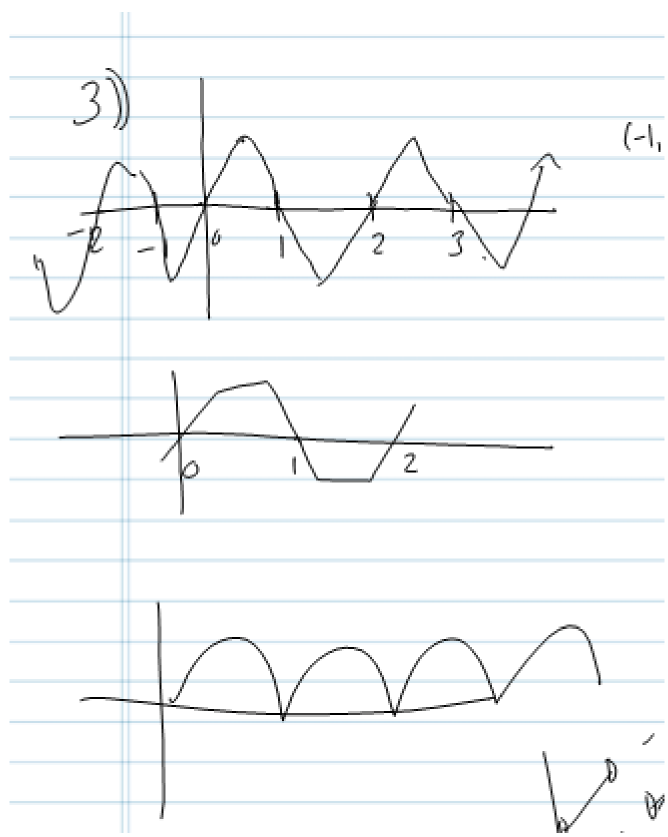

Figure 3. The graphs of fine functions constructed by Raul using the transformation technique.

The instruction. Dr. S rarely modeled example construction during the lecture. Although she presented many examples throughout the semester, she seldom talked about how these examples were constructed. Dr. S did model how to determine which properties an example or counterexample of a statement needs to satisfy, and how to go about verifying that a construction satisfies those properties. When asked what construction techniques she expected from her students Dr. S stated that "It depends on the problem, but to some extent trial and error is the first step." Dr. S continued by saying some students are "not always ready yet" for more sophisticated reasoning, and "I'm okay with them randomly trying at first." To provide students opportunities to practice example construction, Dr. S assigned homework that the student's were to write on the board prior to class. Dr. S began class everyday by reviewing and correcting this student work. Furthermore, Dr. S frequently reminded the students to "make mistakes on [their] homework, and we'll talk about them." She suspected that the students would often fail before they succeeded at example construction, and that the best way to help the students improve would be to review their constructions.

There were two episodes from the lecture where Dr. S emphasized example construction. The first instance occurred shortly after formally defining functions. Dr. S emphasized the importance of a function being well-defined, particularly when the domain is a partition. To do this, Dr. S presented three potential functions:

$$\begin{array}{ll} f:\mathbb{Z}_3\to\mathbb{Z}_6 & f\left([x]_3\right)=[3x+2]_6 \\ g:\mathbb{Z}_4\to\mathbb{Z}_2 & g\left([x]_4\right)=[3x]_2 \\ h:\mathbb{Q}\to\mathbb{Z} & h\left(\frac{a}{b}\right)=a+b \end{array}$$

The first example was generated using numbers suggested by the students, the last two were purposely chosen by Dr. S. Dr. S proved that f and h are not well-defined by producing counterexamples that show that two different representatives of the equivalence classes produce different outputs. For g, Dr. S provided the students with a proof that it was well-defined. Ultimately this episode demonstrated the meaning of a well-defined function, but also included instruction in constructing examples.

Dr. S intended that the students would move towards the *transformation* construction strategy by asking themselves questions such as "is the statement similar to one [I] know?" and then using that response to construct their example. During the an interview, Dr. S reiterated this by saying "I would like to move them toward more directed examples where they are intentionally trying to go certain places but I doubt that most of them are ready for that. Right now I'm happy if they try random examples to see what's going on, as long as they don't stop there." Perseverance was a frequent theme when discussing proof and example constructions in the lecture.

When the students wrote incorrect example constructions on the board, Dr. S would usually ask the student who presented (or sometimes the whole class) to help her revise the construction. In one instance, Carl presented a relation on $A = 1, 2, 3$ that should have the properties of symmetry and transitivity, but not reflexivity. Carl presented the relation $\{(1, 2)(2, 1)(1, 3)(2, 3)(3, 2)(3, 1)\}$, but this example is not transitive. Dr. S argued that if $(1, 2)$ and $(2, 1)$ are in the relation, then transitivity requires that $(1, 1)$ and $(2, 2)$ must also be included. As such, Dr. S changed the relation to $\{(1, 2), (2, 1), (1, 1), (2, 2)\}$, which is symmetric and transitive, but not reflexive because it is missing $(3,3)$. Through this discussion, Dr. S walked the students through using the *transformation* technique for example construction, since she transformed an existing example to satisfy the given criteria.

Comparing the instruction and the students. The students used the *trial and error* construction technique for all of the examples constructed during the first interview, with one exception. However, as the semester progressed the students used the *transformation* technique with increasing frequency, as seen in Table 3. Dr. S predicted this behavior of the students. In the first interview, Dr. S said

> It depends on the problem, but to some extent, *trial and error* is the very first step. You just try stuff. I've seen this even with advanced REU students, where there is a good strategy. They're not always ready yet. I'm okay with them randomly trying at first. Now, I want them to move toward more careful construction. As they go through this, they should be looking for things that are similar and using that to give them a hint.

Dr. S recognized that as beginning students, they would not have the mathematical experience to use the more advanced *informed trial and error*, *transformation* and *analysis* techniques, but she hoped they would grow to that point. The *analysis* technique was not demonstrated by the instructor or used by the students; however, during the member checking interview, Dr. S argued that the *analysis* technique was too advanced to be useful to the students at their current level of understanding.

During the first interview, Dr. S stated that although she expects the students to have some familiarity with using examples from their calculus classes, "they just never had to construct [examples] themselves before." As such, she expected some of the difficulties the students had with example construction.

Dr. S did not explicitly vocalize an expectation of the accuracy problems exhibited by some the students during the initial interviews. Both Raul and Mike had created examples that violated the statement hypotheses. Raul did not seem to realize that failing the hypotheses was a problem. During the member checking interview, Dr. S said students often make these types of construction errors at this point in their development. She furthered this by explaining that many students present counterexamples that are not actually counterexamples, especially on the first test of the course.

Dr. S usually did not talk about the construction technique when she presented examples to the class, focusing instead of how to verify the accuracy. Additionally, she designed the course so that most of the example construction tasks were assigned as student presentations, and that she would talk about example construction as she reviewed and corrected the examples in the presentations. However, the students tended to present problems asking for proofs rather than the problems asking for examples. Consequently, Dr. S did not have the opportunity to talk about construction techniques with the expected frequency.

Overall, Dr. S had the experience to know the capabilities of the students with respect to example construction. She recognized that *trial and error* would be the primary technique at the beginning of the semester, and that some of the students would not be able to move beyond that technique in this course. However, towards the end of the semester, she introduced the *transformation* construction technique for the benefit of the students who were ready for more advanced techniques. The students in the sample were able to apply the *transformation* technique in some circumstances, and likely will be able to utilize it more frequently in their subsequent courses.

Discussion

By the end of the semester, all of the students selected examples with more thought, and used the *transformation* construction technique with increased frequency. It is unclear exactly what caused this growth. Possible explanations include the students' individual development throughout the semester, the influence from the instruction, and the new content.

The mathematical content of the task-based interviews corresponded to the content of the course, which varied throughout the semester. Specifically, the first interview consisted entirely of number theory tasks, the second interview consisted for set theory and equivalence relation questions, and the final interview concerned real-valued functions. The students appeared to have a large sample space for real-valued functions to utilize for example constructions. This means one reason the students were able to use the *transformation* technique more frequently is because they had examples of real-valued functions to use as the starting point for the transformation process.

In particular, when asked to construct an example of a fine function on question 3 of interview 3, the first example constructed by each student was a transformation of $y = \sin x$. The students recognized that the pattern of the zeros in $y = \sin x$ could be adjusted to satisfy the conditions of a fine function. It is unlikely that the students could have constructed an example of a fine function via *trial and error* because of how difficult it would be to verify the conditions. However, it is equally difficult to imagine a students utilizing a *transformation* technique on $a|(bc)$ implied $a|b$ or $a|c$, especially for an initial example of the statement. Most students will not have a sufficient background in the formal language of divisibility to have such examples in their personal example space.

Previous research on undergraduate example construction showed that the students used *trial and error* techniques approximately 80% of the time (Iannone et al., 2011). This percentage is considerably higher than than the 57% *trial and error* observed in this study. It is unclear what accounts for this discrepancy, although the one cause may be the task selection. Additionally, both studies had small samples, this one had four participants and Iannone et al. (2011) had nine, so the individual characteristics of the participants strongly affected the percentages.

Implications for teaching transition-to-proof courses. One implication is that students should be explicitly taught strategies for constructing and verifying examples. One of the hardest parts of trial and error for the students was picking a construction to test. However by explaining how the examples in the course are constructed, it may be possible to guide the students beyond blinding picking parameters to test.

In this study, most of the students became convinced that a *prove or disprove* statement was true after constructing only one or two examples. However, when mathematicians obtain conviction from empirical evidence it is often from multiple examples or for unusual properties (Weber, 2013; Weber, Inglis, & Mejia-Ramos, 2014). Although it is unreasonable to assume that numerous examples should be constructed before trying to prove a statement, we need to teach students to consider the quality of the examples they construct and to view the examples as a collection. For example, a statement that is true for a prime number, a perfect square, and another composite number is far more believable than a statement evaluated only with a prime number. But students need to be taught to consider examples collectively rather than only individually.

Future research. Additional research needs to be completed on the instruction of example construction. How does instruction impact a provers ability to effectively use and construct examples? It is unclear whether or not such instruction will actually help the students learn how to construct examples effectively. Some studies suggest that instruction in problem solving frameworks alone does not help students become better problem solvers (Garofalo & Lester, 1985; Schoenfeld, 1980), so it is possible a similar phenomenon will occur here. This can only be established through additional study.

Finally, it is unclear whether effective example construction will positively impact proof writing. Iannone et al. (2011) found that generating examples provided no benefits to the students as compared to receiving a list of examples. One interpretation of this is that it does not matter where the examples come from, what matters is how the examples are used and what conclusions are drawn from the examples. As such, it is possible that knowledge in using examples effectively can improve a persons ability to successfully write proofs, but additional study is needed on this topic.

An initial look at students' conveyed meanings for probability

Neil J. Hatfield
Arizona State University

Probability is the central component that allows statistics to be a useful tool for many fields. Thus, the meanings that students develop for probability have the potential for lasting impacts. This report extends Thompson's (2015) theory of meanings through the notion of conveyed meaning: the constrained implications that a receiver attributes to the sender's statements. A student's conveyed meanings give insight into his/her initial and/or dominate meanings for a particular idea. This report shares the results of examining 114 undergraduate students' conveyed meanings for probability after they received instruction as well as their instructors' conveyed meanings. The worrisome presence of circular conveyed meanings carries implications for the teaching of probability.

Key words: probability, statistics, meanings, introductory statistics course

Probability is the engine that makes inferential statistics run. In particular, probability is the result of centuries of work towards one goal: the quantification of uncertainty. Since before the 1600s mathematicians, philosophers, logicians, and statisticians have attempted to resolve questions where uncertain outcomes dominate (Weisberg, 2014). Over the course of history, many scholars have engaged in what Thompson (2011) calls quantitative reasoning and quantification. In settling what a measure of uncertainty means (along with how to get a measure and what is meant by measuring uncertainty), scholars have taken different paths and arrived at their own meanings for the same notion, probability. Laplace considered the ratio of the number of outcomes of interest to the number of all possible outcomes under the assumption of "equally likely" outcomes (Weisberg, 2014). Von Mises (1981) considered repeating some process indefinitely to build a collective and that the limit of the relative frequency of an event of interest was the probability of that event. Kolmogorov's (2013) axiomatic, measure-theoretic approach has become the gold standard for probability theory. De Finetti (1974) and Savage (1972) regarded probability as dealing with measuring the amount of belief that an individual had for a particular outcome's occurrence that they called "subjective" or "personalistic" probability.

The opening statement of this paper is one that hardly any practitioner of statistics will disagree with. Regardless of which school of probability you ask (i.e., Frequentist, Bayesian, Conditional Frequentist, etc.) each acknowledges that the central ideas of probability allow us to move beyond merely describing a data set to using the data set as evidence for supporting or refuting claims. The members of these schools of thought have already carried out the quantification of uncertainty, something that students have yet to undertake. How practitioners think is often vastly different from how students think before, during, and after instruction. Kahneman and Tversky (1974, 1982) described how individuals will use different heuristics when making judgments under uncertainty. For example, how representative an event (sample) is to the parent process (population) to can influence a person's estimate of the probability of the event. Another heuristic that they found people use to measure uncertainty centers on the ease (or lack of) with which a person can imagine the event occurring; the more "available" an event is for the person to imagine, the larger the probability (the less uncertainty) there is for that event. Konold (1989) found that for some individuals, their way of thinking about probability did not match the use of heuristics nor was their thinking consistent with the schools of probability. Rather, these individuals appeared to view the goal of uncertainty to be the prediction of the next result; Konold referred to this way of thinking as the outcome approach to probability. Students also have a tendency to view events as equally probable when they do not perceive the many ways a compound event might occur (Lecoutre, Durand, & Cordier, 1990). Lecoutre et al. found that students and adults view the event of getting a five and a six as having the same probability as getting two sixes when rolling two dice. They hypothesized that not recognizing that event of (5, 6) is comprised of two smaller events. This way of thinking across multiple events is what they referred to as the equiprobability bias. Fielding-Wells (2014) found that when trying to pick the best card for playing addition-bingo, Year 3 students (7-8 years) operated as though all of the sums of the numbers 1 to 10 were equally probable. Saldanha and Liu (2014) reviewed much of the literature on students' understandings of probability and proposed that a key conceptual scheme for understanding the measurement of uncertainty is a stochastic conception. They define a stochastic conception as "a conception of probability that is built on the concepts of random process and distribution" (p. 393). They argue that in the quest to support students developing coherent probabilistic reasoning, instructors need to conceive of probability as ways of thinking rather than skills and design curriculum that supports this. While this review of the literature is brief, already apparent is the fact that the quantification of uncertainty is challenging. Individuals of all ages and backgrounds struggle just as mathematicians, statisticians have to construct a meaning for probability.

In a discussion with a university instructor about introductory statistics courses, I was surprised to hear this individual say "I skip by probability because my students don't really need it and we need the time to talk about doing hypothesis tests." This statement caught me off-guard for two reasons: 1) this instructor had a Ph. D. in Statistics, and 2) the instructor continued to talk about how she wanted her students to develop "rich and productive meanings for hypothesis tests and *p*-values". While I believe that students *can* and *will* develop meanings for hypothesis tests in the absence of a way of thinking about probability, I challenge the claim that students can develop "rich and productive" meanings. The sentiment that the instructor expressed about skipping probability is reminiscent of a position that Cobb and Moore (1997) took; "first courses in statistics should contain essentially no formal probability theory" (p. 820). Since they originally took this stance, the American Statistical Association through their Guidelines for Assessment and Instruction in Statistics Education (GAISE) have endorsed the notion of reducing probabilities role in introductory statistics classes (Aliaga et al., 2005). However, there is a critical distinction between Cobb and Moore's position and the aforementioned instructor's: Cobb and Moore's position (echoed in GAISE) is *not* that first courses should avoid discussing probability, bur rather there should be little to no emphasis on *formal rules of calculating* probabilities (e.g., what to for all types of cases for $P[A \cup B]$ or $P[A \cap B]$). They believe that discussing probability is still important for statistical inference. Liu and Thompson (2002) make an excellent argument that trying to debate the question of "What *is* probability?" is a fruitless endeavor in a first course. Rather, in a first course on statistics and probability, our focus should be on what we (us and our students) *mean* by the term "probability".

Students do not learn and instructors do not teach in a vacuum with only each other's company. Course materials such as textbooks play a role in student learning. A quick perusal of four introductory statistics texts indicates that these texts cover probability in the exact way that Cobb and Moore urged against; i.e., each focus almost entirely on how to calculate rather than how to think about (what do we mean by) probability. The introductory text *Statistics for the Life Sciences,* 4th edition (Samuels, Witmer, & Schaffner, 2012) devotes 15 pages to probability. However, there are only two sentences related to how to think about probability. Out of the 29 exercises provided for the students to use for homework, 26 ask for students to calculate a value of the probability of some event, 3 ask students to make a claim about whether or not two events are independent, and no questions ask students to interpret/make use of a way of thinking about probability. Likewise, *Introduction to the Practice of Statistics*, 7th edition (Moore, McCabe, & Craig, 2012) devotes 18 pages to probability and randomness. Of these pages, only 3 sentences (all variations of each other) focus on how to think about probability. There are only two questions of the 45 that focus on something other than a calculation of probabilities or judgment of independence; one asks whether or not a probability value is applicable to a larger set of colleges, and the other asks students to explain what a probability value means. In both of these cases, students' major takeaway is that probability is a calculation. In addition to these two traditional textbooks, I examined two open source texts; *Introductory Statistics* (Illowsky, Dean, & OpenStax College, 2013) and *OpenIntro Statistics*, 3rd edition (Diez, Barr, & Çetinkaya-Rundel, 2016). There are 51 pages devoted to the topic of probability in *Introductory Statistics*, while the *OpenIntro* gives 40 pages to the "special topic" of probability. There is only one sentence in each that focuses on how to think about probability. For the 128 homework questions in *Introductory Statistics*, only three ask for something other than a calculation of a probability value. Those three questions ask students to state what an expression such as $P[A \text{ OR } B]$ means in words. None of *OpenIntro*'s 44 questions ask students to interpret a probability value. I chose these four texts for different reasons. The Samuels text was the textbook used by the students I studied; the Moore text is one of the most popular introductory texts at the undergraduate level. We are seeing a surge in number of open access textbooks across all disciplines and I've had statistics educators recommend checking out both of the texts I did examine. My intent was not to conduct a full-scale text analysis, but rather just to get a sense of how textbooks treatment probability. Worth pointing out is that all four of these texts have publishing dates after the Cobb and Moore article and after the release/adoption of GAISE.

Given the recommendations in GAISE, what I found in the textbooks I examined, and the extant literature on people's understanding of probability, I began to question what meanings students could possibly have for probability *after* instruction. In particular, I wanted to answer the questions:

- What meanings do students convey for probability after they received instruction?
- Are there differences in the students' conveyed meanings based on which instructor they had?

Theoretical Background

To investigate my questions, I turned to the theory of meanings that Thompson and Harel have devised (see, Thompson, 2015; Thompson, Carlson, Byerley, & Hatfield, 2014). *Meaning* refers to the space of implications which includes actions, images, and other meanings that results from an individual assimilating some experience and thereby forming some understanding of that experience (Thompson, 2015). The space of implications, that is the meaning, is the inference that accompanies assimilation (Jonckheere, Mandelbrot, & Piaget, 1958). Central to the radical constructivist perspective is the belief that every individual builds his/her own knowledge through repeated experiences (von Glasersfeld, 1995). The meaning that an individual imbues an experience with is a product of their constructions. Thus, an individual's meanings are intensely personal and researchers do not have access to that individual's meanings. This problem is a familiar one to mathematics education researchers. Thompson (2013) tackled a similar question; if meanings are entirely within individuals, then how can people learn a meaning from someone else? Thompson's found an answer by turning to the notion of intersubjectivity and Pask's conversation theory. Intersubjectivity hinges on an individual having a mental image of another person that is free to think like and not like individual (von Glasersfeld, 1995). From Pask's theory, Thompson (2013) highlights that a conversation is more than just a verbal exchanges; conversation also includes all of the participants' "attempts to convey and discern meaning" (p. 63). He uses the following figure to highlight the blending of intersubjectivity and conversation theory:

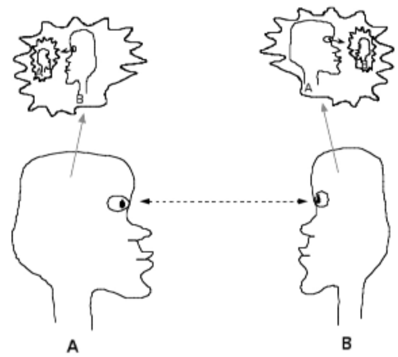

Figure 1. A "meaningful" conversation (Thompson, 2013, p. 64).

As 'A' and 'B' talk to each other, they must each keep in mind not only what they wish to communicate but also how the other person might interpret his/her words/actions. Both 'A' and 'B' build a model of the other person. Thompson's work provides an answer for how the conveyance of meaning from one individual to another might occur. Suppose that 'A' wants to communicate something specific to 'B'. When 'B' assimilates the experience to his schemes, he imbues that experience with a meaning that stems from two sources. The first source is his own meanings; the second is what he knows about 'A'. The meaning that 'B' gives to 'A's is what I refer to as the *conveyed meaning.* A conveyed meaning is the set of implications that a receiver attributes to the sender's message constrained by 1) the receiver's de-centering and 2) the receiver's belief that the sender made an honest effort to convey his/her thinking. These constraints lay the groundwork for intersubjectivity and keep both participants in the picture. While 'A's conveyed meaning might not be a perfect reflection of 'A's actual meaning, this is how 'B' understood 'A' and is the basis for which 'B' to now respond. The notion of conveyed meaning is useful in education in several ways. First, we can use this notion in research to attempt to discern what meanings our students have constructed for various topics. Second, we can use this notion in the planning of lessons. By trying to answer the question of "what have I conveyed to my students?" we can engage in de-centering and design meaningful conversations. This second use is easily extended to a third focused on the generation of curriculum materials such as activities and textbooks. With textbooks, we can imagine to types of conveyed meaning; the first being what the authors conveyed to us and the second being what the authors conveyed to our students.

By examining students' responses, we can characterize those responses by the meaning conveyed. However, to compare categories of conveyed meanings there must be an aspect of the theory that deals with productiveness of the meanings. Thompson (2015) proposes that productive meanings are those meanings that provide coherence to ideas that students have and those meanings which afford students a frame that supports the students in future learning (Thompson, 2015). *Productive meanings* are clear, widely applicable (within reason), and entail an awareness of and need to explicate any assumptions. Notice that the usefulness of a meaning is part of a productive meaning. I take a *useful meaning* to be any meaning that allows a student to meet some performance or learning goal. Consider the following meanings for the associative property: A) move parentheses around vs. B) the choice of which of two structures to impose ($[a+b]+c$ or $a+[b+c]$) does not change the result. Meaning A is useful; students can get correct answers, however, this meaning does not necessarily help students when there are more than three terms. However, meaning B is a productive meaning and useful.

Methodology

To answer my research questions I conducted an observational study at a large, public university located in the Southwestern region of the United States during the Spring 2014 semester. Students enrolled in an introductory statistics course aimed at life science majors took a written survey during a regular class period after they had received instruction about probability. I was only able to secure a five-minute window from the course instructors, so the survey consisted of two questions related to their meanings for probability. The course had four sections, taught by three instructors. Instructor A was a Ph.D. Math Education student who had not previously taught the course, Instructor B was a Senior Lecture (MS-Statistics) who had taught the course many times and served as the course coordinator, and Instructor C was as Ph.D. Statistics student who had taught the course the previous semester. Instructors B and C (B had two sections) followed the textbook (the aforementioned *Statistics for the Life Sciences* (Samuels et al., 2012)) closely. Instructor C made use of many of B's materials. Instructor A departed from the textbook, and instead focused on designing a course that sought to foster students' construction of productive meanings. Each of these instructors also responded to the written survey. The two questions students and instructors responded two were:

Question 1: How do you think about probability? That is, how would you explain probability to another person?

Question 2: Consider the following statement:

The probability of observing a value of 4 when looking at the product of two dice is 3/36.
How should someone think about (interpret) 3/36 given the above statement?

To analyze the responses I used a grounded method consistent with that described by Strauss and Corbin (1990). I initially used open coding for the responses and then I made use of an axial coding system. I used the axial codes in my analysis that follows. This approach partnered with the theoretical perspective is also consistent with the general methodology used in the development the Mathematical Meanings for Teaching Secondary Mathematics instrument described in Thompson (2015).

Results

I used the ten axial codes as shown in Table 1, five for each survey question along with the ordering of the meanings in terms of productivity. The categories of long-run relative frequency and percent of the time both point to the same underlying meaning: if you were to repeat some process an unlimited number of times, the probability of an event is the percentage of the time (i.e., the unlimited trials) or long-run relative frequency of that event. This meaning is the most productive out of the set presented. This meaning is applicable to a wide range of situations (discrete or continuous) and makes relatively few assumptions that are included in the statement (repeating a process indefinitely).

The categories of Frequency and Classical are similar and are the next two most productive meanings. The conveyed meanings in the frequency category appear to reflect a blending of Frequentist language and Classical notions. Classical conveyed meanings are consistent with Laplacian (set-theory based) notions of probability. This notion depends on the assumption of "equally likely" but none of the responses included this assumption.
The third category for Question 1 covers those students' responses that dealt with prediction. The responses that fall into this category are reminiscent of the outcome-approach of probabilistic thinking (Konold, 1989). Often these students only spoke about the very next time you carry out some process. This focus makes the meaning less productive than the proceeding ones. While the conveyed meaning in for the category "Fixed Number of Rolls" is similar to those in the "Classical" category in viewing 3/36 as two numbers; these

meanings convey a sense that we must repeat a process a fixed number of times and we will always see exactly the same number of the events of interest. For example, if we were to roll the dice 36 times, we would then see exactly 3 products of 4 ("fixed number of rolls"). This conveyed meaning points to a meaning that runs counter to all of the schools of thought about probability.

Table 1. Axial Codes for Conveyed Meanings from Survey Responses.

Q1: How do you think about probability?	**More Productive**	**Q2: Interpreting 3/36**
Long-run Relative Frequency (L.R.R.F): The student conveyed that the value emerges from carrying out some process a large number of times; the value is the relative frequency of how many times you see an event with respect to the number of trials.		**Percent of the Time:** the student conveyed that 3/36 was a single number that was the percent (fraction) of the time that you would see a product of four if you were to roll two dice "many, many times".
Frequency: The student conveyed that the value was the absolute or relative frequency of seeing an event but did not convey the existence of a repeating process.		**Classical:** the student conveyed that 3/36 was two numbers; the "first" ("upper") number tells you how many ways to get a four there are and the "second" ("lower") number tells you the number of ways you can roll two dice.
Prediction: The student conveyed that the value referred to the next trial (outcome approach) or the student conveyed that the value was a long-run prediction of something unspecified.		**Fixed Number of Rolls**: the student conveyed that 3/36 was two numbers; the 3 told you how many times you would see a product of 4 when you rolled two dice exactly 36 times (the second number).
Circular: The student conveyed that probability was just "chance" or "likelihood" of something happening.		**Chance:** the student conveyed that 3/36 was your "chance" of getting a product of four.
Other: The student's conveyed meaning did not fit any other category.		**Other:** The student's conveyed meaning did not fit any other category.
	Less Productive	

The fourth category of conveyed meanings for Question 1 is what I call "Circular". Typical responses that fall into this category are "Probability is the chance that something happens", or "the likelihood of some event". In trying to understand such student statements, I spoke with students who were willing to speak to me from the course as well as other students from the mathematics-tutoring center. During these discussions, the students who spoke of probability as being "chance" or the "likelihood" of some event, would often answer the follow up question of "What is chance/likelihood?" with the statements along the lines of "well, chance is, umm, just probability." Several times these students would also introduce the third term or even a fourth ("odds"). If I asked the student to explain probability but banned the usage of the terms "chance", "likelihood", and "odds", the students struggled to say anything. The way that these students thought about probability appeared to be a near unending cycle of labels with little meaning behind those labels. The seemingly only way these students broke out of this cycle was when they had to deal with a concrete situation and a specific value for them to speak about. However, this is did not always work. The conveyed meaning of Chance for Question 2 is a case in point. Responses here conveyed that 3/36 was merely the “chance” that you see a product of four with no further explanation. This circular conveyed meaning is the least productive meaning (other than the Other category). This meaning does not lay any groundwork for future learning and lends no coherence to the idea of probability. The final category of conveyed meanings for both questions is the “Other” category that captures any conveyed meaning not captured by the other categories.

What meanings do students convey for probability after they received instruction?

The following bar chart (Figure 2) shows the frequency of responses that fall into these categories for Question 1. Overwhelmingly, 89 students (78.1%) gave a response conveyed a circular meaning. Nineteen students (16%) appear to think about probability in terms of frequency/relative frequency. Of these students, 15 think about probability as the long-run relative frequency of some process.

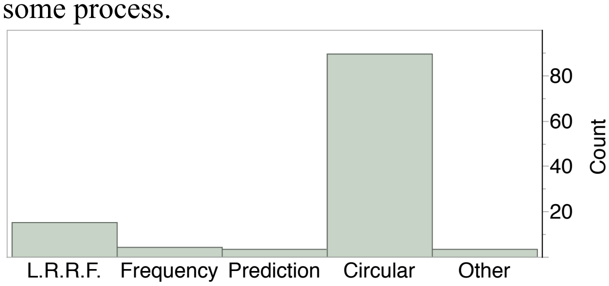

Figure 2. Students' conveyed meanings for Question 1.

As shown in the Figure 3, a majority of students interpreted the probability value (Question 2) as being about a fixed number of rolls of the dice and a fixed number of 4’s (40.5%). Only 17.1% (19) of the students thought about 3/36 as representing the percent of the time we would see a product of 4. Fifteen students appeared to use a “classical” way of thinking, while 19 just substituted “chance” for “probability”.

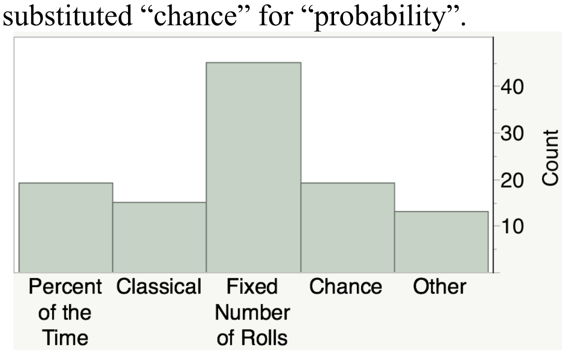

Figure 3. Students' conveyed meanings for Question 2.

A natural question that follows from the previous two questions, is how do the students’ responses to each question relate to one another? Table 2 shows the two-way contingency table for students’ responses to both questions. The vast majority of individuals who appeared conveyed that probability is the long-run relative frequency of some event also conveyed that a given probability value as the percent of the time we would see some event happen in the long run. The majority of students who conveyed that 3/36 as being two numbers separated by a bar (either Classical or Fixed Number) or as a “measure of chance”, also conveyed a circular meaning for probability. The wide range of interpretations given by students with a circular meaning is not surprising. Given that the students’ meaning for probability appears related to a word-exchange, the students would need to draw upon some other meanings to help make sense of the value 3/36. All but one student, who explained 3/36 as the "chance" of getting a product of 4, gave responses that indicated a circular meaning to Question 1.

Table 2. Students' responses to Question 1 by their responses to Question 2.

	Percent of the Time	Classical	Fixed Number of Rolls	Chance	Other	total
L.R.R.F.	12	1	0	1	0	14
Frequency	1	0	1	0	2	4
Prediction	2	1	0	0	0	3
Circular	4	12	42	18	10	87
Other	0	0	1	0	2	3
total	19	14	44	19	18	111

I will quickly mention that three students did not answer Question 2, thus the reduction in the grand total to 111. Taking these results together, we can see most students conveyed meanings that are less productive than what they could have. The overwhelming percentage of students who initial conveyed a circular meaning for probability for Question 1 is worrisome. The prevalence of such conveyed meanings and whether or not this conveyed meaning is truly indicative of the students' actual meanings require further research.

Are there differences in the students' conveyed meanings based on which instructor they had?

To explore this question, I used the ordering imposed on the conveyed meanings by the notion of productive meanings, to establish a multivariate ranking of the students across both questions (Wittkowski, 2004; Wittkowski, Song, Anderson, & Daniels, 2008). This non-parametric approach makes use of my theoretical perspective without adding any assumptions about the data that would be unreasonable (e.g., data are normally distributed). The Kruskal-Wallis test is an appropriate method to see if the there are differences between students' conveyed meanings by instructor. The test statistic has a value of 50.7783; thus, under a χ_2^2 distribution, the approximate probability of observing a value at least as extreme was we did is $p < 0.0001$. A post-hoc analysis using the Steel-Dwass method shows that Instructor A's students' conveyed meanings tend to be more productive than Instructor B's students' ($p < 0.0001$; large effect size of 0.6255) as well as more productive than Instructor C's students' ($p < 0.0001$; large effect size 0.5458). The conveyed meanings from Instructor B's students do not appear to be statistically different from Instructor C's students' in terms of productivity ($p = 0.9268$). To examine the site of the difference at the multivariate level, I also examined each question.

Table 3 provides a good visualization of how students described probability in Question 1. A striking aspect to notice is that all of the students who conveyed that probability is the long-run relative frequency all have Instructor A. Additionally, the vast majority of students for both Instructor B and Instructor C gave responses that conveyed a circular meaning for probability in general.

Table 3. Students' Responses to Question 1 by Students' Instructor

	L.R.R.F.	Frequency	Prediction	Circular	Other	total
Instructor A	15	2	2	8	0	27
Instructor B	0	2	1	58	1	62
Instructor C	0	0	0	23	2	25
total	15	4	3	84	8	114

To further explore this difference, I conducted a Kruskal-Wallis test with α = 0.05. The test statistic has a value of 58.0382. Thus under a χ_2^2 distribution, the approximate probability of observing a difference at least as extreme as we did is $p < 0.0001$. The post-hoc analysis using the Steel-Dwass method shows that Instructor A's students' responses are significantly different from the responses of Instructor B's students ($p < 0.0001$; large effect size of 0.6255) and significantly different from Instructor C's students ($p < 0.0001$; large effect size of 0.4807). However, the responses from Instructor B's and Instructor C's are not significantly different from each other ($p = 0.1752$).

Much like the prior question, a two-way contingency table provides insight into answering the question about the difference in how students interpret a given probability value in relation to the students' instructor. Notice in Table 4 that the vast majority of students conveyed that 3/36 as a percent of time have Instructor A and two-thirds of Instructor A's students gave this type of interpretation. None of Instructor C's students and only 1 of Instructor B's students gave a response that fell into this category. Given that the majority of Instructor B's and Instructor C's students conveyed a circular meaning for probability (see Table 3), the spread of their students' interpretations is not surprising.

Table 4. Students' Responses to Question 2 by Students' Instructor

	Percent of the Time	Classical	Fixed Number of Rolls	Chance	Other	total
Instructor A	18	3	3	1	1	26
Instructor B	1	10	27	12	11	61
Instructor C	0	2	15	6	1	24
total	19	15	45	19	13	111

I conducted another Kruskal-Wallis test (with α = 0.05) to test the difference between the students' responses in relation to instructor. The test statistic has a value of 32.2145. Under a χ_2^2 distribution, the approximate probability that we observe the differences we did or one greater is $p < 0.0001$. Post-hoc analysis using the Steel-Dwass method indicates that Instructor A's students' responses are significantly different from those of Instructor B's students ($p < 0.0001$; large effect size of 0.4995) and Instructor C's students ($p < 0.0001$; large effect size of 0.4262). The responses of Instructor B's students are not significantly different from Instructor C's students ($p = 0.9801$).

Thus, we can say that there does appear to be statistically significant difference between the students' conveyed meanings based upon which instructor they had. This difference exists at all levels of analysis and with consistently large effect sizes. One possible reason for this difference could be the meanings that the instructors conveyed during the course for probability. Table 5 shows how each instructor's responses to the same two questions the students answered fell under my axial coding system for conveyed meaning.

Table 5. Instructors' Conveyed Meanings for Questions 1 and 2.

	Response to Question 1 (probability in general)	Response to Question 2 (interpret 3/36)
Instructor A	L.R.R.F. (55.6%)	Percent of the Time (69.23%)
Instructor B	Circular (93.5%)	Classical (16.4%)
Instructor C	Circular (92%)	Classical (8.33%)

For Question 1, a majority of each instructor's students conveyed a meaning of the same category. However, for Question 2, this does not hold true for Instructors B and C. In both cases, the conveyed meaning that the majority of the students conveyed was the Fixed Number of Rolls (Instructor B: 44.3%; Instructor C: 62.5%). If the meanings conveyed by the instructors on the survey are consistent and representative of their conveyed meanings during instruction, then this data suggests that instructors' conveyed meanings serve as a limiting factor for students' construction of meaning.

Discussion

The vast majority (78.1%) of students conveyed a circular meaning for probability, with roughly 13% (of 114) conveyed probability as being about the long-run relative frequency of some event (given a stochastic process). Similarly, a majority of students (40.5%) conveyed that a probability value, 3/36, was about a fixed number of rolls (of dice) and observing exactly 3 outcomes that were the event of interest. There are differences in the conveyed meanings of each instructor's students. In the case of Instructor A, the most common conveyed meaning for probability (both in general and for interpreting) students gave is consistent with thinking about probability as the long-run relative frequency of an outcome of some repeatable process. For Instructor B's and Instructor C's students, the dominant conveyed meaning for probability focused on a circular word-exchange and a fixed number of trials. While further investigation into each teacher's actual meanings for probability as well as what meanings they convey during instruction is necessary, there is evidence to support the idea that a teacher's mathematical meanings serve as one of the key components of how that teacher teaches (Thompson, 2013).

Circular conveyed meanings

One finding of this study is that a vast majority (78.1%) of the students described probability in way that which I classified as conveying a circular meaning. As I mentioned previously, the origin of this category's label grew out of many interactions with students seeking help from this and other statistics courses in a tutoring center. Any time I worked with a statistics student, I would ask him/her to explain probability and much of the time the student would give a statement nearly identical to those the circular category. When I would press the student and ban any word in his/her cycle (i.e., "probability", "chance", "likelihood", "odds"), the student would often struggle. Only when I would move the student into a specific context did many (but not all) students break free of their circular statements. Since this original study, I've built a set of questions specifically to see test the circular nature of students' conveyed meanings. Preliminary results show that 31 of 35 (88.57%) students believe that at least two of the terms "probability", "likelihood", and "chance" are the same. Twenty of these students explicitly stated that they believe that all three terms as the same. Additionally, their responses to other items suggest that their circular conveyed meanings are reflective of their actual meanings and those meanings are context dependent.

Students are not alone in conveying a circular meaning for probability; textbooks, instructors, and everyday language equate these three terms. The aforementioned *Statistics for the Life Sciences* (Samuels, 2015) explicitly defines probability as "a numerical quantity that expresses the likelihood of an event" (p. 83). The authors go on to use "chance" interchangeably with "probability". The *OpenIntro Statistics* (Diez et al., 2016) uses "chance", "probability", and "likely" interchangeably as well. Even the Moore, McCabe, and Craig (2012) textbook includes "…what chance, or probability, each possible sample has" (p. 193). I will admit that in the past, I supported students in coming the think about "probability", "likelihood", and "chance" as all being the same. However, there do appear to be consequences for this. As instructors, we must be aware that the meanings conveyed to our students are not necessarily the meanings we have nor we intended to support students in constructing (Thompson, 2013, 2015). By intentionally making distinctions between the meanings we want students to construct for "probability", "likelihood", "chance", and "odds" (and "personal (un-) certainty") we can better help students develop more productive ways of thinking about situations involving uncertainty. To this end I propose that instructors, authors, and curriculum designers adopt the following distinctions:

- Probability refers to the long-run relative frequency of an event when you imagine repeating a stochastic process indefinitely. The description of the particular stochastic process includes any assumptions. Probability is a measure that focuses on the occurrence of events given our theory/assumptions.
- Likelihood refers to the long-run relative frequency of a parameter taking on a certain value (more generally, our assumptions being "true") given our observed data.
- Chance refers to the relative size of the subset of outcomes of interest with respect to the size of the sample space. While a stochastic process exists, there is an assumption that each simple outcome has the same chance of occurring as every other simple outcome. This assumption removes the need to carry out the stochastic process.
- Odds is a ratio formed by using one of the above measures and comparing an event's under that measure to the event's complement's under that same measure.
- Personal (Un-) Certainty refers to an individual's belief that a particular result will occur in a non-repeatable process; i.e. there is no stochastic process in the situation.

I must point out that the distinctions here are not new. The distinction I make between probability and likelihood is consistent with how statisticians already treat likelihood functions and cumulative/probability density functions. What I've called chance is also known as "Classical" or "Laplacian" probability (von Mises, 1981; Weisberg, 2014). Von Mises (1981) argued that his notion of probability built upon the notion of long-run relative frequency in the collective was not the same as Laplace's which hinges on the assumption of equal chances. Further he notes that "authors start with the 'equally likely cases', only to abandon this point of view at a suitable moment and turn aside to the notation of probability which is based on the frequency definition" (von Mises, 1981, p. 99). Savage's (1972) notion of "personalistic probability" serves as the basis for what I've called personal (un-) certainty; which he argued is fundamentally different from both probability and chance. What is new is my call for instructors (and researchers) to use different terms for each of these ideas rather than a single umbrella term ("probability") with a modifier ("classical", "frequentist", "subjective", etc.) that often gets dropped when writing. I hypothesize that by using different terms for the different ideas and discussing the differences, fewer students will develop meanings that lead them to convey a circular meaning for probability.

Limitations and Future Directions

A limitation to this study is that responses to two questions do not necessarily provide enough information to confidently describe an individual's meanings for a mathematical topic. However, when considering the role of conveyed meanings, this limitation is not as serious as initial thought. We cannot ignore the fact that the students chose to write what he/she did. I believe that the meaning that the students conveyed is strongly related to each students' initial and/or dominate meaning for probability. If the students' go-to explanation for probability is circular, then this suggests that their underlying meanings are not as productive as we would desire. Further research including a larger survey with a set of more items designed to get at students meanings for probability is in the works. As I mentioned in the previous section, preliminary results from piloting indicate that a majority of students convey a circular meaning for probability. Additionally, given that this was an observational study, we cannot definitively say that Instructor A is the cause for stark differences between the three sets of students' responses. However, given that Instructor A made the decision to follow a curriculum centered on assisting students in developing productive ways of thinking, there is evidence of a strong causal relationship. Further research could substantiate this claim.

The notion of productive meanings for probability joined with the notion of conveyed meaning is useful in the development of a scale to measure students' progress in developing coherent meanings. Such a scale serves as a progress variable which represents "(a) the developmental structures underlying a metric for measuring student achievement and growth, (b) a criterion-reference context for diagnosing student needs, and (c) a common basis for interpretation of student responses to assessment tasks" (Kennedy & Wilson, 2007, pp. 3–4). Establishing a progress variable for probability along with items that measure such a variable has the potential to change how we teach probability at all levels. Additionally, a progress variable for probability is vital for other areas of statistics education research including students' notions of *p*-values, hypothesis testing, and distributions of random variables.

This study serves as but a first step in examining how undergraduate students' conveyed meanings for probability after receiving instruction. I introduced my notion of conveyed meaning as the constrained implications that a receiver attributes to the sender's statements. Conveyed meanings can provide insight into the actual meanings that an individual has. The present study indicates that the dominant conveyed meanings for probability after instruction are circular and calculationally oriented. One section of the course, which used a curriculum aimed to support students in developing rich meanings, does have a number of students who conveyed a highly productive meaning for probability. Further work needs to be done in order to help more students develop a rich and deep meaning for probability that is coherent and does work for the students in statistics.

Exploration of the Factors that Support Learning: Web-based Activity and Testing Systems in Community College Algebra

Shandy Hauk
WestEd

Bryan Matlen
WestEd

A variety of computerized interactive learning platforms exist. Most include instructional supports in the form of problem sets. Feedback to users ranges from a single words like "Correct!" to offers of hints and partially to fully worked examples. Behind-the-scenes design of such systems varies as well – from static dictionaries of problems to "intelligent" and responsive programming that adapts assignments to users' demonstrated skills, timing, and an array of other learning theory-informed data collection within the computerized environment. This short paper presents background on digital learning contexts and describes the lively conversation with attendees at the conference poster session. The topics were the research design and early results of a cluster-randomized controlled trial study in community college elementary algebra classes where the intervention was a particular type of web-based activity and testing system.

Key words: Adaptive Tutoring System, College Algebra, Multi-site Cluster Randomized Controlled Trial

Research Questions

Funded by the U.S. Department of Education, we are conducting a large-scale mixed methods study in over 30 community colleges. The study is driven by two research questions:

Research Question 1: What student, instructor, or community college factors are associated with more effective learning from the implemented digital learning platform?

Research Question 2: What challenges to use-as-intended (by developers) are faculty encountering and how are they responding to the challenges as they implement the learning tool?

Background and Conceptual Framing

First, there are distinctions among cognitive, dynamic, and static learning environments (see Table 1). Learning environments can vary along at least two dimensions: (1) the extent to which they adaptively respond to student behavior and (2) the extent to which they are based on a careful cognitive model.

Table 1. Conceptual framework of the types of instruction based on adaptability and their basis in a theory of learning.

		Static	Dynamic
Is a particular model of learning explicit in design and implementation (structure and processes)?	No	Text and tasks with instructional adaptation external to the materials	Adaptive tutoring systems (Khan Academy, ALEKS, ActiveMath)
	Yes	Textbook design and use driven by fidelity to an explicit theory of learning	"Intelligent" tutoring systems (Cognitive Tutor)

Static learning environments are those that are non-adaptive without reliance on an underlying cognitive model – they deliver content in a fixed order and contain scaffolds or feedback that are identical for all users. The design may be based on intuition, convenience, or aesthetic appeal. An example of this type of environment might be online problem sets from a textbook that give immediate feedback to students (e.g., "Correct" or "Incorrect").

Dynamic learning environments keep track of student behavior (e.g., errors, error rates, or time-on-problem) and use this information in a programmed decision tree that selects problem sets and/or feedback based on students' estimated mastery of specific skills. An example of a dynamic environment might be a system such as ALEKS or the "mastery challenge" approach now used at the online Khan Academy. For example, at khanacadmy.org a behind-the-scenes data analyzer captures student performance on a "mastery challenge" set of items. Once a student gets six items in a row correct, the next level set of items in a programmed target learning trajectory is offered. Depending on the number and type of items the particular user answers incorrectly (e.g., on the path to six items in a row done correctly), the analyzer program identifies target content and assembles the next "mastery challenge" set of items. Above and beyond such responsive assignment generation, programming in a "cognitively-based" dynamic environment is informed by a theoretical model that asserts the cognitive processing necessary for acquiring skills (Anderson et al. 1995; Koedinger & Corbett, 2006). For example, instead of specifying only that graphing is important and should be practiced, a cognitively-based environment also will specify the student thinking and skills needed to comprehend graphing (e.g., connecting spatial and verbal information), and provide feedback and scaffolds that support these cognitive processes (e.g., visuo-spatial feedback and graphics that are integrated with text). In cognitively-based environments, scaffolds themselves can also be adaptive (e.g., more scaffolding through examples can be provided early in learning and scaffolding can be faded as a student acquires expertise; Ritter et al., 2007). Like other dynamic systems, cognitively-based systems can also provide summaries of student progress, which better enable teachers to support struggling students. Some studies have shown the promise of cognitively-based dynamic environments in post-secondary mathematics (Koedinger & Sueker, 1996).

Method

The study we report here is a multi-site cluster randomized trial (note: because the study is currently underway, we purposefully under-report some details). Half of instructors at each community college site are assigned to use a particular adaptive web-based system in their instruction (Treatment condition), the other half teach as they usually would (Control condition). The primary outcome measure for students' performance is an assessment from the Mathematics Diagnostic Testing Program (MDTP), which is a valid and reliable assessment of students' algebraic knowledge (Gerachis & Manaster, 1995).

Using a stratified sampling approach to recruitment, we first conducted a cluster analysis on all 112 community college sites eligible to participate in the study (i.e., in a state that was a study partner and offering semester-long courses in elementary algebra that met at least some of the time in a physical classroom or learning/computer lab). The cluster analysis was based on college-level characteristics that may be related to student learning (e.g., average age of students at the college, the proportion of adjunct faculty, etc.). This analysis led to five clusters of colleges. Our recruitment efforts then aimed to include a proportionate number of colleges within each cluster. The primary value of this approach is that it allows more appropriate generalization of study findings to the target population (Tipton, 2014). Recruitment for our first cohort of participants yielded a study sample of 38 colleges similar to the overall distribution across clusters that was the target for the sample (see Figure 1).

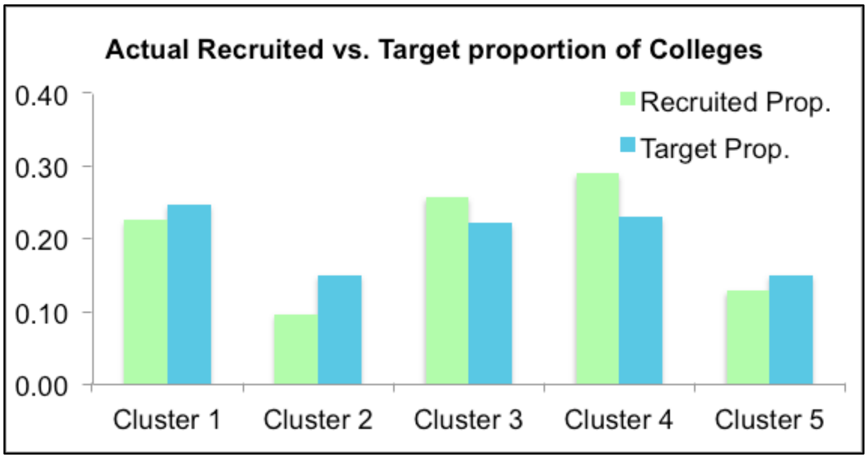

Figure 1. Recruited sample proportions and target sample proportions across clusters.

Sample for this Report

Initial enrollment in the study included 89 teachers across the 38 college sites. For this report on early results, we used the data from the participating students of 30 instructors across 19 colleges. Student and teacher numbers related to the data set reported on here are shown in Table 2.

Table 2. Counts of Teachers, Students, and Colleges in the Study.

Condition	*Teachers*	*Students*	*Colleges*
Control	19	147	15
Treatment	11	80	10
Total	*30*	*227*	*19*

Quantitative Analysis

The primary aim of the quantitative analysis was to address Research Question 1, how and for whom the particular adaptive computer environment might be effective. To this end, ultimately we will employ Hierarchical Linear Modeling (HLM) on the full data set. Models will include interaction terms between instructors' treatment assignment and covariates at different levels (e.g., students' history of course-taking, self-concept of ability), to explore the moderating impact of tool use on student learning. The primary post-test outcome measure is the MDTP elementary algebra assessment. A different but related MDTP pre-algebra diagnostic served as the measure of students' baseline knowledge. For this report, we have focused on the MDTP post-test as an indicator of algebraic knowledge.

Qualitative Analysis

To address Research Question 2, a great deal of textual, observational, and interview data are still being gathered. These data allow careful analysis of the intended and actual use of the learning environment and the classroom contexts in which it is enacted – an examination of implementation structures and processes. Indices of specific and generic fidelity derived from this work also will play a role in HLM generation and interpretation in the coming year.

Preliminary Results

Fall 2015 was the first full semester of data gathering for the project. It was our "practice" semester in that researchers were refining instruments and participant communication processes while treatment condition instructors were trying out the web-based learning tool with their classes for the first time. The "efficacy study" semester takes place in Spring 2016.

At the Conference: Poster Conversations

At the time of the conference, we had early results from the practice semester that suggested an aptitude by treatment interaction. Specifically, students in the Treatment group who started out with lower scores relative to the group mean on their algebra readiness pre-test, showed more benefit than Control group students (i.e., Treatment group students from the lower scores group had higher scores, relative to the group mean, on their post-test in elementary algebra). Some discussions in the poster session at the conference revolved around this interaction. For instance, one conference participant reported finding a similar result using a web-based technology: In his study, lower ability students exhibited higher grades when they were required to use the web-based tutor than when they were not. In another discussion, a conference participant hypothesized that instructors need to gain familiarity with technology before they can effectively use web-based learning tools for teaching. Indeed, after a semester of practice, Treatment but not Control instructors in our study reported an increase in their ability to use technology for teaching mathematics. Though not statistically significant (p = .12), the difference was consistent with the conference participants' hypothesis. Another key set of conversations at the poster were about the idea of an adaptive system that was based on a relatively stable "learning trajectory" or "genetic decomposition" as compared to a "cognitively-based" model approach that includes variability within a trajectory or decomposition, depending on the student, as the mechanism to guide selection algorithms when diagnosing and responding to student work in the computerized learning environment. We believe interactions such as those at the poster help to improve communication between the cognitive science research community and the RUME community.

Since the Conference: Updated Results

Since the conference, we have cleaned more data and have conducted analyses on this updated set. These analyses indicated that the aptitude by treatment interaction that was reported on the poster was no longer statistically significant: Estimate = -0.04, p = 0.71. Nevertheless, findings may continue to change as we continue to collect data in our efficacy semester.

Here we can add information about a new analysis of post-semester test scores that corrected for instructor clustering and students' scores on their algebra readiness pre-test. This analysis indicated that students in the treatment condition (adjusted M = 23.80, unadjusted SD = 6.67, N = 80) performed higher on their post-test than students in the control condition (adjusted M = 22.45, unadjusted SD = 8.27, N = 147), albeit these mean scores, at about 1 point difference, were not statistically different (Estimate = 0.93, p = 0.62). The effect size for this difference was Hedges' g = .12, which is considered small, but within expectation for efficacy trials of this type and is worth noting (Cheung & Slavin, 2015; Hill et al. 2008). As mentioned, this analysis included only a subset of students (data cleaning is ongoing) and results may continue to change as we collect, clean, and add more data to the analysis. Figure 2 shows box-plots of pre-test and adjusted post-test scores.

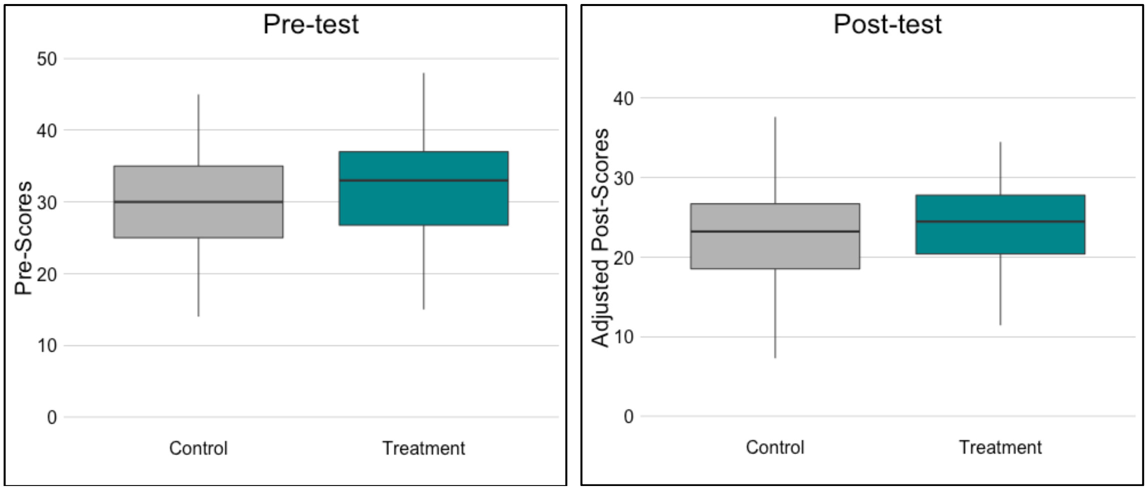

Figure 2. Left: Box-plot of pre-test scores. Right: Box-plot of adjusted post-test scores.

Next Steps

We will continue this study with a second cohort of new participants who will repeat the year-long study in the 2016-2017 academic year. Our specific objectives in the upcoming year are to (1) complete data collection from the first cohort for the primary efficacy study (i.e., data for hundreds of students for Spring 2016), (2) continue reporting findings from the Spring 2016 efficacy study of cohort 1, (3) recruit a second cohort of participants for another practice semester and efficacy study in 2016-17, and (3) begin the practice semester of the study with second cohort of participants.

Of particular interest is how the spread of information shown in Figure 3 might look for the efficacy (Spring 2016) data set. We look forward to having more to report and new questions to discuss at the 2017 conference.

How "Good" is "Good Enough"? Exploring Fidelity of Implementation for a Web-based Activity and Testing System in Developmental Algebra Instruction

Shandy Hauk
WestEd

Katie Salguero
WestEd

Joyce Kaser
WestEd

A web-based activity and testing system (WATS) has features such as adaptive problem sets, videos, and data-driven tools for instructors to monitor and scaffold student learning. Central to WATS adoption and use are questions about the implementation process: What constitutes "good" implementation and how far from "good" is "good enough"? Here we report on and illustrate our work to provide structure for such examination. The context is a study about implementation that is part of a state-wide randomized controlled trial examining student learning in community college algebra when a particular WATS suite of tools is used. Discussion questions for conference participants dug into the distinctions among intended, enacted, and achieved curriculum and the processes surrounding these as well as the challenges and opportunities in researching fidelity of implementation in the community college context, particularly the role of instructional practice as a contextual component of the research.

Key words: Fidelity of Implementation, College Algebra, Research Tools

Background

"How good is good enough?" has plagued humankind since the early cave dwellers wondered if killing three bison would get the family through the cold winter months. Even today, with our technological advances, we still ask questions such as "Do I have enough money for retirement?" "Have I practiced enough hours?" or "Is what I'm doing good enough?"

This ubiquitous question plagues social science researchers who are assessing the whats, whys, and hows of an intervention. Did the instructors have enough support to adequately implement the new curriculum? Were the materials adequate to provide enough practice hours for students? Was the instruction sufficient to prepare students to pass the final exam? Oh, if there were only an answer!

Study Context

We chose to attempt to answer this question of "good enough" in the implementation of a large project investigating relationships among student achievement and varying conditions of implementation for a web-based activity and testing system (WATS) used in community college algebra. We selected an implementation research approach that we had used previously and found to be helpful. In the new study we hope to replicate and to refine our earlier experience. Implementing the WATS is part of a statewide, randomized controlled trial examining student learning in community college algebra. WATS tools include adaptive problem sets, instructional videos, and data-driven tools for instructors to use to monitor and scaffold student learning. The WATS is accessed on the internet and is designed primarily for use as replacement for some in-class individual seatwork.

Research Questions

In what ways does a program-in-operation have to match the program-as-intended to be successful? Well, we have to identify what "success" means and also to identify alignment between intended and enacted implementation. Thus, two major research questions drive our attempt to answer the “good enough” question:

(1) What is the nature of alignment between how the program is implemented and how the developer/publisher envisioned it (i.e., what is the fidelity of implementation)?
(2) What are the relationships among varying conditions of implementation (differing degrees of fidelity) and the extent to which students are achieving the desired results?

Conceptual Framework

The theoretical basis for our approach lies in program theory, “the construction of a plausible and sensible model of how a program is supposed to work” (Bickman, 1987, p. 5). Having such a model in place allows researchers to conjecture and test causal connections between inputs and outputs, rather than relying on intuition or untested assumptions. As in many curricula projects, developers of the program in our study did pay attention to learning theory in determining the content in the web-based system, but the same was not true for determining implementation processes and structures. The pragmatic details of large-scale classroom use were under-specified. Developers articulated their assumptions about what students learned as they completed activities, but the roles of specific components, including the instructor role in the mediation of learning, were not clearly defined.

As Munter and colleagues (2014) have pointed out, there is no agreement on how to assess fidelity of implementation. However, there is a growing consensus on a component-based approach to measuring its structure and processes (Century & Cassata, 2014). *Fidelity of implementation* is the degree to which an intervention or program is delivered as intended (Dusenbury, Brannigan, Falco, & Hansen, 2003). Do implementers understand the trade-offs in the daily decisions they must make “in the wild” and the short and long-term consequences on student learning as a result of compromises in fidelity? Century and Cassata’s (2014) summary of the research offers five core components to consider in fidelity of implementation: Diagnostic, Procedural, Educative, Pedagogical, and Student Engagement (see Table 1).

Table 1. *Components and Focus in a Fidelity of Implementation Study*

Components	*Focus*
Diagnostic	These factors say what the “it” is that is being implemented (e.g., what makes this particular WATS distinct from other activities).
Structural-Procedural	These components tell the user (in this case, the instructor) what to do (e.g., assign intervention x times/week, y minutes/use). These are aspects of the *expected* curriculum.
Structural-Educative	These state the developers’ expectations for what the user needs to know relative to the intervention (e.g., types of technological, content, pedagogical knowledge are needed by an instructor).
Interaction-Pedagogical	These capture the actions, behaviors, and interactions users are expected to engage in when using the intervention (e.g., intervention is at least x % of assignments, counts for at least y % of student grade). These are aspects of the *intended* curriculum.
Interaction-Engagement	These components delineate the actions, behaviors, and interactions that students are expected to engage in for successful implementation. These are aspects of the *achieved* curriculum.

Method

The components in Table 1 are operationalized through a rubric, the guide for collecting and reporting data in our implementation study. A rubric is a "document that articulates the expectations for an assignment by listing the criteria, or what counts, and describing the levels of quality from excellent to poor" (Andrade, 2014). Each component has several factors that define the component. The project's research team has developed a rubric for fidelity of implementation, identifying measurable attributes for each component (for example, see Table 2 for some detail on the "educative" component).

Table 2. *Example of rubric descriptors for levels of fidelity, Structural-Educative component.*

Educative: These components state the developers' expectations for what the user needs to know relative to the intervention.			
	High Level of Fidelity	**Moderate Fidelity**	**Low Level of Fidelity**
Users' proficiency in math content	Instructor is proficient to highly proficient in the subject matter.	Instructor has some gaps in proficiency in the subject matter.	Instructor does not have basic knowledge and/or skills in the subject area.
Users' proficiency in TPCK	Instructor regularly integrates content, pedagogical, and technological knowledge in classroom instruction. Communicates with students through WATS.	Instructor struggles to integrate CK, PK, and TK in instruction. Occasionally sends digital messages to students using WATS tools.	Instructor CK, PK, and/or TK sparse or applied in a haphazard manner in classroom instruction. Rarely uses WATS tools to communicate with students.
Users' knowledge of requirements of the intervention	Instructor understands philosophy of WATS resources (practice items, "mastery mechanics," analytics, and coaching tools),	Instructor understanding of the philosophy of WATS tool has some gaps. NOTE: Disagreeing is okay, this is about instructor knowledge of it.	Instructor does not understand philosophy of WATS resources. NOTE: Disagreeing is okay, this is about instructor knowledge of it.
Users' knowledge of requirements of the intervention	Instructor understands the purpose, procedures, and/or the desired outcomes of the project (i.e., "mastery")	Instructor understanding of project has some gaps (e.g., may know purpose, but not all procedures, or desired outcomes).	Instructor does not understand the purpose, procedures, and/or desired outcomes. Problems are typical.

Results

Our focus here is two-fold. We first offer the preliminary results of rubric refinement from data collected through observation, interview, and teacher self-report in weekly surveys (also known as "teaching logs"). These results were shared on the poster (and handouts) at the conference. Then we summarize the highlights of the conversations about researching fidelity of implementation that emerged at the conference.

Defining and Refining Measures for the Fidelity of Implementation Rubric

The ultimate purpose of a fidelity of implementation rubric is to articulate how to determine what works, for whom, under what conditions. In addition to allowing identification of alignment between developer expectations and classroom enactment, it provides the opportunity to discover where productive adaptations may be made by instructors, adaptations that boost student achievement beyond that associated with an implementation faithful to the developers' view.

The example on the poster was for the procedural component from our WATS intervention (see Table 3, next page). The Structural-Procedural components tell the user what needs to be done (e.g., makes assignments for students to complete using the WATS tool). The table has four rows of expectations. Columns define high, moderate, and low fidelity followed by data sources and notes on the measures used.

We employ a mixed-method, feedback design to capture and communicate about fidelity of implementation. A feedback design for refining an intervention can be driven by qualitative research and supported by quantitative snapshots of student performance, teacher understandings, and systemic growth. Or vice versa. Our rubric (Table 3) lists primary, secondary and tertiary sources of data for gathering information about the four items on the procedural component of the fidelity rubric. These sources are WATS Application programming interface (API) – this provides data from the digital audit trail of WATS usage, occasional classroom observations for some instructors with an associated instructor interview, instructor self-report (through logs and surveys), and student survey. These measures were selected based on available sources and constraints on project time and funding.

We always dance between what we want to know about an intervention and what we are able to measure. Instructor self-report logs are highly useful as they can document what is happening with implementation. For example, logs can tell us how many times an instructor mentioned or used the intervention. And that accretion across weeks gives the area under the curve of what's going on across time, contributing to the big picture, of implementation.

In using the rubric, we assign a number to each level of fidelity. This can be as simple as a 3 for a high level of fidelity, 2 for a moderate level of fidelity, or a 1 for a low level; or the items can be weighted. Note on Table 3 under "amount of instruction – mindset lessons" we will know instructors' use of mindset lessons through logs and an interview question and can then assign a high, moderate, or low level of fidelity to the item (see Table 2, Notes on Metrics).

The score for the intervention will be the total number of points assigned in completing the rubric as a ratio of the total possible, across all instructors. It will also be possible to create a fidelity of implementation score on each row for each instructor – these data will be used in statistical modeling of the impact of the intervention as part of a "specific fidelity index" (Hulleman & Cordray, 2009). We first total points for the item, then the component, and finally all components for a single score as an index of implementation.

We anticipate having data that allow us to answer several questions related to "good enough." For example, for Research Question 1:

- To what extent did the instructors assign WATS activities?
- To what extent did the instructors encourage students to complete the WATS activities?
- To what extent were the mindset lessons implemented?
- How frequently was WATS assigned?

And, for Research Question 2: What is the relationship between level of mastery students achieved and number of WATS activities students completed or number of mindset activities students experienced?

Table 3. *Structural-Procedural.* These components tell the user what to do regarding instruction.

	High Level of Fidelity	*Moderate Level of Fidelity*	*Low Level of Fidelity*	*Primary Data Source*	*Second Data Source*	*Third Data Source*	*Notes on Metric(s)*
Assigns WATS	Instructor assigns all target WATS activities.	Instructor assigns 80% to 99% of target activities.	Instructor assigns fewer than 80% of target activities.	WATS API	Logs	Instruc. Interview	Source of boundary conditions: Developer, who said: "best guess at what a minimally effective dose is. Really, it has to be all."
Amount of instruction - Promotes Completion	Regularly encourages students to complete the mission.	Sometimes encourages students to complete the mission.	Rarely or never encourages students to complete the mission.	Logs	Instruc. interview	Obser-vation	*High & Moderate*: >2/3 of instructors say: Regularly: >75% of weeks (High) Sometimes: >35% of wks (Mod.) *Low*: <2/3 instructors OR Rarely: <35% of weeks
Amount of instruction - Mindset Lessons	Conducts 3 mindset lessons.	Conducts 2 mindset lessons.	Conducts at most 1 mindset lesson.	Logs	Instruc. Interview	N/A	Instructor Interview Q4: What plans do you have for mindset activities with students? Logs: What mindset lessons did your class do this week?
Frequency of instruction	WATS assigned at least 12 of 15 weeks in the term.	WATS assigned at least 7, up to 11 weeks in the term.	WATS assigned in 6 or fewer weeks in the term.	Logs	WATS API	Student survey	*High*: At least 2/3 of Instructors report WATS use in at least 75% of logs. *Moderate*: At least 2/3 of Instructors report use in 50 to 75% of logs. *Low*: not high or moderate.

At the Conference: Poster Conversations

The factors included in the poster were meant as a starting point for conversation. The poster shared the theory behind the protocol and was a touchstone for gathering ideas from RUME attendees on dissemination that might be productive as we move forward into the full study (2015 is a "practice" year for the study). Here we summarize the highlights of the conversations at the poster.

Participant comment: I never thought about this before, that somebody might pick up an activity that I designed and use it in a counter-productive way. Why would they even try it if they didn't think like I did about how to use it?

Response: There are myriad of reasons why someone would change the way they conduct an activity that another had designed. They can be from differences in content, pedagogical, or pedagogical content knowledge, or due to limitations of time or resources or even relate to someone wanting to "brand" the activity as their own. Just remember: what **you** call counter-productive may be seen as a helpful tweaking to someone else. The key lies in the impact of the change on the desired result (e.g., student learning gains).

Participant question: How do you do curriculum development when multiple people develop something for use by multiple people, including some who are not in the room?

Answer: Very skillfully! Your start with using data about your intended audience. As you design, you determine what you think will be your fidelity factors – the ones that drive your anticipated results. Next you implement your activity and then gather data to determine results and confirm the role of your fidelity factors. Further testing can show what happens when you vary a fidelity factor like contact time or dosage. These are all excellent opportunities to document "good enough." Remember you are dealing with human beings. Keep in mind the idea of "close approximation."

Participant question: How do you decide what the "it" is that is being implemented?

Answer. Excellent question. The "it" is the intervention, the project, the curriculum. Determining the "it" is answered in part by asking about a series of diagnostic factors that are part of our model. We start by interviewing developers, asking these diagnostic questions. One of the questions is how the intervention, project, or curriculum differs from others that are similar. Then we layer this information with observation of the training that developers give to faculty and the kinds of questions faculty ask about using the intervention during the training. You might think that determining the "it" is easy – sometimes yes, sometimes no. Unless you zero in on what the "it" is, you will never get to the level of specificity required to evaluate fidelity factors.

Participant question: I like to think of a three-way overlapping Venn diagram for an intervention: the intended curriculum, the implemented curriculum, and the achieved curriculum. Can your framework relate to this concept?

Answer: Our model is a fourth party that attempts to take in perspectives of all these aspects curricula. It can connect them as an important way of monitoring for efficacy (also, see the notes in the second column of Table 1, above).

Participant comment: I am surprised that a component is that instructors might need certain types of knowledge before they are ready to use a particular type of intervention.

Response: Usually something about an intervention is new. Maybe new content. Maybe new pedagogy. The instructor may not have learned whatever is required to carry out the intervention. One of the major reasons interventions fail is that participants are asked to do new things (such is the nature of interventions) for which they are given little or no training.

Participant question: I like the idea of descriptions of performance at the high, medium, and low levels. Can you develop materials that incorporate such descriptions on the front end?
Answer: Sure you can. Such descriptions can be used at each level from the beginning of an activity or program through the implementation and finally for the evaluation at the end.

Participant question: Does your framework help increase equity in any respect?
Answer: The specificity of what fidelity of implementation requires we include in the rubrics is an opportunity for us to address potential challenges to equity and inclusion in the implementation of an intervention. How to make college math accessible to all students is a theme of the work in in the WATS system we are studying. Investigating fidelity of implementation allows us to identify how curriculum and its implementation play a part in that accessibility process.

Participant question: Where is it explicit to a user what the developer's intentions are?
Answer: Sometimes the developers will tell you outright in the introductory material. Other times the intent is buried in the content, and you have to unearth it. Sometimes developers are very cognizant of their intentions; other times, oblivious. Regardless of level of transparency, intentions are always there.

Participant question: As a classroom instructor, where in the rubrics is my relationship with the WATS online resource? My perspective about its use in teaching and learning?
Answer: Yes, that's something we are wrestling with as we develop the details of the Educative rubric (Table 2). Right now, the rubric looks at the degree of knowledge instructors have about the intended relationship (e.g., about the philosophy behind the WATS tool), not at the alignment of the instructor's view with that perspective. We agree success of implementation may depend on how someone sees the resource, but is it necessarily an aspect of being faithful to the intentions of the tool? For an instructor, the resource can be a partner, or a distinctly separate support for teaching, or even an obstacle. The Concerns Based Adoption Model provides some ideas that we are pursing (Hall & Hord, 2014).

Participant comment: It's a new idea to me that implementation could be a major field of study.
Response: It has grown exponentially over the past 20 years, and we have learned much about the implementation process. You have probably heard the cliché, "We tried that once and it didn't work." What actually happens most often is a failure in implementation. Even the best ideas will collapse with insufficient or faulty implementation.

Implications for Practice

By definition, high fidelity implementation of an instructional tool is use that results in greater learning gains than non-use. Instructors and students are better equipped to implement with high fidelity when they have answers to questions like: What are the characteristics of good implementation? Among preferred actions in implementation, which are the highest priority? What are the trade-offs and consequences of making particular decisions about use of the tool?

Answers to these questions provide data for determining what is "good enough" and help users make the best decisions for program efficacy. As the field moves forward, we seek effective ways to communicate implications to college instructors, department chairs, as well as stakeholders in the larger public arena.

A Framework for Mathematical Understanding for Secondary Teaching: The Mathematical Activity perspective

M. Kathleen Heid
Pennsylvania State University

Patricia S. Wilson
University of Georgia

Abstract: *A framework for mathematical understanding for secondary teaching was developed from analysis of the mathematics in classroom events. The Mathematical Activity perspective describes the mathematical actions that characterize the nature of the mathematical understanding that secondary teachers could productively use.*

Mathematics teaching at the collegiate level focuses on enabling students to develop solid understanding of mathematics. Although collegiate mathematics students often describe mathematics as learning specific topics and strategies and applying this knowledge to their work, their instructors may have additional but less explicit goals such as valuing the structure of mathematics, being able to create a deductive argument, or exploring and comparing systems of mathematics. These latter goals are especially important for prospective teachers of secondary mathematics, and college mathematics instructors are attending in new ways to the mathematical preparation of those who will teach mathematics.

Over the past three decades, mathematics education researchers and theorists have increased their focus on the mathematical knowledge of teachers that helps teachers reach their goals of promoting a more robust understanding of mathematics in their students. During that time, researchers have refined the focus from Shulman's (1986) construct of pedagogical content knowledge to constructs such as mathematical knowledge for teaching (MKT) (Ball, 2003; Ball & Bass, 2003; Ball & Sleep, 2007a; Ball & Sleep, 2007b; Ball, Thames, & Phelps, 2008) and knowledge of algebra for teaching (KAT) (Ferrini-Mundy, Floden, McCrory, Burrill, & Sandow, 2005; McCrory, Floden, Ferrini-Mundy, Reckase, & Senk, 2012). Work on MKT is, perhaps, the best known of the research programs focused on teachers' mathematical knowledge. MKT originated with a reflection on the mathematical knowledge involved in the mathematical work of teaching at the elementary level. MKT partitions the territory of mathematical thinking into categories such as specialized content knowledge, common mathematical knowledge, and mathematics at the horizon. While the MKT categories can partition mathematical knowledge at the secondary level as well as at the elementary level, those categories may not characterize the nature of mathematical thinking that seems to distinguish mathematics at the secondary school level.

In their work in secondary mathematics, students expand their mathematical knowledge to include new ideas such as irrational numbers, complex numbers, static and rotating objects, sample spaces, and a variety of ways to represent these ideas. But the differences between mathematics at the elementary and secondary levels are not solely extensions of the topics involved, but also a change in the nature of mathematical thinking involved. Whereas both elementary and secondary mathematics honor deductive reasoning, secondary mathematics places a much stronger emphasis on deductive thinking within a closed mathematical system. It is in the context of secondary mathematics that curricula focus on reasoning on the basis of a well-defined system of given properties and relationships. For example, the work of secondary students in the study of geometry is more likely to occur at the third or fourth van Hiele level (making deductive connections and constructing proofs) rather than the first or second levels (focused on visualizing or recognizing properties of geometric objects) that are more prominent at the elementary level. At the elementary level, students develop ways to represent mathematical relationships. As students progress through school mathematics, their repertoires of ways to represent mathematical relationships expands so that, as they engage in secondary mathematics, they can be expected to link representations of the same mathematical entities and to reason about a mathematical entity in one representation making conclusions about that entity in another representation.

Secondary teachers need to be able to reason flexibly enough to recognize and act on opportunities for their students to build capacities for reasoning in a closed system and for capitalizing appropriately on a range of representations. They need mathematical understanding that enables them to perform such activities as creating examples, nonexamples, and counterexamples of entities encountered in secondary mathematics, to identify special cases of broad categories of mathematical objects, and to explain when a general statement can or cannot be extended to a larger or different domain or set of mathematical objects. Secondary teachers need to make connections across mathematical systems. In order to facilitate learning secondary mathematics, the work or context of teaching requires a depth of specific mathematical understanding that incorporates the more subtle but important goals of mathematics teaching. Mathematics teachers must not only understand mathematics but they must enable others to understand mathematics in the fullest sense. They need to pose interesting questions and tasks that bring the structure of mathematical systems alive. They need to understand the mathematical thinking of students in order to correct or challenge their thinking. They need to be able to reflect on the curriculum and organization of mathematical ideas. The context of learning mathematics requires specific mathematical understanding beyond pedagogical knowledge.

The six faculty involved in our project on Mathematical Understanding for Secondary Teaching (Glen Blume, M. Kathleen Heid, Jeremy Kilpatrick, James Wilson, Patricia Wilson, and Rose Mary Zbiek), recognizing the need to understand better the nature of the mathematical understanding that could best serve secondary teachers, adopted the goal of developing a framework that could account for the mathematics a secondary teacher could productively use in the context of teaching secondary mathematics. We decided to began our inquiry by identifying mathematical opportunities secondary teachers actually encounter, and so we began in the classroom. As we embarked on our study of mathematical opportunities unfolding in the classroom, we recognized many of the ideas expressed by others who have attended to secondary mathematics (e.g., Adler & Davis, 2006; Cuoco, 2001; Cuoco, Goldenberg, & Mark, 1996; Even, 1990; McEwen & Bull, 1991; Peressini, Borko, Romagnano, Knuth, & Willis-Yorker, 2004; Tattoo et al., 2008). While the framework incorporates previous ideas, it attends directly to the secondary mathematics built on data from mathematics classes.

Our source of data was a set of what we came to call Situations. A Situation is a mathematical description, based on an actual event that occurred in the practice of teaching, of the mathematics that teachers could productively use in the work of teaching mathematics. Teams of mathematics education faculty at Penn State and at University of Georgia worked with dozens of doctoral students in mathematics education to develop more than 50 Situations.

Although any one Situation is too large to report in this paper, we provide a brief outline of one of the Situations (from Heid & Wilson, 2015) here. Each Situation includes a Prompt (a description of a mathematical opportunity–an event that one of the authors observed happening in the course of teachers planning or implementing a secondary mathematics lesson) and several Mathematical Foci (development of mathematics that a teacher could productively use in the context of that mathematical opportunity). A short statement about the nature of the mathematical understanding being targeted precedes each Mathematical Focus. Other parts of each Situation are Commentaries (a description of how the Mathematical Foci for the Situation fit together) and PostCommentaries. One of the Situations is outlined in Figure 1.

The Situations we (the cross-university teams) developed suggested a range of mathematical abilities, actions, and settings that could underlie potentially productive mathematical thinking on the part of the teacher. It was on the basis of these abilities, actions, and settings that we embarked on the challenging task of developing our Framework for Mathematical Understanding for Secondary Teaching. As we examined the Situations we had created, we recognized that we needed several different perspectives to explain the mathematics we had identified. Akin to Plato's allegory of the cave, the framework on which we settled consisted of three perspectives, each of which cast a different shadow representing a student's mathematical understanding (See Figure 2).

We adapted one perspective, Mathematical Proficiency, from *Adding it up: Helping children learn mathematics* (National Research Council, 2001). We found that we could identify the mathematical understandings in our Situations as examples of the strands of proficiency in this document: conceptual understanding, procedural fluency, strategic competence, adaptive reasoning, and productive disposition, supplemented by an additional strand focused on historical and cultural knowledge. This perspective accounted for mathematical knowledge and its use, but did not account for the mathematical actions that secondary teachers could productively take in the context of teaching mathematics. The second perspective addressed this focus on mathematical actions as Mathematical Activity. However, neither the first nor second perspective accounted for the settings in which teachers needed to call on their mathematical knowledge. The third perspective, Mathematical Context of Teaching, addressed the mathematical context in which teachers could productively call upon their mathematical knowledge.

The first perspective, Mathematical Proficiency, is likely to be familiar as a way to think about students' mathematical capability. The third perspective, Mathematical Context, provides a description of the mathematical understanding that is particularly relevant to teaching. This perspective was more implicit than explicit in our data, but we realized that the Mathematical Context of teaching indicates why it is critical to recognize and attend to the importance of Mathematical Activity. In this paper, we confine our discussion to the development of the second perspective, Mathematical Activity. The reader can find more detail on the Mathematical Proficiency and Mathematical Context perspectives in the Heid and Wilson book (Heid & Wilson, 2015).

CHAPTER 22. INVERSE TRIGONOMETRIC FUNCTIONS (originally identified and developed by Rose Mary Zbiek)

Prompt

Three prospective teachers planned a unit of trigonometry as part of their work in a methods course on the teaching and learning of secondary mathematics. They developed a plan in which high school students would first encounter what the prospective teachers called *the three basic trig functions*: sine, cosine, and tangent. The prospective teachers indicated in their plan that students next would work with "the inverse functions," which they identified as secant, cosecant, and cotangent.

Commentary

The Foci draw on the general concept of inverse and its multiple uses in school mathematics. Key ideas related to the inverse are the operation involved, the set of elements on which the operation is defined, and the identity element given this operation and set of elements. The crux of the issue raised by the Prompt lies in the use of the term *inverse* with both functions and operations.

Mathematical Focus 1

An inverse requires three entities: a set, a binary operation on that set, and an identity element given that operation and set of elements.

Secondary mathematics involves work with many different contexts for inverses. For example, opposites are additive inverses defined for real numbers and with additive identity of 0, and reciprocals are multiplicative inverses defined for nonzero real numbers and with multiplicative identity of 1. [Discussion follows about the nature of inverses, the role of an identity in inverses, and the importance of domain and range in consideration of inverses.]

…

Mathematical Focus 2

Although the inverse under multiplication is not the same as the inverse under function composition, the same notation, the superscript -1, is used for both.

[Discussion follows about notation used in different inverse relationships, and the specific use of that notation in consideration of trigonometric functions.]

…

Mathematical Focus 3

When functions are graphed in an xy*-coordinate system with* y *as a function of* x*, these graphs are reflections) in the line* y = x *of their inverses' graphs (under composition).*

The graph of a function reflected in the line $y = x$ is the graph of its inverse, although without restricting to principal values, the inverse may not be a function. Justifying this claim requires establishing that the reflection of an arbitrary point (a, b) in the line $y = x$ is the point (b, a). [A geometric proof follows, using a coordinate plane representation of the reflection of a point (a,b) over the line $y = x$.]

MATHEMATICAL ACTIVITY

We used the set of Mathematical Foci from the Situations as data from which to generate our Framework for Mathematical Understanding for Secondary Teaching. First we identified mathematical actions implicit or explicit in each of the Foci. We then developed categories that seems to capture those actions, including categories such as creating mathematical entities, interpreting mathematical representations, and orchestrating movement among them.

Creating

One set of mathematical actions that seemed to group into a single category included the following actions:

- Creating a counterexample for a given structure, constraint, or property
- Creating an example or non-example for a given structure, constraint, or property
- Creating equivalent equations to reveal information
- Creating problems to foreground a concept
- Creating a file (a computer application) whose creation requires mathematics beyond what the file is used to teach
- Constructing an object given a set of mathematical constraints
- Generating specific examples from an abstract idea
- Creating a representation for a mathematical object with known structure, constraints, or properties

Each of these actions involves the generation of a new mathematical entity. Some of the actions involve the generation of a new (to the creator) mathematical object such as an instance of a counterexample for a mathematical conjecture, some of the actions involve the creation of specific examples that illustrate mathematical concepts that have given sets of properties, and some of the actions involve the creation of mathematical tools such as computer files that display a representation of the motion of a bicycle. In every case, the mathematical entity that was created was one fitted to a given set of mathematical conditions.

Having grouped these actions into a single category, we developed a description of a mathematical action that encompassed these actions. In this case our description was “Creating a mathematical entity or setting from known (to the one creating) structures, constraints, or properties." An example of a specific mathematical action that might fit this category is the task of constructing a quadrilateral with specific characteristics. Other mathematical actions were developed in a similar fashion. A few of the final set of mathematical actions at this juncture, along with specific examples drawn from the Situations, are shown in Figure 3.

Extending

A similar process underpinned the development of a subcategory we called extending. Mathematical actions that fell into this category could be described as those involving extension of a domain, argument, or class of objects for which a mathematical statement is or remains valid. The following mathematical actions fell under the "extending" category:

- Structuring an argument so that it extends to a more general case;
- Determining mathematical extensions to a given problem or question;
- Recognizing mathematical relationships that allow one to extend a conclusion to a larger class;
- Considering a definition in an expanded sense or altering the "universe" being considered; and
- Extending domain while preserving structure.

Just as "extending" the domain of a mathematical relationship is an essential mathematical process for teachers, so is restricting or constraining the domain. Examples in the set of Situations that involved extending are: extending the absolute value function from the real to the complex domain; and extending the object "triangle" from Euclidean to spherical geometry

Category	Example
Create: Creating a new (to the one creating) mathematical entity or setting from known (to the one creating) structure, constraints, or properties	Sketch quadrilateral ABCD with $m\angle D = m\angle A = 90$ and $\overline{AB} \parallel \overline{DC}$ such that ABCD is not a parallelogram.
Recognize: Recognizing mathematical properties, constraints, or structure in a given mathematical entity or setting, or across instances of a mathematical entity	Recognizing that strategic choices for pairwise groupings of numbers are critical to one way of developing the general formula for summing the first *n* natural numbers
Choose: Considering and selecting from among known (to the one choosing) mathematical entities or settings based on known (to the one choosing) mathematical criteria	The mathematical meaning of a/b (with $b \neq 0$)) arises in different mathematical settings, including: slope of a line, direct proportion, Cartesian product, factor pairs, and area of rectangles. One might choose slope of a line as a setting to illustrate the need for $b \neq 0$.

Figure 3. A few of the set of mathematical actions that comprised the Mathematical Activity perspective of the Framework for Mathematical Understanding for Secondary Teaching, along with specific examples drawn from the Situations.

Use representations: For given representations, interpret them in the context of the signified, orchestrate movements between them, and craft analogies to describe the representations, objects, and relationships	Using tabular and graphical representations to estimate the value of $2^{2.5}$
Assess (interpret and adapt) the mathematics of the situation: Interpret and/or change certain mathematical conditions/ constraints relevant to a mathematical activity	Recognize the desirability of a modulus definition of absolute value in evaluating $f(x)=\left\|\sqrt{x-10}\right\|$
Extend: Extend the domain, argument, or class or objects for which a mathematical statement is/remains valid.	Extending: the absolute value function from the real to the complex domain; "triangle" from Euclidean to spherical geometry
Connect: By recognizing structural similarity, make connections between: representations of the same mathematical object; different methods for solving a problem; mathematical objects of different classes; objects in different systems; or properties of an object in a different system.	Identifying structural similarities of the Euclidean algorithm and the long division algorithm
Reason: Reason about a mathematical entity in more than one way, including, but not limited to: from mathematical definitions, from given conditionals, from and toward abstractions, by continuity, by analogy, and by using structurally equivalent statements.	Reasoning about the sum of the first n natural numbers by appealing to cases, by making strategic choices for pair-wise grouping of numbers, and by appealing to arithmetic sequences and properties of such sequences.

Figure 3, continued.

Creating the Mathematical Activity perspective

Finally, we organized the set of mathematical actions to account for the actions arising in the Situations as well as mathematical actions that we could readily imagine and that were not captured in the categories that were derived from the Situations. The final set of categories is displayed in Figure 4.

The final categories differed from existing frameworks in their mathematical nature. The mathematical actions we described derived from the mathematical decisions that teachers confront. Their work in mathematics classrooms would benefit from their ability to notice similar mathematical structures. Being comfortable enough with mathematical entities, properties, and structures to create and modify new representations would allow them the freedom to pursue their students thinking. They could productively use a flexible and robust repertoire of techniques for justifying their mathematical work.

The framework is intended to be a work in progress. It can serve as a research tool to study the mathematical understanding of secondary teachers. Researchers might investigate, for example, what collegiate mathematics courses contribute to the development of the capabilities suggested in each of the perspectives. They might also investigate how the aspects of secondary mathematics teachers' own mathematical understandings as described in the Framework influence the mathematics to which they expose their students.

I. Mathematical noticing: *Recognize and choose from among known mathematical entities or settings based on known mathematical criteria such as:*

- A. Structure of mathematical systems
- B. Symbolic form
- C. Form of an argument
- D. Connections within and outside mathematics

II. Mathematical reasoning**:** *Reason about a mathematical entity in one or more than one way, including, but not limited to: from mathematical definitions, from given conditionals, from and toward abstractions, by continuity, by analogy, and by using structurally equivalent statements.*

- A. Justifying/proving
- B. Reasoning when conjecturing and generalizing
    - 1. Investigate (*Take a mathematical action to find out more about structure, constraints, or properties of a mathematical situation or a mathematical object)*
- C. Constraining and extending

III. Mathematical creating. *Create (Creating a mathematical entity or setting from known (to the one creating) structure, constraints, or properties)*

- A. Representing
- B. Defining
- C. Modifying/transforming/manipulating

IV. Integrating strands of mathematical activity. *Coordinate (Coordinate mathematical knowledge, student mathematical thinking, school curricula, and knowledge development); Reflect (self-reflect) (Reflect on mathematical aspects of one's practice or on one's own doing math); and Apply (Employ algorithms, definitions, and technology in mathematical settings and/or real world quantitative settings when applicable.)*

Secondary teachers' responses to embedded mathematical uncertainty: Cases from an assessment item on exponents.

Heather Howell	Heejoo Suh	Yvonne Lai
Educational Testing Service	Michigan State University	University of Nebraska – Lincoln

A growing body of research recognizes uncertainty as an inevitable part of teaching. Yet still little has attended to the potential of uncertainty as a space for mathematics teacher education. In this paper, we report on an analysis of interview data in which secondary teachers were asked to think aloud as they solved a task with embedded uncertainty. We present examples of teacher responses and discuss ways in which they assign valence to their experience of uncertainty. We found that teachers do not always engage with mathematical uncertainty, but also that their (dis)engagement did not necessarily signal their ability to reach the intended answer, and was not always predicted by the valence they assigned the uncertainty. These results suggest that, while tasks containing embedded uncertainty may be rich sources to draw on, facilitating the resulting discussions is likely to be complicated and needs to account for a number of factors.

Keywords: Secondary Mathematics Teachers, Uncertainty, Algebra, Teacher Education, Teacher Assessment

"Teaching is evidently and inevitably uncertain" (Floden & Buchmann, 1993, p. 373). In acknowledgement of this, education researchers have attended to what causes uncertainty and to how teachers might respond productively to uncertainty. We build on this work by attending to *mathematical* uncertainty, by which we mean uncertainty whose source is mathematical. In this study, we examine a set of interviews with secondary mathematics teachers who responded to a task involving mathematical uncertainty. In the sections that follow, we first locate this study in the literature on uncertainty in teaching and teacher education. We then discuss the task, called the *Williams item*, originally designed to assess mathematical knowledge for teaching, and discuss the mathematical uncertainty embedded in that task. We then describe our data and the context in which the teacher interviews were conducted, and outline our analysis process. In presenting the results of the analysis, we describe teachers' reactions to uncertainty as well as the valence they assign that experience. The term valence, in this paper, means one's opinion of uncertainty that can be positive, negative, both, or neutral. Our goal is to populate an example space within which teacher educators can think through what might make such reactions more or less productive. We finish by discussing how the types of reactions we observed suggest that tasks containing mathematical uncertainty may potentially serve as tools for mathematics teacher education.

Background

Uncertainty in thought, encountered while teaching, can be conceptualized as cognitive "perplexity, confusion, or doubt" (Dewey, 1933) that can originate in various sources and that may exist within or outside of the individual. Uncertainty can result from instructional content (e.g., Capobianco, 2010), pedagogy (e.g., Midthassel, 2006; Wheatley, 2005), and student traits or school culture (e.g., Labaree, 2003; Villaume, 2000). Education researchers have used the term uncertainty to describe everything from unpredictable classroom situations (e.g., Midthassel, 2006) to low self-efficacy (e.g., Wheatley, 2005). Some strands of literature describe it more as an external, contextual attribute (e.g., Floden & Buchmann, 1993) while others locate it as an emotion experienced by the teacher (e.g., Meister & Nolan, 2001). In other words, uncertainty is defined in the literature in various ways, and it covers a range of aspects of teaching.

Studies suggest that when teachers confront uncertainty and conceptualize teaching as open and fluid, they encounter greater opportunity to develop their practices and their subject matter knowledge (Floden & Buchmann, 1993; Labaree, 2003). And this may be as true for expert teachers as for novice teachers. Floden and Chang (2007) suggest the metaphor of a jazz score for teaching, where certain frames of reference can be nailed down and others are, of necessity, open to creativity and interpretation; a sign of expertise is the ability to make use of uncertainty rather than the ability to avoid uncertainty. Denying uncertainty may restrict teachers' opportunities to look for alternative teaching methods and in turn limit students' learning (D. Cohen, 1988; Helsing, 2007; Munthe, 2003).

In this paper we focus on uncertainty that is mathematical in nature. Mathematical knowledge can be open to revision and hence it does change (Ernest, 2004, 2015; Lakatos, 1976; Stinson & Bullock, 2012). In other words, uncertainty can be embedded in the subject matter, and this type of uncertainty will never be fully resolved no matter how well a teacher prepares, even if preparation can reduce some uncertainty. Mathematical uncertainty can be as irreducible as other uncertainties.

Although uncertainty is worth examining from the view of teacher education, little empirical research has been done in the context of *mathematics* teacher education. Some research has attended to unexpectedness in teaching mathematics (e.g., Cavanna, Herbel-Eisenmann, & Seah, 2015; Coles & Scott, 2015; Mason, 2015; Rowland, Hodgen, & Solomon, 2015; Rowland, Thwaites, & Jared, 2015), with more focus on classroom interaction and general pedagogical situations. Zaslavsky (2005) focused on providing teachers with tasks designed to provoke mathematical uncertainty by having teachers generate competing claims, work with unknown paths or questionable conclusions, or deal with non-readily verifiable outcomes. The teachers, in interviews after engagement with the tasks, showed appreciation and reported deep engagement due to the uncertainty. The mathematical uncertainty encountered allowed the participants to engage with the mathematics more deeply. As a result of this activity with teachers, Zaslavsky recommended that teacher educators reflect on task implementation and make modifications so as to invite teachers to confront mathematical uncertainty. Buchbinder and Zaslavsky (2008) also reported teachers being satisfied and excited after resolving mathematical uncertainty.

Conceptualizations of the work of teaching associated with mathematical knowledge for teaching suggest that teachers need to hold specialized content knowledge, a form of pure mathematical knowledge uniquely needed by teachers (Ball, Thames, & Phelps, 2008). This knowledge often manifests in the consideration of unconventional student solutions, which may need to be examined for mathematical coherence, validity, generality, efficiency, or appropriateness. This type of work is clearly a component of the daily work that teachers do, but is also *mathematical* work. The need to respond quickly to student-generated mathematics suggests that the more open a classroom is to student-generated ideas, the more likely it is that teachers will need to respond rapidly to unfamiliar mathematics. In other words, one can characterize responding to mathematical uncertainty as an inevitable part of the work of teaching. Jordan, Kleinsasser, and Roe (2014) suggested teacher educators might support teachers' professional growth by deliberately inducing uncertainty.

Previous work on uncertainty has conceptualized how a mathematical task can provoke uncertainty and has provided empirical evidence that confronting uncertainty can help teachers *as learners of mathematics* to acquire deeper mathematical understandings. They do not take on the question of how confronting mathematical uncertainty *in their roles as teachers* might be leveraged by teachers to, for example, provide a window into the student experience and model approaches to uncertainty for their students. This skill has taken new relevance in view of recent work on K-12 standards. The Common Core State Standards (CCSS) have set forth a list of key mathematical practices that students should be able to take in solving mathematical problems. We see a potential in mathematical uncertainty for providing opportunities for teachers to engage with multiple standards for mathematical practice, including "Make sense of problems and persevere in solving them" and "construct viable arguments and critique the reasoning of others" (Common Core State Standards Initiative, 2012). If students are to learn these practices, it is important for teachers to model the practices explicitly (Charalambous, Hill, & Ball, 2011; J. Cohen, 2015; Morrison, Robbins, & Rose, 2008). Though scholars have explored, more generally, productive approaches to uncertain mathematics from learners' perspectives (Cuoco, Goldenberg, & Mark, 1996; Komatsu, 2016), there has been less study of approaches to mathematical uncertainty as a part of the work of teaching and how teacher educators can support teachers' ability to leverage the emotional component that may inevitably accompany the experience of confronting uncertainty in front of a classroom full of students. To better support teacher educators utilizing uncertainty, it is important to understand the strategies teachers use and how they feel when confronted by uncertainty in the work of teaching.

For the purposes of this paper, we conceptualize mathematical uncertainty following Zaslavsky (1995): any mathematical situation in which competing claims, an unknown path or questionable conclusion, or non-readily verifiable outcome occurs. We take uncertainty to be both a condition of the situation (that something cannot be known) and the associated emotions. We use the term *valence* to describe a teacher's positive or negative opinion of the consequences of uncertainty. Valence may be neutral, as a person may not have a strong opinion, and it does not itself have a truth value. Valence is not often discussed in the literature, although it might be read into certain work that accepting uncertainty means assigning a positive valence to uncertainty (Jordan, Kleinsasser, & Roe, 2014; Meister & Nolan, 2001; Villaume, 2000; Zaslavsky, 2005). We question this assumption. Our research questions are:

- What did participants do to attempt to resolve uncertainty?
- What types of valence do participants assign to the uncertainty they experience? To what do they attribute the valence (the mathematics, the teaching situation, etc.)?

In this paper we examine a set of teacher responses to a teaching situation in which mathematical uncertainty was embedded. Our analysis is qualitative and interpretive. We do not attempt to generalize our claims to the general population of all teachers in forms such as "X% of teachers have valence type V". Rather, our goal is to generate a set of response patterns that teacher educators might consider in using such tasks and to consider the ways in which the participants' valence interacts with their attempts to resolve uncertainty. We begin by introducing the Williams item and its embedded mathematical uncertainty.

The Williams Item

This study focuses on teachers' responses to the Williams item (see Figure 1). This item was originally drafted as an assessment item to evaluate teachers' mathematical knowledge for teaching. Specifically, the item assesses whether the teacher is aware of limitations of the exponential identity $(x^a)^b = x^{ab} = x^{ba} = (x^b)^a$ in numerical expressions, in particular, for evaluating $\left((-9)^{\frac{1}{2}}\right)^2$. Although the identity does hold for nonnegative bases without issue, complications arise when the base is negative, or when $x < 0$. Applying the identity to the example expression yields a contradiction. The identity implies that $\left((-9)^{\frac{1}{2}}\right)^2 = (-9)^{\frac{1}{2}\cdot 2}$ $=(-9)^{2\cdot\frac{1}{2}}$ $=((-9)^2)^{\frac{1}{2}}$. However, $((-9)^2)^{\frac{1}{2}} = (81)^{\frac{1}{2}} = 9$, whereas $\left((-9)^{\frac{1}{2}}\right)^2$ is either undefined if square roots of negative numbers have not been defined yet, or $\left((-9)^{\frac{1}{2}}\right)^2 = (3i)^2 = -9$. In either case, the result is not equivalent to +9. Hence applying the exponential identity in this case constitutes an invalid application of exponential laws. The Williams item features the work of two students who have performed this invalid application of the exponential identity. One student, Craig, obtains +9, and the other, Katlynn, coincidentally obtains -9, the "correct" numerical answer, by an invalid process. The intended response is that neither student's application of the laws of exponents is valid. We use the term "correct" carefully here, as one complexity embedded in the item is that there is not an unambiguous correct evaluation of the expression the students have been given. It is true that over the complex number system the given expression evaluates to -9, but it is not clear whether the students are working in this system, and if they are assumed to be working over the real numbers, the "correct" evaluation of the expression is that it is undefined.

Ms. Williams is reviewing a set of homework problems on which students were asked to evaluate exponential expressions, including the expression $\left((-9)^{\frac{1}{2}}\right)^2$. Ms. Williams asks two students to share their work.

For each of the following student's work, indicate whether it demonstrates a valid application of the laws of exponents to solve the problem.

	Valid Application	**Not Valid Application**
Craig said: I used the exponent rule to change the order of the squared and the one half because that way you don't have to take the square root of a negative number. $(-9)^2 = 81$ Then the square root of 81 is 9.		
Katlynn said: I did it an easier way. 2 and $\frac{1}{2}$ cancel, so it's just -9.		

Figure 1. The Williams item (Copyright 2013 by Educational Testing Service).

There are a number of potential sources of uncertainty embedded in the item. A participant might be uncertain about what the students actually thought or did, or struggle to make sense of the student work as presented, although this was not a pattern we observed in the data and is not one we would classify as *mathematical* uncertainty. A teacher who is solving the item does not know in this situation whether Ms. Williams' students are working in the domain of real or complex numbers, an issue that makes the correct evaluation of the expression uncertain. This uncertainty does not affect the correct response to the question posed in the item, as laws of exponents have been applied incorrectly regardless, but *is* a source of mathematical uncertainty about the underlying mathematics in the problem presented to the students. This example resembles one presented by Tirosh and Even (1997) in which the expression $(-8)^{1/3}$ similarly can be argued to have different correct evaluations because the base is a negative number, and which Zaslavsky (1995) categories as a type of mathematical uncertainty called 'competing claims'. In this case, it is a claim that cannot be resolved because the uncertainty is embedded in the mathematics itself. Needless to say, a participant might simply not have encountered this mathematics before, leading to a different type of mathematical uncertainty, one that potentially could be resolved with greater familiarity.

Responses to this particular item, because of the embedded mathematical uncertainty, and because a large proportion of the teacher responses demonstrated uncertainty, afforded an ideal opportunity to examine patterns of reasoning in response to uncertainty. In particular, this item provides an opportunity to explore the strategies participants used to resolve their own mathematical uncertainty and the valences they attached to this process.

Methods

Context and Data

This study represents a secondary analysis of data originally collected as part of a larger project intended to provide validity evidence for a set of assessment items developed for measuring teachers' mathematical knowledge for teaching. The items used in this larger study were developed at the Educational Testing Service in 2013 following an assessment design theory that originated at the University of Michigan (e.g., Study of Instructional Improvement, 2008). The items require test takers to apply mathematical knowledge in the context of teaching. Teachers with secondary mathematics certification were selected to participate in think-aloud interviews in which they shared their reasoning for selecting each answer. Participants were selected for strong mathematical proficiency as measured by the Praxis secondary mathematics content test, and varied between 0 and 13 years of teaching experience. 14 participants were female and nine were male. The present study used transcript data collected for one item, the Williams item, because of the opportunity to observe engagement with mathematical uncertainty. The data set included 13 transcribed responses to the Williams item. Among these, four answered correctly that both students' work were invalid, eight responded that Craig's work was not valid but Katlynn's work was valid, and one responded both were valid.

Analysis

Drawing on thematic analysis, we conducted multiple iterations of theme searching from the transcripts. Thematic analysis is "a method for identifying, analyzing and reporting patterns (themes) within data" (Braun & Clarke, 2006, p. 79). Patterns, or themes, are not strictly defined in thematic analysis. A researcher may pick as a theme what was observed multiple times across the data. Alternatively, the researcher may pick impressive events that all together address the research questions. Because of such nature of thematic analysis, the themes are not easy to describe at the beginning of the analysis, but becomes clear towards the end of the analysis.

We began our analysis by each closely reviewing transcripts for the Williams item to produce an initial list of themes. We also noted the statements participants made about how they would deal with a situation such as that presented in their classroom teaching, which were occasionally prompted by the interviewer but more often spontaneous. We then narrowed the themes of interest to the following list, for which we systematically recoded the entire data set. Themes for which we coded data at this point were the presence (or absence) of explicit statements of uncertainty, the valence assigned to that uncertainty by the participant where applicable, the presence of incorrect mathematics in the participant's response, and the types of mathematical approaches each participant used to resolve uncertainty if approaches were taken.

Among these themes, the ones that stood out most strongly were those of type of mathematical approach and valence. Mathematical approaches were quite varied, in some cases sophisticated, and often showed signs of being potentially productive regardless of the end result. And statements reflecting valence were quite mixed, including some strong statements.

We grouped responses in which a mathematical approach was taken by type of approach, and we operationalized valence as a personal perception of uncertainty. Through multiple iterations of analysis with the data, we observed participants negatively framing their acknowledged uncertainty. Reading such cases from the transcripts, we came to see the gap between acknowledging uncertainty and welcoming uncertainty. We wanted to examine the relationship between valence, uncertainty, and teaching. From our observation of the data, we recognized that the participants can have positive, negative, or no valence to uncertainty. These observations informed us with refining the theme and selecting excerpts to share in this paper.

Results

We divide our results into two sections in which we describe teachers' responses to each of the research questions. First, we discuss the types of responses we saw from participants when confronted with uncertainty. Second, we discuss the valence they assigned it. Responding to each research question, we share major themes we encountered. These themes are major because they were worth attending to, not because they were most common. Thematic analysis allowed us to pick impressive events, instead of counting instances of each theme. We refer to participants by pseudonym numbers (e.g., "4016").

How Did the Participants Respond to Uncertainty?

Where participants were uncertain about the mathematics, responses fell into three categories. We first share the cases in which responses over-relied on the correctness of the numerical answer to determine validity. Then, we show cases in which responses demonstrated engagement in doing the mathematics in the moment to figure out the solution. These cases included a number of different and potentially productive mathematical approaches. Lastly, we present cases of seeking external resources to resolve the uncertainty.

Correctness of student answer

In responding to the item, some participants acknowledged their uncertainty but seemed to give the numeric answer the student produced disproportional weight as a signal of validity. For example, when determining the validity of Craig's work, a participant (4016) first determined the answer -9 using complex arithmetic and then compared her answer to Craig's answer, stating:

> So I disagree with Craig's answer as far as did he apply properties of exponents, yes he did, but he did not get the same answer that I deem valid, and therefore I think there is something wrong with his application.

The participant, however, did not explain what exactly is wrong with Craig's application of the law, and when prompted by the interviewer to guess at what might be wrong, stated, "I guess it's just some properties of exponents must not apply to imaginary numbers." This participant was aware of her uncertainty regarding the properties of exponents, and qualified her answer as a guess. Instead of exploring whether or not the properties of exponents applied, she relied on the correctness of the answers to determine validity. It is worth noting that this did not, for this participant, lead to an incorrect analysis of the second student's work. Participant 4016 concluded that Katlynn's work was not valid, even though it produced a correct answer, and engaged in exploration of why. However, the logic of discarding Craig's use of the exponent laws on the basis of it producing an incorrect answer is subtly flawed—in such a case Craig might have applied the laws correctly and have made an arithmetic error that produced the erroneous answer. Although it is mathematically valid to conclude that something about reasoning is incorrect when an incorrect answer is obtained, the item asks whether the error can be attributed to a particular source, not just whether the reasoning is on the whole invalid or valid.

It would be equally flawed to conclude that Katlynn's work was correct simply because it led to a correct answer. We did not see clear evidence of participants basing their answers only on Katlynn's answer, but we did see those in which responses seemed swayed by the correct answer. One participant (4023) simply stated that Katlynn's work was correct, and when pushed to explain why Katlynn could simplify the expression to -9 if Craig could not, said, "I mean she's got the right answer but actually I'll put a question mark in terms of like the way she did it," hinting that this participant must have considered the answer more heavily than the method in marking 'valid' as his answer for Katlynn.

In one striking case, interviewer error gave a window into how vulnerable a participant's reasoning can be to the correctness of answer. A participant (4020) engaged in strong initial reasoning about Craig's work, initially solving using complex arithmetic and correctly pointing to the sign of the radicand as a potential issue:

> If I do what this student [Craig] did I'm squaring –9 first, which gives me 81, and then I'm taking the square root of 81 and then that would be +9 so… So if, I guess if the number inside the radicand there was positive then it would be okay to assume that this would be good.

He goes on to conclude that Craig was making an "incorrect generalization," and when asked to explain the validity of Katlynn's work, he initially replied "1 and ½ I don't think that they cancel," indicating that he does not think Katlynn's work to be valid. The interviewer, who misheard the response, then made a mistake and asks how he would reconcile this with Katlynn's "correct answer", and the participant reported that he "didn't look at the final answer." He then changed his original answer, saying, "I'm squaring the square root, so actually that is valid, isn't it?" and went on to state that it would work for both negative and positive bases, which is not true. In other words, with only a slight prompt from the interviewer, a participant whose reasoning was quite strong to that point reversed course and presented contradictory reasoning to justify the student's correct answer, suggesting that the numeric answer influenced his thinking about the reasoning quite strongly. It is also worth noting that a number of participants, asked later in the interview how they approach figuring out if student work is valid in general, discussed the 'false positive' logic, when a student's answer is correct it could be simply coincidence and one needs in such case to dig more deeply into the reasoning. However, in several cases participants who made these statements still showed signs of being unduly influenced by the answer, indicating that perhaps even strong understanding of the pitfalls in general terms is vulnerable in the face of uncertainty around the underlying mathematics.

Mathematical investigation

The second type of responses we noted among our responses was that of engaging in mathematical investigations in an effort to resolve the uncertain mathematics. This is a response that the literature might describe as embracing uncertainty, and we view this type of engagement to be a positive response type in general as it has the potential to lead to deeper mathematical understanding. The examples we are sharing here, however, also show that *engaging* with uncertainty does not guarantee that the participant will respond correctly to the item. In some ways this may be a limitation of the data, which was not collected for the purpose of exploring uncertainty. Interviewers did not, in general, push participants to resolve uncertainty, as they were cautious to avoid leading the participants during the interview. Because of time constraints of the interview, they moved on from discussion once the desired evidence had been collected, and so we simply do not know whether participants might have reasoned through their uncertainty productively given sufficient time or support to do so. We describe the approaches below as *potentially productive* because from a mathematical perspective they are approaches from which one could reason to an understanding, not because these participants necessarily succeeded in doing so. Our purpose in noting this pattern of engagement is not to suggest a certain set of 'right' teacher approaches so much as to describe a set of reasonable approaches in ways that may support education researchers and teacher educators in anticipating possible teacher reactions to uncertainty in algebra. We discuss an algebraic approach, a graphical approach, and an approach involving examination of the boundary.

Algebraic approach

A number of participants engaged in an algebraic approach at some point during the course of responding to the item, in some cases in the course of evaluating the expression independently using complex arithmetic, and in some cases in unpacking the work of one or both students. In some cases the participant engaged in more extended mathematical investigation. We share the response of a participant (4028) who used an algebraic approach to understand Craig's work to solve the task in his own way, and then engaged in a more extended abstract investigation. When he first read Craig's work, it seemed plausible to him, and he unpacked line by line what he believed Craig to have done algebraically: "I said based on reading this sentence, yes, that makes sense. Powers of power, that's the rule, that how I remember them, powers of power, you multiply them, and when you multiply by two numbers is associative. So we can change the location, I just commute... So I said, oh that's going to work, so in that case 9^2 is going to give me 81, and then I do 81 to the 1/2 power that means square root, which is equal to +9." As he considered each line of Craig's work, he judged each step to be valid, and concluded initially then that Craig's work was valid, a reasonable conclusion. The participant goes on however, to do a deeper examination by solving the task in his own way:

> But after that, I said wait a minute, let me try this out on my own, and then I did my work down there if you see in that $(-9)^{1/2}$, and that give me the imaginary number I brought in the complex number system. And then $(3i)^2$ I got 9 times i^2 and in definition i^2 is –1. I got –9. So I said wait a minute, if I follow this the way to do it this outer from inner, from the inner computation go to the outer bigger picture, I got –9. But the first student got 9, okay that cannot be right.

The participant's algebraic examination, like other participants who solved the task in their own way, mainly involved computation with imaginary numbers. This algebraic examination led him to conclude that Craig's work is not valid because Craig's final answer was different from the answer he arrived at. At this point he potentially might have allowed the correctness of the numeric answer to overwhelming thinking, but instead he continued to explore, finding it necessary to figure out why algebraic steps that seemed reasonable to him would lead to an answer she believes is incorrect. He moved to a general case to explore further:

> I tried to write out the general case, that's……I'm thinking along the same rule, use letter A you see the numerical, algebraically, $(A^B)^C$ this is powers of power, this is the same as A^{BC} but since B times C we can commute we can rewrite as A^{CB} is equal to$(A^C)^B$. So that's really like what is the first student describe in words. And usually I take this view is correct, but based on the numerical calculation I did down there, it seems this answer going to change if A is negative in this case A is –9. So the correct answer should be –9 as I calculated. So that's how to me is a concept of my general experiment maybe not valid 100% depends what is A, B, C.

By moving to a more abstract representation of the rule Craig applied, the participant is able to articulate what it is he would generally consider correct and state that the contradictory evidence makes his question that conclusion. He continued to explore, stating:

> I'd written originally A, B, C belong to the real number, I do realize that, is this always true? That for B and C, that could be real? Whether it's a positive exponent or negative exponent I think that doesn't matter, but for the base... so that's why I erase A I put A belongs to R positive, or A is greater than or equal to zero I personally try to make a generalization here. But I'm not quite sure with this generalization I get is 100% right mathematically. And then I wrote a sentence, "If base A is a negative, then the rule does not always work."

The participant remained uncertain about whether the domain restriction he has identified is exactly correct as stated, but makes substantial progress through this exploration in figuring out what the key uncertain mathematics is and why it is uncertain.

Graphical approach

Another participant (4016) used a graphical approach to address her feeling of uncertainty about Katlynn's approach:

> I know that there is something weird about the way we define the square root, if you look at like the graph of $f(x)$ squared it's a parabola and it's in you know the first and the second quadrant but then if you take the inverse which would graphically be the equivalent of... reflecting over the line y equals x now you have a problem you would have like a sideways parabola in quadrant one and quadrant four but it won't pass the vertical line test, it won't be a function. So we just kind of say like oh no we're just going to take the positive part. And I think that kind of where some of the trouble occurs by the way that we define the square root. Because technically the inverse of squaring something is plus or minus the square root so it's not, the x^2 function doesn't have a true inverse, the inverse of the x^2 function is not a function so we have to have to kind of restrict the domain to make it a function, we say the square root has to be positive yeah. So then I was like well let me figure this out. So I decided to graph both of them like both ways like f of x equals the square root of x squared and when I did that I got the line $f(x)$ equals x but only when I took positive. Then I tried to graph it the other way and do $f(x)$ equals the square root of x^2 and I got the absolute value function.

The participant, who had already noted that Katlynn's answer was numerically correct, went on to attend to her method, and connected the cancellation to the relationship between a function y equals x^2 and its inverse, touched on the issue of restricting the domain, and used a graphic calculator to graph the functions. From this graphical investigation, the participant concluded that "squaring the square root doesn't give you back x all the times" and "the square root of x^2 doesn't always give you x all the time." The participant tried through this to come up with a viable argument on why Katlynn's method may not always work. That is, she actively explored mathematical uncertainty by taking a graphical approach. Although the participant did not articulate fully the set of domain restrictions under which Katlynn's method would be valid, her exploration was sufficiently productive to point her to the correct conclusion that Katlynn's method was not valid.

Examining the boundary

Some participants tried to determine the validity of student work by examining the boundary of the laws, specifically by selecting other test cases to see if the law would hold. For example, a participant (4020), once forced to confront the disconnection between Katlynn's 'correct' answer and her method, searched for example cases to justify why her method should be valid: "Maybe that is valid. Because if I would have done 100 times [inaudible] 1/2 to the square root I would get 10, 10^2 is 100. I'm squaring the square root, so actually that is valid, isn't it?" The participant applied Katlynn's strategy to 10, a positive number, and this selection may be intentional since the originally given value, −9 was negative. In general, selecting examples that are different from one another is a productive choice when testing the generality of a rule. In this case, however, it leads the participant to an erroneous conclusion because Katlynn's method does, in fact, work with positive bases regardless of the exponent. We note that we do not have strong evidence here to infer the classic error of using isolated examples to demonstrate the truth of a rule; this participant was not asked to provide a mathematical proof and was simply engaged in informal reasoning to try to make sense of an apparent contradiction. As mentioned above, he had been unintentionally prompted to conclude Katlynn's work was correct, so may have simply been looking for any explanation that would make this a plausible conclusion. His approach, however, had the potential to be productive, because testing a rule's generality by selecting well-chosen examples to test is typically a productive starting point.

Seeking external resources

A third pattern we observed was a willingness to draw on external resources. For example, when the interviewer asked a participant (4016) what she would do if Craig and Katlynn were in her classroom and were forced to respond, the participant said she would search on the web:

> I mean honestly I would just go try to Google and figure out what the problem is or I would tell them to think on it tonight and see what you can find online and I would definitely try to explore it further and come to like an answer. I don't have any problems with revealing my hesitancy in front of the students.

We point out this response type for a number of reasons. First, it is worth noting that it is also a potentially productive response to uncertainty. It might be argued, in fact, that in the moment of classroom teaching, pausing to engage in extended exploration might not always be appropriate, and finding a way to buy time by saving the question for another day is a strong pedagogical response. We often think of teachers as reasoning through difficult mathematical situations that come up in teaching in isolation and in the moment, but this participant reminds us that this need not be the case, that one can respond to students by simply saying 'I don't know but I'll find out" and by consulting with external sources—in this case via internet search, but perhaps also by consulting with colleagues or mentors.

Approaches were not mutually exclusive

We also note here that we have chosen to present responses from one participant (4016) as examples across three categories in order to illustrate that these response patterns were not mutually exclusive. Participant 4016 used one type of reasoning in considering Craig's work and another in considering Katlynn's work. She was willing and able to engage in mathematical investigation but still reported that if faced with such a situation in actual instruction she would likely turn to an external resource instead. Although she selected the intended answer to the item, that neither student's work was valid, she experienced uncertainty throughout her response, using phrases like "I'm not sure" and "my understanding is limited." But she also indicated a level of comfort with that uncertainty, seeming untroubled by revealing it to the interviewer, and stating explicitly that she would be comfortable revealing it to her students. This comfort with uncertainty hints at our second theme, the assignment of valence.

What Types of Valence Do Participants Assign to the Uncertainty They Experience?

In addition to how the participant reacted to the uncertainty, we examined statements in which they assigned valence to the uncertainty or to their experience of it. Not surprisingly, the valence varied. More surprisingly, we did not see many cases of negative valence even when respondents reported uncertainty or answered incorrectly, and the expressed valence did not show a strong connection with the approach taken to resolving the uncertainty; in other words, assigning a positive valence did not necessarily predict potentially productive investigation, nor did assigning a negative valence preclude it. In the next sections we describe what these statements of valence looked like when we saw them in the data.

Positive valence

One participant (4012) assigned a strong positive valence to uncertainty, demonstrating not just comfort but genuine excitement about the ways in which uncertain situations can be pedagogically useful:

> I have had times when I'm like whoa I didn't think about this, how did this happen? But the important thing is just that I just throw away back to my student. That's a very good observation, why did you think this happened? You know, it kind of makes

> them be more kind of curious about it, but then like I go home and I'm like dying, I'm like okay I got to figure this out why is this happening you know. But yeah... but it's very nice I love when situations like these come out because it forces to think of why, and also different ways to actually justify our thinking.

This particular participant did engage in mathematical exploration, and expressed explicit uncertainty throughout the interview, even saying "I had a hard time with this." In the end, despite her expression of need to figure out what is happening, she did not arrive at the intended answer to the item during the recorded interview.

Mixed valence

Participant (4014) expressed mixed valence. This participant, who self-identified to "have a pretty significant mathematical background," displayed a strong understanding of the inherent ambiguity in the expression and disliked the idea that Ms. Williams had presented such a task to students. As he commented:

> It gives you something, ambiguous is just like really the best word here it gives you something that's ambiguous. It doesn't define the meaning for you. Where mathematics is very precise in its meaning and its definition. And having such a question that creates such a gray area, kind of isn't that great, like you really shouldn't have that there but that's just my opinion.

This participant's negative valence originated from the task being "ambiguous," and unlike other responses seemed less about his own experience of uncertainty and more about his perception that the students would experience uncertainty in a pedagogically inappropriate way. He did, however, recognize the potential for other types of open tasks to elicit interesting classroom discussions:

> So there's this great problem where they're like "Can you raise an irrational number to an irrational number and get a rational number?" That's an amazing question and a great activity for a day or two for students to explore. And it's something I want to use with a different population of students who would be able to access that question more.

The two excerpts above shows that the participant appreciates uncertainty as what intellectually stimulates students to have mathematical discussions. We hypothesize that this participant has a positive valence to uncertainty that is originated from students' feeling, but has a negative valence to uncertainty that is from the mathematics in the task. In other words, it seems that the participant values students' mathematical exploration, but the exploration should only happen within a mathematically safe space. Teachers like this participant might not think that mathematical knowledge is open to revision (Ernest, 2004, 2015; Lakatos, 1976), hence inherently uncertain.

Discussion

In the first set of results we discussed a range of approaches that participants took toward the uncertain mathematics presented in the Williams item. We noted that the correctness or incorrectness of the given numeric answer seemed to be given disproportionate weight in some participants' thinking, at times overshadowing their thinking about the validity of the methods. Some participants explicitly mentioned being aware of the logical error in which one assumes that a correct answer means correct reasoning was used to reach it, but mentioning this did not seem predictive of resisting the influence of the answer. This may not be a shocking result—people do not always do in specific cases the things they describe as general approaches. But we wonder if it might also be a function of the uncertain mathematics. Confronted with uncertainty, there might be a tendency to fall back on methods for evaluating student work that are simply not valid methods even when the person doing so knows that they are not valid methods. Several participants fell into the accompanying error of assuming that because Craig's numeric answer was incorrect his method must also be without examining his work in detail. These examples suggest to us a number of points that might be taken up specifically in teacher preparation, including explicit discussion of the relationship (or non-relationship) between students' methods and their answers, but perhaps more importantly suggesting that prospective teachers need opportunities not just to discuss these things in general terms but also support in learning to recognize cases where these things might be happening in their own thinking.

Overall we observed many responses in which participants engaged in potentially productive mathematical investigations. We presented examples of an algebraic approach, a graphical approach, and an examination of the boundary, but recognize that this is only one way of categorizing these responses. Most of the algebraic approaches also might have been labeled as attempts to explore the generality of the rule, which has some overlap with exploration of boundaries, or we might have categorized those approaches in terms of use of examples or whether a general proof argument was attempted. We do not claim that our categorization is necessarily best or comprehensive, and certainly one would expect that different tasks would present opportunities to engage in different types of strategies. We called out these three approaches because we believe they are approaches that are likely to generalize to other task types and that therefore deserve attention in teacher preparation. The participants of this study demonstrated their *mathematical habits of mind* (Mark, Cuoco, Goldenberg, & Sword, 2010) by looking at extreme cases or using abstraction. That is, the embedded mathematical uncertainty provided an opportunity for the participants to practice their mathematical habits of mind. This seems particularly important to attend to in the context of the CCSS standards for mathematical practices, which ask teachers to help students learn how to engage in some of these very habits. Situations in which uncertainty is available might constitute the very opportunities teachers need to model this type of engagement to their students as they themselves think through the mathematics in a public way.

The second set of results in which we observed the valence assigned to uncertainty is harder to interpret. We expected to see case of strong emotional reaction to the item, as is often the case with tasks that participants find difficult. We also expected we might see a fairly simple relationship between valence and approach in that people who experienced uncertainty as positive might engage productively, but the story was more complex. We see from the data that we cannot predict the participants' correctness of their responses from their valence. We also see that with the valence, we cannot predict whether they would deeply engage with the uncertainty. We observed cases where valence was assigned to different aspects of the uncertainty at in different ways. All this are to say that the relationship between valence assigned uncertainty and meaningful mathematical investigation is not straightforward.

Being aware of this complexity between valence and resolution of uncertainty is important for teacher educators and researchers. Teacher educators should be careful not to assume that teachers with negative valence will not engage with uncertainty and those with positive valence will conduct an in-depth mathematical investigation or will know how to do so productively. This awareness is important for researchers, too, because teacher valence is often not explicitly addressed in the literature. While literatures encourage teachers to acknowledge uncertainty, we would argue that *acknowledging* uncertainty should not be interpreted as having a positive valence toward uncertainty. Our examination presents cases suggesting that the relationship between valence and engagement might be more complex than we thought, and therefore further examination on such matter is necessary to support better teacher learning.

We learn from literature that cultivating an orientation toward engaging with uncertainty is important for teacher development (e.g., Capobianco, 2010; Meister & Nolan, 2001; Munthe, 2001, 2003; Munthe & Thuen, 2009; Wheatley, 2005), but this is clearly only the first step. Teachers also have to have ways to work *productively* with that uncertainty, regardless of the valence they assign it, in order to figure the mathematics out for themselves. To teach students to engage in mathematics by exploration, teachers must think about modeling the practices as they engage in order to utilize uncertainties as opportunities to learn.

Conclusion

The examples we shared in the paper, rather than providing a catalogue of responses, present possible approaches teachers can take. The point of these examples is to illustrate that uncertainty is a slippery space in which teachers' mathematical and emotional response varies, and one that can easily arise even in the context of fairly simple mathematics. We do not advocate a "right" response to uncertainty, but think that these considerations might be useful to teacher educators in considering how to prepare teachers for dealing with such situations. We see a strong potential of uncertainty as a resource for teacher education. We draw on the notion of *specialized content knowledge* (Ball, Thames, & Phelps, 2008) to understand the potential of uncertainty. When responding to the Williams item, the participants used mathematics to understand student work. That is, uncertainty from the item invited the participants to use mathematics that are unique to the teaching situation.

We echo Zaslavsky's (2005) suggestion to include tasks with embedded mathematical uncertainty in teacher education to cultivate mathematical understanding. We take a step farther and claim that teachers should be supported in acknowledging uncertainty, confronting and engaging it, finding productive approaches, articulating those approaches, and thinking through how such moments could be transformed into "teachable moments." This is partly mathematical skill, partly an emotional response to uncertainty, and partly developing a disposition that values such opportunity. The field has acknowledged the importance of teachers' modeling the mathematical practices for their students (e.g., Charalambous, Hill, & Ball, 2011) and we posit that the best modeling may come in response to a genuine, unexpected mathematical problem in a case where the teacher truly does not know the answer. By providing teachers opportunities to engage in mathematical uncertainty, we expect them to become more skillful at productively responding to uncertainty, and in turn more able to model such practice in front of their students. Teacher educators needs to provide opportunities for novice teachers to engage in approximations of the work of teaching (Grossman, Compton, Igra, & Ronfeldt, 2009), where responding to the range of unexpectedness presented by classroom interactions (Coles & Scott, 2015; Mason, 2015) is part of that work of teaching, and one type of unexpectedness can be in the form of uncertain mathematics. Responding to mathematical uncertainty is not simple, and we see it comprises at least the following steps: (a) notice their uncertainty about what a student is proposing (b) understand that it might be worth pausing for or attending to (c) constructively direct the class in a way that leaves the question open and allows time to think (d) explore the uncertain mathematics and (e) make a judgment about how to engage the students productively depending on the result of that exploration. We believe that engagement with appropriate tasks can provide opportunities for prospective teachers to practice performing each of those steps, with appropriate support.

Reasoning about changes: a frame of reference approach

Surani Joshua
Arizona State University

In a RUME 18 Theoretical Report, my co-authors and I presented our cognitive description of a conceptualized frame of reference, consisting of mental commitments to units, reference points, and directionality of comparison when thinking about measures. Here I present a pilot study on how a focus on conceptualizing a frame of reference impacts students' ability to reason quantitatively about changes. The two-part empirical study consisted of clinical interviews with several students followed by teaching interviews with three students, who were chosen because of their varying abilities to conceptualize a frame of reference. This initial evidence shows that the ability to conceptualize a frame of reference benefits students as they attempt to reason with changes.

Keywords: Frames of Reference, Quantitative Reasoning, Quantities, Changes, Additive Comparisons

In a RUME 18 Theoretical Report , my co-authors and I presented our cognitive description of a conceptualized frame of reference (Joshua, Musgrave, Hatfield, & Thompson, 2015). At the same time, my experiences working with reform curricula for Precalculus (Marilyn P. Carlson, Oehrtman, & Moore, 2013) and Calculus 1 (Patrick W. Thompson, Byerley, & Hatfield, 2013) at a large Southwestern public university led me to be surprised at how much students struggle with thinking and reasoning about changes. Rate of change is known to be a central idea in calculus (Marilyn P. Carlson, Jacobs, Coe, Larsen, & Hsu, 2002), and important to introduce as early as Algebra 1 with the idea of slope. But in order to reason about rate of change, a student must be able to conceptualize and reason about changes themselves.

My own anecdotal data and conversations with other Precalculus and Calculus 1 teachers showed that students frequently struggled with conflating the idea of a total quantity's measurement with a change in a quantity's measurement. These discussions led me to realize that a fundamental differentiation between measures of total quantity and change in quantity is coordination of reference points from which to measure. Hence, student struggles in reasoning with and about changes fit squarely within my current research topic of frames of reference.

Theoretical Perspective

A survey of both math education and physics education literature revealed few papers that focused on student thinking about frames of reference (Bowden et al., 1992; Dede, Salzman, & Loftin, 1996; Marshall & Carrejo, 2008; Monaghan & Clement, 2000; Panse, Ramadas, & Kumar, 1994; Shen & Confrey, 2010) and many of those did not explicitly state what they meant by a "frame of reference", taking that phrase to have a shared meaning between the authors and the readers; even a paper on alternative conceptions of frames of reference (Panse et al. 1994) only stated what a frame of reference is *not*. However, it is not clear that there is a shared definition of a frame of reference in these fields. The few concrete definitions we found in the literature or textbooks ranged from physical objects like "welded rods" (Carroll & Traschen, 2005), or "a set of observers" (de Hosson, Kermen, & Parizot, 2010) to a coordinate system (Young, Freedman, & Ford, 2011).

More significantly, none of these definitions focus on the cognitive actions of a student that is thinking about *measures within a frame of reference*. In tasks that involve thinking about a frame of reference (such as relative motion, special relativity, etc.), the focus of the task is never the frame of reference itself. Rather, it is that a student must organize the measures of quantities such as distance, velocity, and time within one or more frames of reference in order to keep track of what those measures mean. In a 2015 paper, my colleagues and I introduced our cognitive definition of what a conceptualized frame of reference entails:

> An individual can think of a measure as merely reflecting the size of an object relative to a unit or he can think of a measure within a system of potential measures and comparisons of measures. An individual conceives of measures as existing within a frame of reference if the act of measuring entails: 1) committing to a unit so that all measures are multiplicative comparisons to it, 2) committing to a reference point that gives meaning to a zero measure and all non-zero measures, and 3) committing to a directionality of measure comparison additively, multiplicatively, or both (Joshua et al. 2015).

One important implication of our definition is that it places frames of reference squarely within the larger construct of quantitative reasoning (Patrick W. Thompson, 1993a). Though people may frequently speak of a frame of reference as a noun, it is actually a set of decisions that a person makes about how to think about quantities and their measurements. Thompson writes "[a] person constitutes a quantity by conceiving of a quality of an object in such a way that he or she understands the possibility of measuring it" (Patrick W. Thompson, 1993b). In 2015 we expanded on his previous definition by defining a *framed quantity* "which refers to when a person thinks of a quantity with commitments to unit, reference point, and directionality of comparison".

Our definition expands the utility of frames of reference from its traditional application of relative motion to almost any situation in which quantitative reasoning is necessary. Of course, our definition provides a strong starting point to analyze student difficulties for working with relative motion. However, we have already identified additional contexts were these ideas can be applied: concavity of functions, rate of change, electric potential, and the difference between quantity and change in quantity.

Research Questions & Methodology

My initial hypothesis was that student struggles in reasoning with and about changes were due at least in part to the fact that measures of changes in quantities had reference points and directionality, but that they did not think about *framed quantities* – quantities whose total measures necessitated commitments to unit, reference point, and directionality of comparison in order to make sense of them. Therefore, they did not have parallel attributes with which to compare and contrast the ideas of quantities versus changes, and to distinguish the two in their minds. From this hypothesis I developed seven research questions for this pilot study, four of which are discussed in this paper.

Changes in Quantity vs. Values of Quantity:

- RQ#1: How do students conceptualize a change in a quantity versus the value of a quantity?

- RQ#2: Does a focus on frames of reference affect students' ability to reason about changes in quantity and values of quantity, by drawing explicit attention to reference points?

Changes in Changes:

- RQ#3: How do students think about changes in changes, in tasks such as being asked to identify whether a function is increasing/decreasing at an increasing/decreasing rate?
- RQ#4: Does a focus on frames of reference affect students' ability to reason about changes in changes, by drawing explicit attention to a directionality of comparison?

To investigate these research questions, I designed and carried out an empirical study on the connections between a student's ability to conceptualize a frame of reference and his or her ability to reason about changes that involved both clinical and teaching interviews. Clinical interviews are conducted for the purpose of gathering information about a student's current understanding; with such a goal it would be counterproductive to engage in any form of teaching, including questioning designed to help the student make connections. In contrast, teaching interviews developed as a data-collecting tool in the 1970s because "researchers explicitly acknowledged that mathematical activity in school occurs as a result of students' participation in teaching" (Steffe & Thompson, 2000). The goal of a teaching interview is to ascertain both a student's current understanding and to examine how and to what extent a student progresses in understanding in the context of teaching (such as probing or guiding questions, didactic objects (P. W. Thompson, 2002), conversations with the interviewer, direct instruction, etc.). Even with a teaching interview, a student's progress is still affected by the mental resources that she brings to the interview, and a teaching interview can help to illuminate those resources.

The first part of the study consisted of clinical interviews with seven students who had taken at least one algebra class and one physics class in college or high school. These interviews helped me form models of each student's current ability to conceptualize a frame of reference. I then picked three students that I found demonstrated varying abilities to conceptualize a frame of reference. Hayden, a recent college graduate in graphic design, consistently gave high-level responses that were situated within a frame of reference and referred to directionality and reference points when explaining his answers. Miranda, a biochemistry major in a reform Calculus 1 class, performed at a medium level, sometimes giving answers that indicated a conceptualized frame of reference. Luigi, a full-time worker with an Associate's degree, rarely gave answers situated within a frame of reference and often could not explain his answers. The second phase consisted of teaching interviews with these students to study to what extent their varying abilities to conceptualize a frame of reference would help them to move forward in their ability to reason about changes.

All interviews were videotaped and analyzed to form models of how the student thought about measures and measure comparisons before, during, and at the end of the teaching experiment. I also used the videos to build hypotheses about how these ways of thinking about measures (within a frame of reference or not) affected each student's ability to reason about changes. For Luigi's interview the video recording malfunctioned, so I wrote detailed notes with Luigi directly after his interview.

Results from Clinical Interviews

In this section I present results from the clinical interview stage of this study. I focus on tasks that elicited responses that helped me to build models of how Hayden, Miranda, and Luigi did or did not conceptualize a frame of reference.

Land of the Midnight Sun

The second part of our cognitive definition of a conceptualized frame of reference is that a person commits to a reference point that gives meaning to both a zero measure and all non-zero measures. To see to what extent my students could make such a commitment, I created the graph in Figure 2 of a flagpole's shadow length in an imaginary Land of the Midnight Sun, where there is sunshine in the middle of the night. The labels "length of shadow" and "o'clock" on the axes were left deliberately vague.

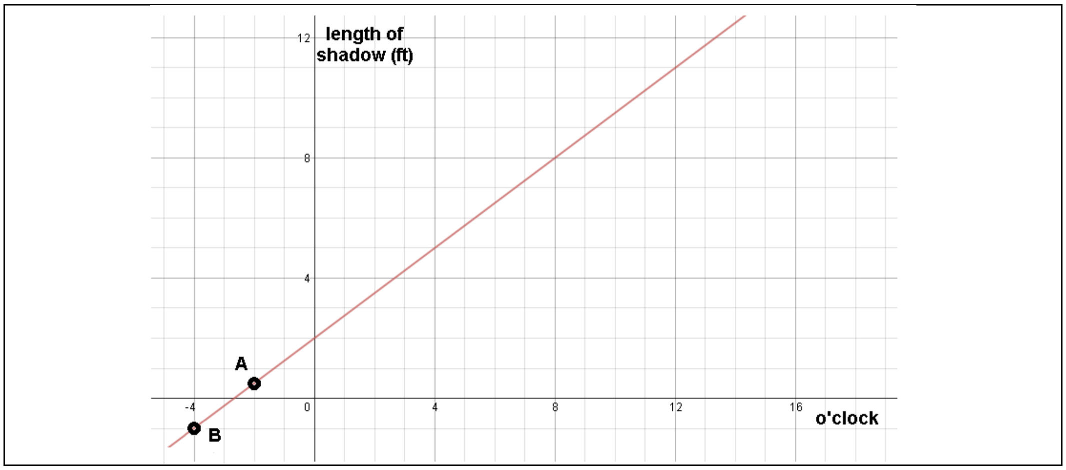

Figure 2. Land of Midnight Sun graph.

Part 1's purpose was to make sure that the students understood what the vague axes labels meant. They were shown the portion of the graph for x ≥ 0 and asked "What does this point mean?" while highlighting the points (4, 5) and (14, 12.5); all three easily said that at 4am the shadow was 5 feet long and at 2pm the shadow was 12.5 feet long.

For Part 2, I extended the visible graph to the domain x ≥ -3 so that point A was visible, and asked the students what the meaning of point A was. Hayden immediately said that at 10pm the night before the shadow's length was 0.5 feet. When asked how he decided that the time was 10pm, he said "It's like this 12 o'clock is the point of reference of when to use…". Miranda originally said that point A was the length of the shadow at 2 o'clock, but with some prompting was able to say 10 the night before. There was a clear difference in how Hayden and Miranda thought of measures of time; while Miranda seemed to have some idea of using zero/midnight as a reference point, her meaning for her own reference point did not help her to find meanings for negative measures. In contrast, Hayden's explicit mention of a reference point and immediate response showed that for him the reference point gave meaning to all non-zero measures both positive and negative, which is the second part of our 2015 definition of a conceptualized frame of reference introduced in the Theoretical Perspective above.

In Part 3 I showed the entire graph and asked the students to interpret the meaning of point B. Here Miranda started by assuming that the meaning of point B somehow related to the area under the curve. When asked to justify her answer she eventually said that the length had started increasing again as time went backwards. Luigi clearly stated that the shadow's length was 1 foot, and when questioned further he merely shrugged and smiled and said that he didn't know how to account for the negative. He did not seem upset by his lack of a systematic way to deal with the negative. Hayden was the most clear, saying that "the fact that it's going negative in feet now could mean one of two things. It could mean the shadow is just like going beyond existing, which is not realistically possible, so… The other explanation would be that the shadow is now going in the opposite direction. So, if the shadow was extending to the right, now it's extending to the left." Here Hayden was incorporating both a commitment to reference point and a commitment to directionality of comparison that allowed him to make these comments; these commitments are the second and third parts of our 2015 definition of a conceptualized frame of reference.

Hayden, Miranda, and Luigi revealed their varying abilities to commit to a reference point by their treatment of the vague axes labels. This task was designed to answer the question 'What meanings could each student give to the definition of zero on each axis so that negative measures made sense?' Miranda and Luigi were unable to give such productive meanings to 'zero o'clock' and 'zero shadow length' while Hayden could. This suggests that Hayden had ways of thinking – specifically, committing to a meaningful reference point and directionality of comparison - available to him that Miranda and Luigi did not have. Because of this he was able to work with a conceptualized frame of reference, as defined by our three-part definition above, to make sense of all the interview tasks in a coherent way.

Comparing Spousal Heights

The third part of our cognitive definition of a conceptualized frame of reference is that a person commits to a directionality of measure comparison additively, multiplicatively, or both. If a student always calculates changes by saying "3 less pounds" or "4 more pounds", then the student is constantly changing her directionality of comparison to keep the comparison measures positive. The measures themselves (3 and 4) do not carry all the information needed to make sense of them. While this is usually not a problem for a single comparison, it becomes extremely important when reasoning about multiple comparisons.

As with my unit task, I did not expect students to spontaneously commit to a directionality of measure comparison. Instead, I created a series of increasingly detailed questions and looked to see how much prompting (if any) could elicit such a commitment. Even though this was still part of the clinical interview, it was also the first time I had an opportunity to ask the students about changes (additive comparisons).

husband's height (ft)	wife's height (ft)	
5.6	6.2	a) Compare the heights of each couple.
3.2	4.9	b) How much taller or shorter?
6.1	5.9	c) Now only use the words "taller than"
4.8	3.2	d) Now only use the phrase:
5.9	7	"Wife is ___ taller than husband"

Figure 3. Comparing Spouses' Heights Task

All three students did not maintain a directionality of comparison for prompts a-c. When I asked them to maintain a comparison from one spouse to the other and also maintain the comparison "taller than" Luigi was unable to do, and Hayden and Miranda had similar answers but with very different levels of comfort, which demonstrated their varying abilities to conceptualize a frame of reference.

Hayden: So, the wife is point 6 feet taller than the husband in the first couple. Second couple; the wife is four…second couple, the wife is 1 point 7 feet taller. I guess I have to use the word taller?

Interviewer: Yeah. Than the husband.

Hayden: Than the husband. Okay. So, if I have to keep saying the wife first, then uh... use the word taller, then the wife is…The third couple, is negative point 2 feet taller than the husband. And for the fourth couple, the wife is negative point 6… negative 1 point 6 feet taller than the husband. And the last couple, the wife is 1 point 1 feet taller than the husband.

Interviewer: Okay. You hesitated before you did the third couple. May I ask why?

Hayden: Cause usually when talking about people's height, you don't really use a negative number. So I just had to think for a second… like, if that's the way that I wanted to describe it.

Interviewer: Okay. Can you tell me about why you decided that's the way you wanted to describe it?

Hayden: I mean, given the parameters, there's not really much else… other way you can describe it. If you have to use the word wife first, and if you have to say taller, there's not that many other ways to describe it.

Interviewer: Do you think that that is actually a mathematically legitimate way of describing the situation?

Hayden: I'd say it's a similar situation to the graph before [Midnight Sun task]. So, where in this case the negative number either means that there's such a thing as negative length. Like, theoretically, like measuring something that you would actually be able to measure negative amounts. Or it means that it's going in the opposite direction. In this case, it would technically mean shorter, even though you're using the word 'taller'.

Interviewer: All right.

Hayden: So, like if I'm …if someone's shorter, then basically negative taller would be shorter, or negative shorter would be taller.

Interviewer: Now, say that sentence, and be filling in the blank each time.

Miranda: Can I say… do I have to say taller?

Interviewer: You have to say 'the wife is blank taller than the husband.'

Miranda: Okay. The wife… For couple one the wife is point six feet taller than the husband. For couple two, the wife is one point seven feet taller than the husband. For couple three, the wife is not…hmm. For the wife…I don't think…

Interviewer: Just say whatever you feel should go in that blank. Honestly.

Miranda: There's two things that could go.

Interviewer: Okay. Go ahead.

Miranda: Okay, so the first thing is; the wife is not taller than the husband, but the husband is one point two taller than the…wait. Hold on. The wife is not taller than the husband, but the husband is taller…is point two taller than the wife in terms of the change between the wife and the husband. (Laughs)

Interviewer: Okay.

Miranda: Or you could just say the wife is negative point two feet taller than the husband.

Interviewer: Out of those three things, which one do you instinctively go towards, and also which one do you suspect is probably, like, the most mathematical way of saying it?

Miranda: Negative two is the most um…mathematical way of saying it.

Interviewer: And what was your instinct?

Miranda: I just want to switch it to make it positive. So, I just want to switch the…I want to switch the – the input and output …so it's the… it's supposed to be less…it's less confusing.

While maintaining a directionality of comparison in this task was not natural for either Hayden or Miranda, Hayden quickly adjusted to my request and made reference to earlier tasks in which he had made and maintained mental commitments so that all of his responses were coherent. His spontaneous explanations at the end of the excerpt and his analogy between the couple's height task and the midnight sun task showed that he thought about both kinds of measures within a consistent system – a conceptualized frame of reference. In contrast, Miranda had a vague understanding that a negative was a mathematical tool likely to be useful in this task, but was deeply uncomfortable with using it. Both her words and her body language indicated that she was giving her answers against her own better judgment, which indicates that if she was not repeatedly pressed to do so she simply would not commit to a directionality of comparison and therefore not conceptualize a frame of reference within which to think about such tasks.

The husband and wife height's task was followed by a red car vs. blue car speeds task that was formulated in the exact same way, except that one car's speed was always an integer multiple of the other's speed. In order to maintain a directionality of comparison a student would have to go from, for example, "Red car is 5 times as fast as blue car" to "Red car is 1/3 times as fast as blue car." I was surprised to see that all three students completed the car speeds task with much less discomfort! Their speed in coming up with statements could be explained by the fact that they were primed by the couple's heights task, but the difference in their comfort levels and body language was evident. This difference in comfort between maintaining a directionality of comparison additively and multiplicatively will be a point of focus in my further study, and I plan to have the cars going in different directions to see how students coordinate both additive and multiplicative comparisons.

The data from clinical interviews shows that Hayden, Miranda and Luigi had varying abilities to conceptualize a frame of reference. Luigi could not commit to either a reference point or a directionality of comparison, Miranda could partially commit to both in somewhat vague ways that were not always productive, and Hayden could commit to both a reference point and directionality of comparison in ways that allowed him to move forward on tasks.

Results from Teaching Interviews

Of the seven students who participated in the clinical interviews, I chose Hayden, Miranda, and Luigi to participate in teaching interviews because of their varied abilities to conceptualize a frame of reference and their willingness to verbalize their thinking. In this phase my primary goal was to examine these students' ability to reason about changes, and to look for any indications that their reasoning did or did not involve a conceptualized frame of reference.

Tom and Padma

The Tom and Padma task is designed to see whether students understand that all quantities are measured with respect to a reference point, and that any choice of reference point is arbitrary. A total quantity's measurement is therefore a change from a measurement of zero, and what we call a change in quantity is a change from any starting point. Yet even a measurement of zero depends on the definition of the quantity itself. In any given task "total water I drank" might be this day or week but is likely not all the water I have drunk in my entire life, "total wheat sold" is never defined as since man first crawled out of the oceans, and "velocity" by the principle of relativity (citations) has no absolute zero except with reference to another object taken to be at rest. Even what we commonly call "zero velocity" is only a change of zero in velocity with respect to the surface of the Earth.

To see whether the students could, with help, reason about velocity measurements as changes, I created the two-part Tom and Padma task. All three students got stuck and fell silent after 5-7 minutes, so I started asking them about what an observer from space would see to try and elicit a definition of velocity measurement that was specifically with respect to the surface of the Earth. My hypothesis was that once a student acknowledged that even our "everyday" velocity measurements were with respect to a reference point, they might conclude that all velocity measurements have a reference point as well.

> Tom watches Padma's car go by, makes some measurements, and announces that Padma's car is moving at a speed of 15 mph. What can you tell me about the car?
>
> What if I tell you that Padma's car continues at the same constant speed, and ends up making a 200 mile trip in only 4 hours? How can this be? Note: Tom did everything correctly.

Figure 4. The Tom and Padma task.

Miranda had a great deal of trouble with Tom and Padma, asking if Tom only measured the very beginning of her trip when she accelerated, Tom incorrectly measured the time, or that Tom made incorrect calculations. Then, nine minutes after she started working on the task, she made a sudden breakthrough.

Interviewer: How could I look at this [pencil on desk] and say, 'this is at rest?' It's at rest relative to what?
Miranda: My position in time?
Interviewer: Actually, your position in space, right?

Miranda: In space!

Interviewer: Not time. Right now, it's not moving with respect to you, right?

Miranda: No.

Interviewer: Anything else that's not -

Miranda: ***WAS HE RUNNING??!?!***

Interviewer: - moving with respect to you?

Miranda: Was... (laughs and smiles) If he's moving…or was he…. Does this mean…okay…if he's going…if this is slower…Okay…mmm… if this car….

Interviewer: Do you need this pencil?

Miranda: Yes! [Picks up both pens to represent Tom and Padma] (laughs) If this car is going this fast, and he's going really slow…[moves pens parallel to each other, one faster than the other] er, like, he's not at a constant place if this is going super fast, and he thinks it's going really slow…so…does that mean that…ah…is that…. (shakes pens)

Interviewer: Yes!

Miranda: Does….Yeah?

Interviewer: Yes! Yeah!

Miranda: Yeah? He's going really slow and the car's going really fast? That is how you think it is?

Interviewer: Right. Tell me…can you tell me-

Miranda: Like fifteen miles per hour?

Interviewer: Can you be really specific…exactly what's going on, so that he thinks… he honestly…like it is accurate to say, right? Isn't it accurate to say that this [pencil] is at rest with respect to Brittany right now?

Miranda: Mmm hmm.

Interviewer: It's also accurate to say that it's moving with respect to what? What is it moving with respect to?

Miranda: Space.

Interviewer: The problem is, what's space? (laughs) Give me something specific instead of space. Something else that's out there.

Miranda: The speed of light!

Interviewer: That is not an object….or a location.

Miranda: Hmmm.

Miranda was able to see that if Tom was running, as she put it, he could accurately measure Padma's speed as less than 50mph, but that qualitative description was all she could achieve. We spent a total of 45 minutes on the Tom and Padma task (at her request, she did not want to give up) and she could never tell me that Tom must be driving at 35mph on the road to measure Padma at 15mph. Luigi was able to say that Tom must be moving after only a few minutes of thinking, but also was never able to tell me how fast Tom must be going. Neither Miranda nor Luigi could think about the different velocity measurements within conceptualized frames of reference, and so could not coordinate them to finish the task.

In contrast, when Hayden realized that Tom could be moving, he conceptualized both measures of Padma's speed as framed quantities, and could then reason about a change between them. As for the other two students, after he was stuck for 6 minutes I engaged him in a discussion about how we measure velocity.

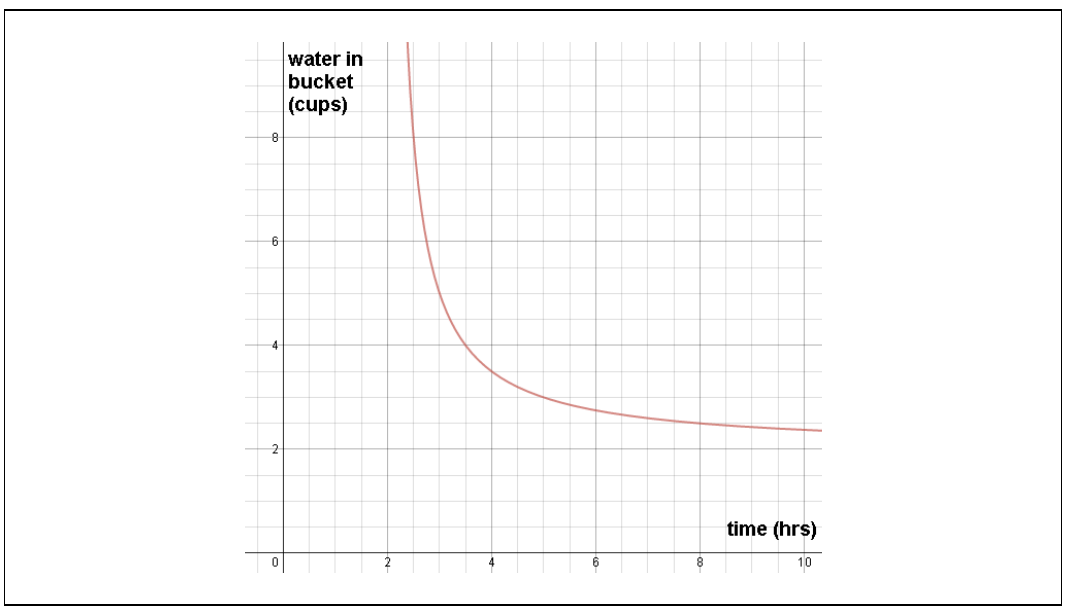
Interviewer: Now imagine the solar system. And the earth is whirling around the sun.
Hayden: Okay. Yes.
Interviewer: And the earth is spinning on its axis. And Padma's driving. Are you sure that her car's going at 50 miles an hour?
Hayden: Ohhhh. It's um, if you weren't factoring in the speed of the earth's rotation, she would be going 50 miles an hour, but if you factor that in, technically she would be going faster than that.
Interviewer: So…can that give you a hint as to what, maybe, is going on here?
Hayden: So, I was making the assumption that we are just considering like, just space… I was going to make the assumption that we were just talking about like, driving like from here to Las Vegas, or something…and just considering that distance on the earth's…
Interviewer: Okay.
Hayden: …just on the earth's surface itself.
Interviewer: Wonderful. On the earth's surface. Or with respect to the surface of the earth.
Hayden: Yeah
Interviewer: Good, okay. Now. You make that assumption, but that assumption is not here. So, how could Tom have taken this measurement and gotten a true 15 miles per hour?
Hayden: [after brief diversion where he tries to incorporate planetary speeds] So, if he's going… so if he's also moving, then technically he would get some reading that's less than what the speedometer is.
Interviewer: Could there ever be more?
Hayden: If he was going the opposite direction.
Interviewer: Wonderful. So, you're saying that he's moving in the same direction?
Hayden: Yes.
Interviewer: Okay. And do you know how fast he was going?
Hayden: [after first correctly saying that Tom was going 15/50 as fast as Padma] But, um… see, he would have to be going 35. Yes, 35.

Not only could Hayden reason that Tom was going in the same direction as Padma at 35mph with respect to the surface of the Earth, but also he spontaneously commented that Tom would measure Padma's velocity as more than 50mph if he was going in the opposite direction from Padma. He was able to use 15mph and 50 mph as framed quantities in different conceptualized frames of reference and coordinate the two frames to reason about changes between them.

There is a clear difference in the way Luigi, Hayden, and Miranda were able to move forward in reasoning about changes with my guiding questions about velocity that address Research Questions #1 and #2: 'How do students conceptualize a change in a quantity versus the value of a quantity?' and 'Does a focus on frames of reference affect students' ability to reason about changes in quantity and values of quantity, by drawing explicit attention to reference points?' Luigi was able to discern that Tom was moving after only a few minutes, and Miranda came to the same conclusion after nine minutes, which meant that they were eventually able to conceptualize velocity measurements as a change in velocity with respect to another object taken at rest (in this case Padma's measurement of her own speed held the surface of the Earth to be at rest, and Tom's measurement of Padma's speed took held *himself* to be at rest). However, neither were able to utilize these realizations to reason that when both measures are considered within a single conceptualized frame of reference, such as the one Padma used, then Padma's speed measurement is a quantity and Tom's speed measurement is a change in quantity. Without this ability to coordinate quantity versus change in quantity, neither were able to make a conclusion about how fast Tom must be going to make sense of the task. Hayden, whose clinical interview showed that he was able to conceptualize a frame of reference, could complete the task by coordinating changes, which required him to commit to reference points for both Tom and Padma's measurements of Padma's speed. Moreover, he was also able to move beyond the planned task to reason about how Tom might measure Padma's velocity as more than 50mph by committing to a directionality of comparison of [Padma's velocity with respect to Earth's surface] – [Tom's velocity with respect to Earth's surface] = [Tom's measurement of Padma's velocity].

Leaky Bucket Task

The leaky bucket task is designed to see if students can reason about changes in changes. The graph in Figure 5 shows the relationship between time and the number of cups of water left in a leaky bucket. Because Luigi was showing signs of discomfort and stress I skipped this task with him and only presented it to Hayden and Miranda.



a) What is happening to the water as time increases?
b) Starting with point (2.5, 8) can you illustrate how much the water changes as the time increases by 0.5 hours?
c) Can you illustrate changes in water along the entire graph for x-intervals of length 0.5 hours?
d) Look at the changes in the water as time increases. What can you tell me about the changes?
e) If necessary: Can you also tell me how the changes are changing?

Figure 5. Graph and Prompts for Leaky Bucket task.

Both students struggled with prompt d. To describe the set of changes drawn in prompt c, a person can say that the changes are negative, and that the changes are increasing as time increases (since the sequence -3, -1, -0.5 is increasing). In order to conclude that the changes are negative a student needs to choose a directionality of comparison $f(\text{time}_{\text{final}}) - f(\text{time}_{\text{initial}})$, and to conclude that the changes are increasing a student needs to continue to commit to that same directionality. While both students chose the above directionality and said that the changes were negative, both then broke that commitment and used a comparison [larger change] – [smaller change] to conclude that the changes were decreasing.

Interviewer: So, as time goes by, what is the water doing?
Hayden: So, the water is decreasing.
Interviewer: Decreasing. Okay…. First let's just look at the changes in time. So look at these changes. Are they increasing, decreasing, or staying the same?
Hayden: Staying the same. Each one's half an hour.
Interviewer: Now, what about these changes?
Hayden: The change is becoming less and less…each time.
Interviewer: Okay. So the change is…
Hayden: So the greater change is first, and it's getting to the less of a change.
Interviewer: Are the changes increasing, decreasing, or staying constant?
Hayden: Decreasing.

Miranda gave a similar response to Hayden. I then asked both students to estimate the value of each change. Hayden did so and initially tried to tell me whether the changes of the changes were increasing, decreasing, or staying constant, but when I redirected him to speak about the changes he said they were increasing.

Hayden: Oh, yeah. But like the size between, if I actually took like accurate measurements and put it on a timeline the size between these changes would start decreasing. So like, E [fifth labeled change] would be closer to D [fourth change] than B [second change] would be closer to A [first change].
Interviewer: So, as we're going from A to E are the changes increasing, decreasing, or staying the same?

Hayden: Okay. That's what you meant by that. I thought you meant something else.
Interviewer: Tell me what you meant by something else.
Hayden: I thought you meant like, was the distance between the two changes… like was it like a greater amount of change, or was it a less amount of change.
Interviewer: Right. Well, you're talking about comparing the changes of changes.
Hayden: Yeah.
Interviewer: But what about comparing the changes?
Hayden: The changes themselves, it's increasing each time.

When I gave Miranda the same prompt to estimate the changes, she found a negative increasing sequence but continued to say that the changes were decreasing. We spent 10 minutes talking about the meaning of the measures of changes but she was not able to independently say that the changes were increasing. In response to her increasing frustration I told her the sequence was increasing and explained why by placing the measures of changes on a number line and asking her to drag her finger from one change to another.

Interviewer: Why do you think that you saw negative three, negative one, and negative point five, and you said decreasing?
Miranda: The negative value.
Interviewer: What about it?
Miranda: That's why I said it's decreasing.
Interviewer: Oh, just because they were all negative?
Miranda: (Nods)

Hayden and Miranda's answers reveal their different abilities to reason about changes in changes which addresses Research Questions #3 and #4: 'How do students think about changes in changes, in tasks such as being asked to identify whether a function is increasing/decreasing at an increasing/decreasing rate?' and 'Does a focus on frames of reference affect students' ability to reason about changes in changes, by drawing explicit attention to a directionality of comparison?' Miranda repeatedly confounded comparisons of changes with changes themselves, (a parallel problem to confounding changes with quantities themselves) shown by her explanation that she thought negative changes meant that the changes were decreasing. Even when I directly instructed her to look only at the measures of the changes in changes she could not keep track of quantities, changes, and changes in changes in a way that allowed her to make sense of all the information she was given. In other words, since the only difference between the three aforementioned quantities are reference points and directionality of comparison, Miranda was not coordinating these ideas within a conceptualized frame of reference per our 2015 definition. Though Hayden struggled in the beginning by inadvertently looking at the changes in changes in changes, he recovered and then was able to reason about changes in changes by comparing the changes measures in ways that made sense to him. He considered the changes in changes by means of both measuring each with respect to its own reference point $f(\text{time}_{\text{initial}})$ for that x-interval, and also by committing to a directionality of comparison. His conceptualized reference frame is what allowed him to arrive at his final conclusion that the changes were both negative and increasing.

Conclusion

Through this pilot study, I found evidence that students need to commit to and think about a reference point in order to reason about changes versus total quantities (Research Question #1) and need to commit to and think about a directionality of comparison in order to reason about changes in changes (Research Question #3) as explained with the excerpts above.

I also found strong initial evidence that a student's ability to conceptualize a frame of reference – that is, commit to a unit, reference point, and directionality of comparison when thinking about measures - had a significant positive effect on their ability to reason about changes versus quantities (Research Question #2) as well as reason about changes in changes (Research Question #4). The evidence for this conclusion is two-fold. First, the students' abilities to reason through tasks about changes in the teaching interviews frequently reflected the initial positions of 'high' 'medium' and 'low' that I had placed them simply on their abilities to reason about a frame of reference in the clinical interviews. More significantly, the language that the students' used to explain their reasoning about tasks involving changes was often about a reference point or direction when the students – especially Hayden - were successful, and almost never about any of the three aspects of a frame of reference in our cognitive definition when the students gave up or were unsuccessful.

The results of this pilot study are being used to inform the creation of a larger study with more tasks, a longer time frame, and more students on how their capacity to conceptualize a frame of reference affects their ability to reason about changes. My preliminary results also suggest that a student's ability to reason about changes within a conceptualized frame of reference has implications for his ability to make sense of rates, first and second derivatives, concavity, addition of vectors, velocity, acceleration, and the principle of relativity, among other ideas. If so, this work can provide starting places in both math education and physics education for better instructional design.

Acknowledgements

I would like to thank Pat Thompson for his guidance through this project, Dov Zazkis for his help with this manuscript, and Cameron Byerley for the conversations that led to the application of our frames of reference construct to reasoning about changes.

Connecting symbol sense and structure sense

Margaret T. Kinzel
Boise State University

Novotná & Hoch (2008) propose that structure sense is an extension of symbol sense, which is an extension of number sense. Data collected initially to explore symbol sense were re-examined in terms of possible instances of structure sense. Preliminary thoughts on this re-examination are presented in this paper.

Key Words: symbol sense, algebraic notation, structure sense

One of the benefits of presenting early at a conference is the opportunity to have conversations with colleagues. In this case, I was able to have conversations with Stacy Musgrave, Duane Graysay, and others on possible connections between my notion of symbol sense and elements of structure sense in their work. These conversations prompted me to revisit my interview data with undergraduate mathematics students and mathematicians in search of possible evidence of structure sense. Task-based interviews were conducted with nine mathematicians and eleven undergraduate students enrolled in a proof-based mathematics course. Tasks for the interviews were selected to be accessible to a range of participants but to also provide enough complexity so that a participant's approach to notation becomes apparent and an explicit focus of the interview.

Characterizing Symbol Sense

In my short paper in these proceedings, I proposed a framework for characterizing algebraic symbol sense. Within work on a task, an individual may be *looking at, looking with,* or *looking through* the notation, with the assumption that for a fluent user of notation, these viewpoints are more interconnected, so that shifts between the viewpoints are fluid and reasoned. This supports my earlier definition of symbol sense as a coherent approach to algebraic notation that supports and extends mathematical reasoning (Kinzel, 2000). Brief examples from each viewpoint are presented here with the goal of connecting to elements of *structure sense.*

Looking at the notation involves noticing particular aspects of a notational form and considering potential actions. This can happen in both productive and non-productive ways. One mathematician participant (M8), when asked to solve the system of equations shown below, responded:

$$\begin{cases} xy = 100 \\ (x-5)(y+1) = 100 \end{cases}$$

> "What I see right off the bat is that I can subtract these. Left-hand side also has *xy* in it. Left with something in terms of *x+y*. Does that help me solve it though? If I subtract them, I know *x+y* is equal to something. Yeah. That will allow me to solve for *y* in terms of *x* plus a number and plug it back in and that will give me my answer."

This seems a productive instance of *looking at* the notation and considering the effectiveness of possible operations. In contrast, a student participant (S1) recognized the common term of 100, set the left sides equal to each other, and proceeded to solve for *y*, expecting to arrive at a numeric value. Surprised by the result of a linear equation in x and y, the student applied a familiar process and found the intercepts of this equation. In this case, *looking at* the (unexpected) linear equation prompted a known procedure that actually has limited relevance for the given task. Both instances seem to involve the participant considering structural aspects of the task and using their understanding of these aspects to guide choices.

Looking through the notation intends to capture those instances in which participants seemed to read through the symbols to the underlying relationships described by the symbolic forms. For example, a few participants (both students and mathematicians) recognized the system of equations shown above as representing products, and used this relationship to quickly find solutions to the system. One student participant (S7) found the solution (25,4) quickly without writing anything down. When asked if this were the only solution, he considered negative factors and proposed (-20,-5) as a second solution to the system. Another student participant (S10), surprised by finding two solutions to the system, was able to reconsider the original equations as products and reasoned:

> "Generally with a system of equations, you should be able to get the correct result using only one factor of x and y each. Considering that you have two multiplication problems, I suppose—instead of more addition and subtraction—I guess I can understand why it might be two factors. Because they can both be negative and then they can both be positive."

Although S10 did not seem to interpret the equations as products initially, his unexpected result prompted him to reconsider the equations and he was able to recognize them as products. Again, both participants seemed to draw on some aspect of the structure of the task within their work.

Looking with the notation is intended to capture instances in which an individual introduces or constructs notational forms to represent relationships within a context, specifically with the intent of understanding or manipulating the quantities involved. Once such forms are constructed, one's sense of algebraic structure could then be evidenced through articulations and choices made. It may also be that evidence of a sense of structure can be found within the construction process. Consider the Treasure Hunt task:

> A treasure is located at a point along a straight road with towns A, B, C, and D on it in that order. A map gives the following instructions for locating the treasure:
>
> a. Start at town A and go half of the way to C.
> b. Then go one-third of the way to D.
> c. Then go one-fourth of the way to B, and dig for the treasure.
>
> If AB = 6 miles, BC = 8 miles, and the treasure is buried midway between A and D, find the distance from C to D.

Constructing appropriate expressions for the distances traveled requires focusing on and coordinating various steps, and thus can be challenging even for fluent users of notation. Within their work on this task, several participants referred to expressions or terms within expressions as "this guy" or "this thing" and in some cases replaced a term or expression with a new variable. As a mathematician (M4) explained: "Sometimes introducing a simpler expression allows you to see things." She further stated that the simpler expression can allow you to see things from a different perspective, and perhaps indicate different potential operations. Such considerations may indicate strategies to isolate relevant structure within a representation.

Connections to Aspects of Structure Sense

Hoch (2003) suggested that structure sense includes the ability to recognize algebraic structure and to use appropriate features of that structure to determine useful operations. It seems this draws on aspects of both *looking at* and *looking through* the notation. M8's productive *looking at* the notation as described above could be interpreted as recognizing particular forms and using that recognition to guide his choices. Similarly, S7's recognition of the equations as products allowed him to apply a perhaps more efficient trial-and-error approach to this particular task. Some participants, when working on the Treasure Hunt task, wondered whether the location of the treasure is uniquely determined by the given information. Recognizing and drawing on the relationship between the number of variables and the number of constraints within a context may also be an aspect of structure sense

The tasks used in my interviews were chosen to elicit a range of interactions with algebraic notation and thus were not specifically aimed at exploring participants' ability to capitalize on algebraic structure. (See the list of tasks at the end of the paper.) All participants completed the Rational Equation, Treasure Hunt, Age Ratio, and System of Equations tasks; the Percent and Permutations tasks were used at the discretion of the interviewer. Of these, the Rational Equation and System of Equations tasks come closest to being aimed specifically at revealing an individual's use of algebraic structure.

Aspects of Structure Sense within the Rational Equation Task

Results. All participants were given the Rational Equation task as the first task in the interview: Solve for x: $\frac{x+16}{x^2-3x-12} = 0$. All nine of the mathematician participants and six of the eleven student participants (S1, S2, S5, S7, S10, and S11) focused primarily on the numerator and checked in some way that x=-16 would not also produce a value of 0 in the denominator. In fact, one mathematician participant (M5) commented that the identification of x=-16 was "so easy, it's got to be that -16 makes the denominator zero as well." This check was usually done by evaluating the denominator for x=-16, although M2, M4, and S1 initially attempted to factor the denominator. When this proved nontrivial, all three confirmed that x=-16 would not produce a zero value in the denominator and were satisfied with their solution. An additional student (S8) identified x=-16 as the solution, but with no explicit attention to possible implications for the denominator. It should be noted that one mathematician (M4) initially focused on the left side of the equation, thinking in terms of the shape of the graph, rather than noticing the value of zero on the right side of the equation. The remaining four students focused on the denominator, attempting to factor in order to cancel with the x+16 in the numerator. Most persisted with this approach even when it became apparent that (x+16) would not be a factor of the denominator.

Discussion. Hoch and Dreyfus (2004) include in a proposed definition of structure sense the ability to "recognize an algebraic expression or sentence as a previously met structure." All the participants discussed here seemed able to recognize the rational equation as a familiar structure, but they focused on different components of that structure. The nine mathematicians and six students seemed able to identify "expression = 0" as the most relevant structural aspect of the task and this allowed them to quickly propose x=-16 as a potential solution. They all went on to acknowledge that the left side being a rational expression required further verification of the solution. It is not clear whether the additional student (S8) recognized this aspect of the equation.

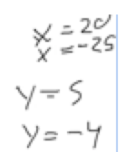
Further, M4 initially focused on the left side as a rational function and its related graph, only focusing on the "expression = 0" aspect later in her work. In contrast, the remaining four students seemed to attend more to the quadratic structure within the denominator, prompting them to apply known procedures for identifying factors of a quadratic expression. We can assume that all twenty participants had encountered rational expressions set equal to zero previously, and so this should exist for them as a "previously met structure." For the four student participants, however, the familiar quadratic structure of the denominator seemed to take precedence. This is perhaps an example of what Musgrave and colleagues (2015) refer to as responding to contextual cues rather than structural awareness; that is, a quadratic expression presented within a "solve" context may trigger factoring strategies and may limit or inhibit a participant's attention to the overall structure of the task.

Aspects of Structure Sense within the System of Equations Task

Results. The System of Equations task was presented above and some sample excerpts discussed. Nearly all of the participants successfully completed this task. One student (S1), as described above, found the intercepts for an intermediate linear equation and assumed these points would be solutions to the system. When this proved to not be the case, he was unable to make further progress on the task. Four additional students (S3, S6, S9, and S11) found appropriate values for one or both variables, but their articulations reveal potential problems in terms of algebraic structure. Although appropriate procedures were applied to the task, the interpretation of values as solutions to the system was problematic for these four participants.

When S6 encountered a quadratic equation within his solution process, he applied the quadratic formula to find two values for *x*; these values were written as (25, -20) and he stopped work on the task. When asked if he had solved the system, he replied "I think so. Is it right?" but did not check his solution in any way. A similar situation occurred in S11's work; he chose to solve for *y* and, finding that *y* could be -5 or 4, initially assumed that these two values constituted the solution to the system. He did eventually find -20 and 25 as values for *x*, and these were written under the appropriate values for *y*, but S11 does not clearly articulate that there are two ordered pair solutions to the system.

Both S6 and S11 initially assumed that the two possible values for one variable constituted a solution to the system. S11 did make further progress on the task, but did not clearly identify two ordered pairs as solutions. A similar result was seen in the work of S3; he also solved for *y* and used the first equation to find values for *x*: "*y* equals 5 or *y* equals -4. Easiest will be *xy*=100." These values are written but not explicitly connected as ordered pairs (see figure at right). Finally, S9 also found two values for *x* (-20 and 25) and two values for *y* (-5 and 4), but then created the four possible ordered pairs: (-20, -5), (-20, 4), (25, -5) and (25, 4) and checked each pair in the equations. In this way, he did identify the two ordered pairs that are solutions to the system but for him and the other students described here, there is clearly an issue with understanding the algebraic structure within this task.



Discussion. Participants who were successful on this task seemed to acknowledge the algebraic structure in some way, appropriately identifying the two ordered pair solutions and perhaps recognizing the equations as representations of products (as in the work of S7 and S10 described in the description of the framework). This recognition of structure seemed to allow S10 to make sense of his unexpected result of two solutions to the system. In contrast, the four less successful participants (S3, S6, S9, and S11) recognized the system as a familiar form and applied appropriate procedures but their interpretations of the nature of the solutions were limited and this limitation is likely related to not attending to the nonlinear nature of the given equations.

Aspects of Structure Sense within Contextual Tasks

The remaining tasks used in this particular set of interviews were presented as contextual situations and may or may not have introduced specific symbols. Returning to Hoch and Dreyfus' (2004) definition of structure sense as it applies to high school algebra, several abilities are included:

- see an algebraic expression or sentence as an entity,
- recognize an algebraic expression or sentence as a previously met structure,
- divide an entity into sub-structures,
- recognize mutual connections between structures,
- recognize which manipulations it is possible to perform, and
- recognize which manipulations it is useful to perform.

A full analysis of these interview data with respect to this list of abilities will not be attempted here. I will offer a few preliminary observations that seem to be related to the overall notion of structure sense.

Across interviews, when the task required the construction of a notational representation, the more fluent and/or successful participants often expressed the notion of being "done" once an appropriate representation was produced. Particularly on the Treasure Hunt task, once a (perceived) correct equation was constructed, participants felt the task had been completed and only carried out the algebraic manipulations for confirmation or as a reaction to the interview setting. That is, the "work" of algebra was accomplished in the construction of the equation. In the specific case of the Treasure Hunt task, this is an appropriate view of the structural aspect of the task: confidence in the appropriateness of the equation combined with confidence in one's manipulative skill should indicate successful completion of the task. Such a view was also seen in some participants' work on the Permutations task, particularly with respect to claim (a). For this task, a place-value based representation leads easily to noticing that the average of the permutations will be 37 times the sum of the three digits. Once this relationship was recognized, participants generally did not feel the need to produce a formal written proof for claim (a); the relevant structure had been identified so the "work" was done.

A second theme that emerged across interviews is the tendency to think in terms of a general case and how the notation is used in service of this. The Age Ratio, Permutations, and Percent tasks each are open to either a numeric or notational exploration. Both approaches were observed in the work of more than one participant on each task. The approaches did not align with mathematician or student status; that is, not all mathematicians took a notational approach and not all students took a numeric approach. Varying degrees of success were observed across participants. In some cases, a numeric approach was used in hopes of revealing the structure of the general case. In these cases, even when what was written involved specific values, the articulations indicated that these values were recognized as "stand-ins" for the general case. In contrast, other participants seemed to focus on the specific values themselves, and so were less likely to be able to recognize the values as stand-ins for generic quantities in the tasks. In both the Age Ratio and Percent tasks, the specific values of ages or salaries drop out when appropriate notational forms are constructed and manipulated, revealing the underlying relationship between the ratios or percentages. More fluent users of notation were able to see the notation as a tool capable of revealing underlying structure that is perhaps not evident in specific numeric instances.

Closing Thoughts

As I reexamined these interviews, I was struck by a few particular comments. These comments seem related to a sense of algebraic structure so I share them here as food for thought. Two students, S3 and S5, made comments that may indicate their awareness of structure but also potential limitations within that awareness. In contrast, comments from mathematician participants more frequently indicated not only an awareness of, but an intention to capitalize on aspects of structure.

As S3 began work on the Rational Equation task, he indicated a desire to cancel factors in the denominator with the numerator, and made this comment regarding the denominator: "I'm really hoping this isn't a quadratic." Further articulations indicate that he meant that he hoped that the (obviously quadratic) expression in the denominator would factor so that he would not need to use the quadratic formula. This may just be a careless use of "quadratic," but given that the goal was to cancel with the numerator, *not* seeing x-16 as a potential factor of the denominator should eliminate the quadratic formula as a useful manipulation in this case. Later in his work on the System of Equations task, S3 commented on his chosen process, "Hope I'm not backing myself into a corner." When asked how he might know, he responded, "For me, personally, probably wouldn't realize it until it was too late. I imagine people with more advanced algebraic skills would, like with chess, be thinking a few moves ahead." This comment seems to indicate that S3 may be aware that there is more structure inherent in tasks than he feels completely capable of recognizing and using to guide his work.

Related to the notion of where the "work" of algebra takes place, a comment from S5 on the System of Equations task is unsettling. She used substitution to approach the task and produced the quadratic equation $20 = y + y^2$. At this point, she paused and said, "I kinda already know what the answer is, but it's not, for me, solving." She was able to look at the equation and reason that y=4 satisfies the condition since "4 times 4 is 16 and plus 4 is 20." She did not see this as a legitimate "solving" process. I would argue that this is an indication of recognizing the represented relationship and a perfectly legitimate, perhaps even desirable, means of solving this particular equation.

Comments from mathematicians often referred to possible structural awareness, such as a general comment from M5 while working on the Treasure Hunt task: "Sometimes in mathematics, what you choose to let your variable be affects the complexity of the solution." A poignant comment from M2 reflects an *awareness of being aware*. He recounted his memory of his first "purely mathematical thought" at around age 12: "Rules for pushing symbols around were one thing, but the empty spaces being inhabited by virtual numbers was a different thing."

Other authors have indicated that it is difficult to capitalize on structures not "previously met"; ensuring that all students have the opportunity to meet all possible structures would seem a daunting task. It seems potentially more useful to consider how to develop the structural awareness indicated by the mathematician comments in the previous paragraph. The interview data examined here suggest that a possible approach would involve developing the ability *and tendency* to think in terms of a general case, coordinated with developing thoughtful fluency with manipulations of a variety of notational forms. Such an instructional approach should emphasize the role of notation as a tool capable of both representing and revealing algebraic structure.

Tasks

Rational Equation Task

Solve for x:

$$\frac{x+16}{x^2-3x-12}=0$$

Treasure Hunt Task

A treasure is located at a point along a straight road with towns A, B, C, and D on it in that order. A map gives the following instructions for locating the treasure:

a. Start at town A and go half of the way to C.

b. Then go one-third of the way to D.

c. Then go one-fourth of the way to B, and dig for the treasure.

If AB = 6 miles, BC = 8 miles, and the treasure is buried midway between A and D, find the distance from C to D. (Charosh, 1965)

Age Ratio Task

The ratio of John's age to Mary's age is now r. If $1<r<2$, express in terms of r the ratio of John's age to Mary's age when John was as old as Mary is now. (Saul et al., 1986)

xy System Task

Solve the system for x and y:

$$xy = 100$$
$$(x - 5)(y + 1) = 100$$

Permutations Task

The average of the six permutations of 1, 2, 8, (that is, 128, 182, 218, 281, 812, and 821) is 2442 ÷ 6 or 407. It is observed that (a) the average is an integer; and (b) 1 + 2 + 8 = 4 + 0 + 7. Are these observations valid for any three digits? (Charosh, 1965)

Percent Task

A person's salary is reduced by *p* percent. By what percent would the salary then have to be raised to bring it back to the original amount? (Charosh, 1965)

Online Calculus Homework: The Student Experience

Andrew Krause
Michigan State University

Ralph Putnam
Michigan State University

Online homework is propagating rapidly across the nation, especially in large, introductory courses in STEM fields. The literature provides some evidence that the implementation of online homework is correlated with higher exam scores and course grades, but theory about how online homework supports learning is lacking, as is research on how students engage with and experience online homework. This study examines student experiences with online homework by identifying various homework environments, resource use, perceptions, and strategies that characterize diverse student experiences and learning opportunities. This portrayal demonstrates that aggregating student experiences through statistical analyses is sometimes an oversimplification that limits the inferences that can be made from achievement data and is evidence that qualitative data is vital to understand how online homework supports learning and inform improvements to its implementation.

Key words: online homework, calculus homework, screen recording, interviews, observation

Addressing the problem of persistence of students working toward a degree in the science, technology, engineering, and mathematics (STEM) fields is an enduring challenge of educators across the Unites States. It is estimated that between 40 and 60 percent of students who enter postsecondary education with the intention of pursuing a degree in a STEM field will switch their study to a non-STEM field (Bressoud, Mesa, Hsu, & Rasmussen, 2014). Poor instruction in mathematics and science courses, especially calculus, is cited as a reason that students decide to switch out of STEM fields (Seymour, 2006; Sonnert & Sadler, 2015). Even academically successful students sometimes leave STEM fields because of negative reactions to the pedagogy they experience in mathematics and science courses, meaning that factors other than student success should be considered to address the issue of STEM retention.

As the use of online calculus homework propagates across the country (for example, over 700 institutions use WeBWorK nationwide), online homework is taking on a growing role in students' experiences with calculus. My experiences as a student, tutor, and instructor led me to believe that online homework is large component of students' experience with calculus, and students have expressed both positive and negative perceptions about their online homework.

The goal of this study is to portray student experiences with online calculus homework to better understand how online homework facilitates learning and to inform instructional decisions about online homework. A deeper understanding about the strengths and weaknesses of online homework, especially about the ways in which online homework facilitates learning opportunities, can inform how online homework is implemented to maximize its effectiveness. For various reasons described later, online homework appears to be positioned as a permanent component of college calculus instruction, so improving its implementation is one way to improve students' experiences with calculus.

Why has Online Homework Propagated so Rapidly?

Two factors have contributed to the rapid adoption of online homework systems across the nation. First, there is evidence in the research literature (summarized in the next section) that students in calculus classes that use online homework perform slightly better, in terms of exam scores and course grades, than those without online homework. Second, several features of online homework provide instructional alternatives that indirectly contribute to improved student support. Online homework can free up department resources, allow for assigning students individualized homework sets, and can provide immediate feedback while automatically grading entire assignments. Although the evidence suggests that online homework may slightly improve student success in calculus courses, it is important to recognize that the following opportunities offered by online homework may have contributed to its propagation independent of a critical analysis about how online homework supports learning.

Freeing up department resources. In many university courses, especially large courses, assigning paper-and-pencil homework entails a large commitment to grading. Often, graders are hired to assist with grading, which incurs a significant financial burden on the departments. Online homework systems can automatically grade assignments, alleviating the financial burden of grading homework. Those resources can be redirected to other programs designed to support student learning, such as tutoring centers (Bonham, Beichner, & Deardorff, 2001; Carpenter & Camp, 2008; Richards-Babb, Drelick, Henry, & Robertson-Honecher, 2011; Zerr, 2007).

Immediate feedback and grading. Online homework systems offer instantaneous grading and feedback. This feature enables instructors to grant multiple solution attempts to students, which allows students to work through their mistakes without having to turn in an assignment and wait for grading and feedback (Bonham et al., 2001; Carpenter & Camp, 2008; Kortemeyer, 2014; Zerr, 2007). Furthermore, immediate feedback has been shown to improve learning opportunities (Epstein, Epstein, & Brosvic, 2001). Immediate grading also enables continual formative assessment, both because automatic grade reports can inform instructors about the progress of their students and by providing a means for students to self-assess (Demirci, 2007).

Individualized homework sets. Online homework systems can generate problems algorithmically, so students can be assigned unique problems. Problems can be authored using several random parameters, so that each student's homework sets have problems that are identical in structure but that have unique numbers. Many instructors see this capability as a means to deter cheating (Carpenter & Camp, 2008), but this capability can also be employed to allow students to generate an unlimited number of practice problems.

Does Online Homework Help Students Learn?

To determine the effectiveness of online homework in supporting student learning, assumptions must be made about the types of evidence that inform such an evaluation. The following vignette illustrates that one type of evidence that is valued is achievement data, gathered through an experimental comparison between control and experimental groups. This perspective undergirds much of the research about online homework, but the neglect of the student perspective has left a gap in the literature. This study portrays student experiences with online homework and demonstrates the importance of the student perspective in understanding how online homework supports learning.

Assumptions about Measuring Learning

During a course meeting while data for this study was being collected, a faculty member respectfully asked, "Do we even know if online homework helps students learn?" Although I attempted to provide some insights during the meeting, it is clear, in retrospect, that I should have been mindful of the differences in the assumptions about what evidence to answer that question might look like.

My colleague politely inquired for evidence from an experimental study, revealing his conception that the measurement of learning can be accomplished through comparison between a treatment group and a control group. That kind of evidence does exist; Hirsch and Weibel (2003), for example, found that students performed slightly, but significantly, better on a final exam in a general calculus course when enrolled in a section for which online homework was used, scoring 4% higher on average. In an introductory calculus-based physics class, Bonham, Beichner, and Deardoff (2001) found that students scored slightly better on tests in sections that employed online homework (78%) in comparison to sections using paper-and-pencil homework (75%). A similar effect has been reported in other introductory STEM courses (Cheng, Thacker, Cardenas, & Crouch, 2004; Cole & Todd, 2003; Richards-Babb et al., 2011).

This evidence, while providing some insights about the value of online homework, is incomplete. The gap in these results is clear; measuring the systematic improvement to the structure of a course is more complex than finding a 4% improvement on final exams. The results of that variety of research are unquestionably important, but student learning is more than complex than student outcomes on exams. We must include the student perspective to understand how learning opportunities are facilitated by online homework. Student success data is information about the results of students' experiences with online homework, but data from the student perspective is required to understand how students' experiences support learning.

A New Perspective

Each of the previously described studies have a commonality: they are all inquiries from the instructional perspective. The student perspective is missing from these results, and thus only half of the story has been described. Hirsch and Weibel (2003) found a substantial difference (of two letter-grades) between students who attempted every online homework problem and those "who did not attempt many" (p. 14). These findings describe, with more nuance, qualities of the student experience that we could try to facilitate to maximize the effectiveness of online homework as a learning tool. The evidence collected from the instructional perspective provides a limited portrayal of the mechanisms by which online homework might support learning, which is why we must look to the student perspective for more insight.

By examining the ways that students experience online homework, I was able to capture students' perceptions about how online homework supports their learning, the study behaviors facilitated by online homework, and the ways in which students use resources to complete their assignments. From this perspective, this study describes how online homework facilitates student behaviors and perspectives that lead to learning opportunities, and identifies homework environments and study strategies that shape students experiences with online homework.

Research Method

My research combined a quantitative survey with observation to determine general trends in tandem with providing a detailed portrayal of individual student experiences with online homework. My research is guided by the four following questions:

1. What homework environments do students experience during online homework?
2. What resources do students employ while completing online calculus homework?
3. What perceptions do students have about online homework?

4. What strategies do students employ to complete online homework?

Sample

The survey was administered to all students in the mainstream calculus course at a large public university via email and was completed with a 24% response rate.

Participants for the observation study were solicited via email from two sections taught by two different graduate teaching assistants. Both of the graduate teaching assistants had at least one full year of teaching experience and had previously participated in a teaching mentoring program, which is a typical of the graduate students assigned to teach calculus at the institution. Four students were selected to participate from a pool of 9 volunteers, with attention given to selecting participants with varying backgrounds in terms of experience with AP Calculus, with other calculus classes at the institution, and as repeat students for the same calculus course.

The Survey

The survey gathered data on students' demographic information, mathematical backgrounds, perceptions of online homework, study habits, and resource use. I analyzed the survey data by examining graphical representations and basic descriptive statistics to identify general trends.

Qualitative Study

I gathered two main forms of qualitative data: (a) video recordings of student homework sessions and (b) transcribed, audio-recorded interviews. As a secondary data source, I drew on notes from informal conversations with the participants, most of which occurred while meeting with students briefly to collect the video recording files.

Video recordings. The video recordings of homework sessions include two data streams. Screen-recording software (Screencast-O-Matic) was installed on the participants' computers to capture the details of their computer work. The screen recordings provide details about students' exact input into the online homework system, and also captured students online activity outside of the online homework system, such as browsing the internet for support and using online calculators such as WolframAlpha. A webcam was used to simultaneously to capture students' real-world activity, but did not capture the same level of detail that was captured by the screen recordings. In the webcam recordings, I can identify when students are working with paper-and-pencil during their online homework session, but it is not possible to determine exactly what students are writing.

Interviews. Each of the four students participated in an interview administered using a semi-structured protocol, with the goal of identifying individual study habits and perceptions about online homework. I also informally discussed the students' experiences with their online homework several times while I was transferring the videos from their computers.

Results

To analyze my data, I conceptualized students' experiences with online homework as being characterized across the following dimensions: (a) the homework environments that students create, (b) the resources that students utilize, (c) the perceptions that students have about online homework, and (d) the strategies that students employ to complete homework. The homework environments that I describe illustrate variation in the amount of time that students spend on online homework, the setting in which homework is completed and the people present in that setting, and the time when homework is completed. Then, I describe the resources that students use, along with variation in the ways that those resources are used. Next, I describe student perceptions about online homework, including the perceived usefulness of online homework as a learning tool. Finally, I will describe several strategies that students employ related to how and why they complete homework.

Homework Environments

The context that students create to complete their online homework determines learning opportunities afforded by that experience. I found variation in the homework environments across three dimensions: (a) the length of time that students study, (b) the physical setting, including the location and people, and (c) when students choose to study relative to the course schedule.

How much time do students spend on online homework? The survey, interviews, and observations all suggest that students spend about 5 hours per week working on online homework. Of course, the amount of time required to complete an online homework assignment varies from assignment to assignment and student to student, but it appears that students spend more time working on their online homework than on studying calculus through other means.

Survey data. Figure 1 is a histogram that displays the time that students reported spending on online homework, per week, as well as the amount of time that they spend studying calculus otherwise. This data was gathered through a free response question and responses were binned by 1-hour intervals.

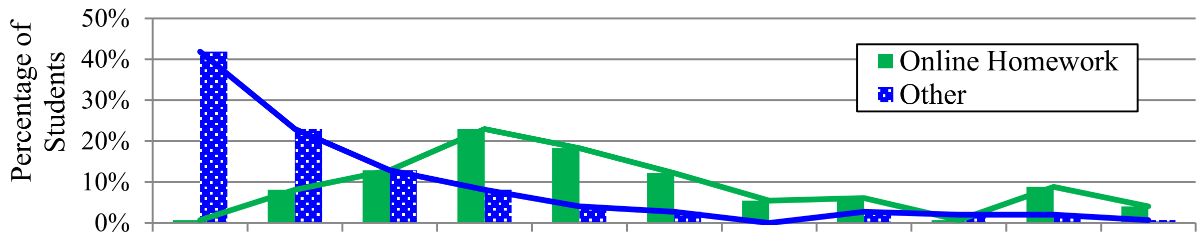

Figure 1: Amount of Time Studying Calculus (hours/week)

Interview data. Aesha and Brittany provided some insights into the amount of time that they spend working on online homework. Aesha reported that she "spends three hours on it to finish it, three for two assignments", so approximately 4.5 hours per week for the three assignments each week. Aesha also indicated that her study routine only consisted of working on online homework and doing practice exams, without studying otherwise, but Aesha was a high-achieving student who had taken a college calculus course previously. Brittany suggested that she worked on online homework for long hours, but was not explicit about the number of hours. Brittany did complain, however, that "Even though the [online homework] takes 90% of your time, it's worth like a fraction of what your grade is," indicating that a large portion of her study time is spent working on homework, which matches the trend in the survey data.

Observation data. The video recordings provided an exact record of the amount of time that students spent on each problem that that worked on during a recorded homework session. For the four observed students, the average time to solve one problem was 6.2 minutes (SD = 3.4) and the average time needed to complete one homework set was 35.0 minutes (SD = 15.5). All of the students completed multiple homework sets during one homework session on some occasions, and the average homework session time was 105.0 minutes (SD = 33.7). Being that three homework sets were assigned per week, the observed students spent about 105 minutes on online homework per week.

Where do students do online homework, and with whom? The setting in which students do online homework varies along two dimensions: (a) the physical space in which the homework is completed and (b) the people present in that space. I have grouped these components of students' homework context together because the place that students choose to study in determines, in part, the types of people that will be present.

Survey data. Students reported spending more time, per week, than in a collaborative setting, as shown in Figure 2. The tutoring center appears to facilitate collaboration.

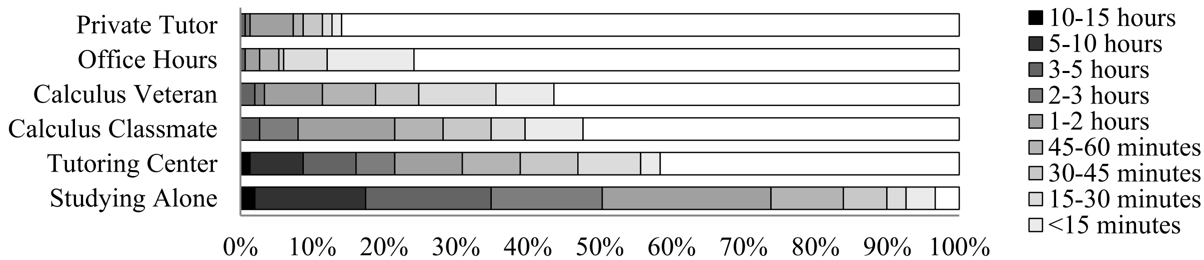

Figure 2: Homework Environments (time per week)

Interview data. I found variability in the physical homework setting described across the interviewed students. Aesha reported that studying alone in her dorm room to complete her online homework was the primary studying she did outside of class (A:65-78)[1]. Brittany started her online homework assignments alone in her dorm room, and then finished them in the tutoring center. While Brittany studied in the tutoring center, she usually worked alone, but was happy to work with other students, even though she not seek out study partners (B:433-443). Chris usually studied with his roommate, who was enrolled in a different section of the same calculus course; they worked together on entire problem sets and compared work to progress through the assignment (C:286-300). Dan studied with his friend occasionally, but studied alone is his dorm more often than he had in a previous semester, when he was taking the same course (D:127-140).

Observation data. All of the students that were observed recorded homework sessions in their dorms; Brittany was the only one who recorded another setting when she recorded one homework session in the tutoring center. The variety of students' study settings is not well-captured by my research, due to limitations of the technology. While the screen recording software runs seamlessly in the background of the computer, the recording of the student requires an external webcam that is awkward to set up in a public setting.

When do students do online homework? The day of week (and time of night) that students complete online homework is influenced by the due dates placed on that homework. Homework deadlines tend to determine when students start assignments, and coinciding due dates for multiple assignments tend to determine how assignments are grouped into homework sessions. Note that during this study, homework assignments opened 3-7 days before the content was scheduled in class (it was a uniform course) and was due the following Thursday. Quizzes over the material were given in class on the Friday *before* the homework was due.

Survey data. Although the survey response options shown in Figure 3 were both vague and overlapping, a trend is still apparent: large numbers of students complete the majority of their online homework assignments close to the due date.

[1] References to interview transcripts are formatted as ([Appendix]:[Line Numbers]). Appendices are available electronically: A: https://goo.gl/bajW1x; B: https://goo.gl/Uq88SN; C: https://goo.gl/CPKREb; D: https://goo.gl/jWO8kz

"**When do you typically do the majority of online assignments?**"

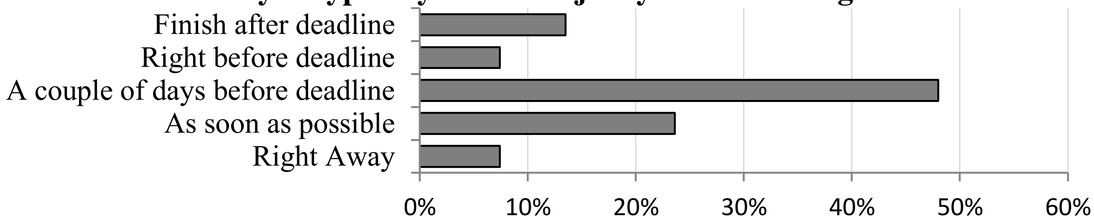

Figure 3: Student-reported Homework Timing

Interview data. The students who were interviewed all described ways in which their studying was structured, at least partially, around online homework. Aesha explained, "I'm like a lazy person...If I don't have the homework which is due like in 1 or 2 days, I just let it go and not study until the exam is coming." Similarly, Chris talked about online homework helping him to structure his studying, "It is like an annoying mother that actually ends up helping," but he also explained that he attributed his success in precalculus, in part, to his habit of working on his online homework as soon as possible following the lesson on that material (C:237-268). Chris explained that he had recently been waiting until just before the due date to complete his online homework, which was set for the week following the quiz, and had felt unprepared for quizzes as a result (C162-180). Dan also explained that the misalignment of the homework due dates and the quizzes had negatively impacted his quiz preparation (D39-63).

During this study, all three of the homework assignments from any given week were due on Thursday the following week, at the same time. As a result, Aesha, Brittany, and Chris all explained that they completed multiple online homework assignments during the same homework session (A:79-89; B:99-106; C:241-252). The interviews clarify the survey data displayed in Figure 3, which shows that many students complete online homework close to the deadline, meaning that they are likely grouping the content in ways that are similar to those described by Aesha, Brittany, and Chris.

Observation results. Video recordings confirmed that students often work on multiple online homework assignments as a group during a single homework session. The recordings captured the students working on multiple assignments with the same due date during the same session.

Resources

Students use a variety of resources when working on online homework. Popular resources include class notes, viewing a similar example within the online homework system (which will be referred to as See Similar Example hereafter), online calculators, YouTube videos, and informational websites. Traditional resources such as the textbook, on campus tutoring centers, office hours, study groups, and private tutors were used less frequently. See Similar Example is a feature of the online homework system in use for the calculus course that was studying; there is a button on the interface, which is available on each problem, that is a link to a solution of a problem that is similar to the assigned problem, in PDF format. An instructional website is a website, such as *Paul's Notes*, that provides explanations of math content and reads much like a textbook. Online calculators include WolframAlpha and Symbolab, which have advanced capability to solve essentially any calculus problem, both symbolically and questions posed in common language, such as "What is the derivative of x^2?" Online help forums allow students to post questions that other users can answer (i.e. physicsforums.com, Yahoo Answers, and mathforum.org), and preserves the communication so that students can find answers to questions by Google searching for homework questions using the text of the problem verbatim; often full solutions and even exact answers can be located using this strategy.

Survey data. Figure 4 shows student response data about the frequency of resource use during online homework. Students reported using the "See Similar Example" feature the most, followed by class notes and online calculators. Traditional resources, such as the textbook and office hours, were used sparingly.

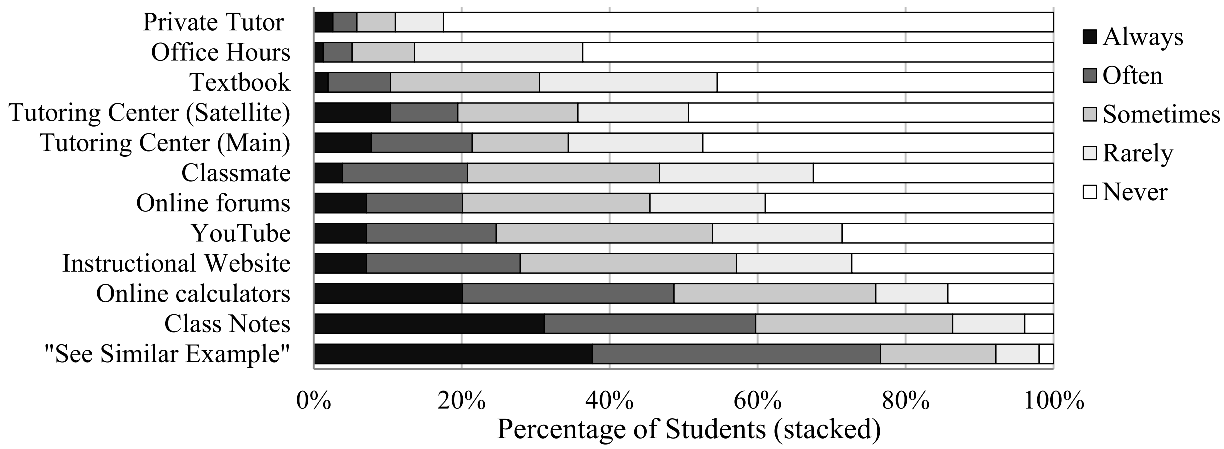

Figure 4: Resource Use for Online Homework

Interview data. Interview data pertaining to the frequency that various resources are used is described below, but descriptions of the strategies related to different resources are presented in the following section of the paper. Interviews revealed variability in the types of resources students use when completing online homework, but the use of online symbolic calculators (i.e. WolframAlpha) was mentioned by all four interviewed students. Aesha shared that she never uses the textbook, but often used WolframAlpha, the "See Similar Example" feature, and her class notes (A:96-117). Similarly, Brittany questioned her decision to buy the textbook because she primarily used online resources including online calculators and informational websites as resources; Brittany also indicated that she worked in the tutoring center for 30-40% of her online homework (B:225-248;427-430). Chris estimated that his use of online calculators accounted for half of his total resource use, with the other half split between looking at similar examples and going to the tutoring center (C:308-335). Dan also indicated that he used online calculators and the "See Similar Example" feature, while also using the textbook (D:134-142).

Observation data. Observations of the students revealed complexities in the ways that students use online resources, particularly with four electronic resources: (a) the "See Similar Example" feature, (b) online calculators, and (c) instructional websites and online forums.

"See Similar Example". Observation data aligned with the survey and interview data in that I observed students using this feature on many problems; this is often the first source that students turn to when they are stuck. Sometimes students look at the similar example immediately after they read the problem, other times they look at the example after they have attempted the problem and have submitted an incorrect answer, but students almost always turn to this resource first when they are not able to complete the problem on their own. It is difficult to infer exactly how students are interacting with the PDF, but informal conversations with the students match the observed behavior in that it appears as though the primary goal is to determine similarities in the structure of the problem to try to figure out how the numbers in the example can be manipulated to yield the answer to the problem at hand. In this sense, the similar example serves more as a recipe to complete the necessary calculation, rather than a support for students to make sense of the problem that they are trying to complete.

Online calculators. Observations of the students revealed two distinct uses of online calculators, which I will call troubleshooting and circumventing. First, when students are troubleshooting using online calculators, they have already worked through the problem on their own, submitted an incorrect answer, and are trying to find their error. Students talked about this behavior informally, explaining that they used online calculators to double check complex arithmetic and algebra because it is difficult to maintain exact precision throughout the calculations that involve unruly numerical values. Second, students sometimes use online calculators to circumvent a problem, meaning that they use the technology to calculate the answer without first attempting the problem on their own. Brittany and Chris spoke informally about sometimes completing their online homework by circumventing problems using online calculators, but both recognized that they tried to avoid the strategy because they thought it was hurting their learning.

Instructional websites and online forums. In the observations, students accessed instructional websites (e.g. Paul's Notes) and online forums (e.g. YahooAnswers) exclusively through the use of a search engine, such as Google, which is why I have grouped these two resources together. Consider the two following searches queried by the students during recorded homework sessions: (a) Brittany: "How do you find a second derivative?" and (b) Aesha: "Use interval notation to indicate where on the interval [-2, 4] the function $f(x)$ is differentiable." The results of Brittany's search were links to several instructional websites that explained the process of finding second derivatives, one of which Brittany read before going back to her notebook to complete her problem. The results of Aesha's search were links to several online help forums, one of which Aesha visited and found the full solution to the exact problem that she was working on. Aesha read through the explanation and several comments, and then copied the posted answer and submitted it for credit. The slightly differing strategies for internet searching led to quite different kinds of resource use and learning opportunties.

Student Perceptions of Online Homework

The survey and interview data were used to determine student perceptions about online homework. Many students reported that the online homework was a useful tool for learning calculus, but several aspects were identified that could improve students' experiences.

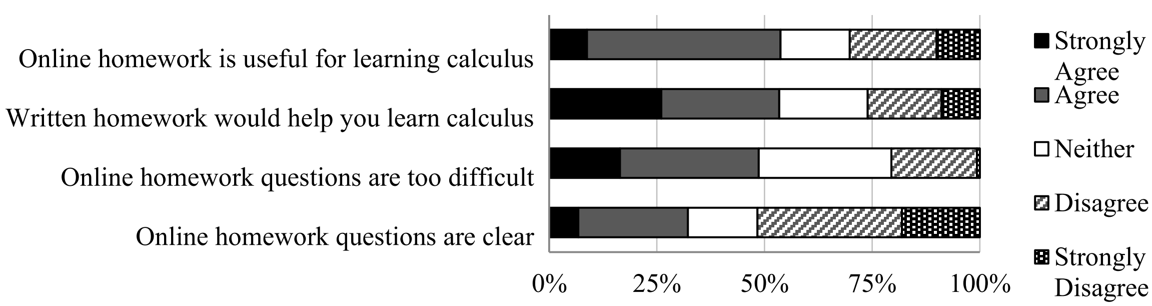

Figure 5: Student Perceptions of Online Homework

Survey results. Figure 5 shows student responses to Likert-type survey questions about perceptions of online homework. Students generally perceive online homework as a useful tool for learning calculus, but also expressed a need for written homework as a compliment.

Interview results. Each of the four students who were interviewed stated that online homework helps them learn and provided details about the specific aspects that were helpful, including: (a) using online homework to structure and schedule studying, (b) receiving immediate feedback, and (c) having an opportunity to practice problems. Several issues were identified including: (a) being overburdened by the size of assignments, (b) misalignment of due dates, (c) the numerical complexity of problems, and (d) the need for written homework to supplement online homework.

Structuring studying. Aesha described how online homework helps her to keep up with her homework and hypothesized that she would do less homework without online homework assignments (A:20-33). Chris agreed that a more structured schedule, with more frequent due dates, would help his learning, joking that "it is like an annoying mother that actually ends up helping." Dan explained that the online homework was easy to study from (D:29-30).

Immediate feedback. Both Brittany and Chris found the capability of online homework to provide immediate feedback useful for their learning (B:291-296; C:127-136). Brittany noted this capability as advantage over written homework, explaining that "you don't really get feedback about if it's right or wrong until like after you turn it in and you're sort of like detached from it 'cause it might be like a week before you get it back." Chris described, "I like the online part because then you can know what the answer is after a while like eventually, but if you are doing homework and you've got the answer wrong you might keep going in your homework and continuously do that wrong, like, yeah, this is how to do it and there is no way to check unless you go to the learning centers...[online homework] gives you that instant…What's right and what's wrong."

Practice. Brittany and Chris both explained that the practice provided by doing online homework problems was helpful (B:30-33). Chris suggested that adding a feature to regenerates new problems would be helpful (C:217-230), "I would make the problems able to be solved infinite amount of times. Like in [chemistry]... And I would like if the problems would change when you try to do them." This feature has been added since the time of this study and both students and tutors in the tutoring center have found the feature useful, anecdotally.

Overburdening . Brittany and Dan both explained that the learning opportunity presented by online homework is diminished when they feel overburdened by the size of the assignments (B:6-37; D:164-168). Brittany explained, "it's not helpful when there's like you know, 15 questions and trying to finish them in an hour and you're just putting it all into WolframAlpha and getting the answers...I end up doing a lot of that because it's like, crunch time, got to get this done." Note that Brittany talked about online homework in a positive light overall.

Due date misalignment. Brittany, Chris, and Dan each explained that their study habits, in terms of when they do their homework, are at least partially determined by the due dates on the homework assignments. It was problematic for students that the assigned due dates were after the weekly quizzes. Chris explained that he completes his online homework after he takes the corresponding quiz, "Most of the time, I don't really study that much and I'll take the quiz and then do my [online] homework... most of the time I feel kind of unprepared [for the quiz]." Dan echoed Chris's sentiment, "This semester I have noticed it was like a week off, a couple of days off...what I've noticed now is that with the things are off, I'm not doing too hot on the quizzes."

Numerical complexity. Aesha, Chris, and Dan each talked about the numerical complexity of some of the online homework problems as being a barrier to their learning (A:43-56; C:19-32; D:19-33). Each student is assigned the same problem set, but individual problems are generated using random parameters, leading to answers that are not easily simplified. Students are not allowed to use calculators on quizzes and exams, so complicated answers are intimidating to students and can be difficult to input into the system with all of the parentheses.

Written homework. Aesha thought one advantage of written homework is that it allows the teacher to provide feedback about the entire solution process, but she admitted that she would not do written homework that was not graded (A:169-187). Brittany found the optional written homework provided by her instructor useful (B:217-221), and estimated that her work on those written assignments accounted for approximately 70% of her learning (B:314-344), but she thought that most students would not do homework that was not graded (B:291-299).

Strategies

Each of the four students interacted with their online homework in unique ways, so I will provide a short description of each students overall strategy. I will provide some references to the formal interviews, but much of the description is informed by informal conversations and hours of video data that are more difficult to reference specifically.

Aesha. Aesha generally attempted each problem on her own before turning to resources; she her class notes, WolframAlpha, the See Similar Example feature, and occasionally Googled the question when she ran into problems. According to Aesha, "see similar example in online homework is more useful than the notebook. Sometimes the notebook doesn't cover the knowledge they want us to do." If she could not solve a problem using those resources, which was rare, she would, "…sometimes Google it…really, really seldom to the Google." She would find an exact solution on an answer forum, would read the accompanying explanation, and would submit the answer provided in the forum.

Aesha recognized that working on problems was integral to her learning process and appreciated that online homework provided a structure for her to do that. She identified one limitation of online homework, "usually on the [online homework] you only show the answer of the result, but on the written paper you need to show your processing… and if there any wrong in your processing…maybe the instructor can like talk about these question." Aesha's recognition of this shortcoming demonstrates the value that she places on homework extends beyond its value in the grade book; she truly values homework as a learning opportunity. She often spoke about the importance of completing her online homework to her understanding; on several occasions Aesha dismissed her temporary struggles with confidence that she would understand the content after she completed her online homework.

Even though Aesha claimed, "so I'm like a lazy person. If I don't have homework, I usually don't do much effort on math," she completed nearly all of her online homework independently (A: 65-68). Her learning routine was consistent throughout her experience: (1) attend class and take notes, (2) complete the online homework individually using notes, textbook, and online resources, (3) succeed on weekly quizzes, (4) study for the exam, and (5) succeed on the exam.

Brittany. Brittany's experience with calculus was more like a mission to complete her online homework, which aligns with her perception of the role on online homework in her learning. Brittany appreciated that she was able to persevere to complete those assignments, but her frustration that the grade weighting was so low (10%) demonstrates that she valued online homework more for the grades rather than the learning experience. She explained, "…even though the [online homework] takes like…. 90% of your time, it's worth like a fraction of what your grade is which I think is kind of dumb…I've really tried to work really hard on the [online homework] just because… rather than like an exam if you don't know the answer you just get it wrong, but at least on the homework you can get help to get the answers right." Brittany explained that, "in some ways [online homework] can be helpful…because it is practice…we do some example problems in class and the [online homework] works…to practice applying those skills like if we were in class," but she never specifically identifies how online homework supports her learning or talks about online homework as a way to master the material.

Brittany often procrastinated her online homework, which led to study habits that she recognized as being less productive than was possible:

> It's not helpful when there's like you know, 15 questions and trying to finish them in an hour…and you're just putting it all into WolframAlpha and getting the answers…I end up doing a lot of that because it's like, crunch time got to get this done… and I've no idea what I just did but, it's green so….that's when I think it's not helpful…it's when it gets to the point where you're just getting it done, to get done and not really focusing on how to do it.

Brittany recognized that doing her homework herself was valuable, and explained that she would always attempt problems before she turned to other resources, namely the MLC and online calculators (B:30-47; 409-430). Brittany explained, "I try not to just get the answers on the computer and then put it right into my work and not really even process what that means. 'Cause then, that's not gonna help me on a quiz or an exam when I don't have the computer to use," which further demonstrates the value that she placed on online homework as a means to practice problems similar to those on the quizzes and exams. When she talked about online homework as a way to practice, language about the importance of doing those problems as a part of learning the materials was always missing, which indicates that she sees her online homework more as a component of her grade than as a learning tool that would help her master the content. In other words, Brittany was concerned about completing the online homework problems rather than learning *how* to complete the online homework problems.

Chris. Chris valued online homework based on his previous experience and success in a precalculus class that utilized online homework, but his study habits did not align with those values, and he recognized the discrepancy. He often worked on his precalculus online homework immediately following the classes in which the content was covered, but abandoned that strategy for calculus and instead completed his calculus homework based on the due date, which was after his quizzes. He recognized that his study strategy was less beneficial than more regular studying, and suggested that pushing students to work more regularly through more structured due dates would be, "like an annoying mother that actually ends up helping." Chris clearly recognized that online homework was most helpful when he worked on it more regularly, but there were a number of factors that contributed to his habit to utilize the online homework in a less effective way.

Like Brittany, Chris valued online homework as a way to practice problems, and suggested, "I would make the problems able to be solved infinite amount of times." Chris compared his experience with online calculus homework to his experience with online chemistry homework and explained that the online homework helps him learn by providing him with example problems, and that having an unlimited number of problems helped him use online homework more effectively in his chemistry class (unlimited problems, solutions provided) than in his calculus class (specific homework set, no solutions provided). This is indicative of the value that Chris ascribed to online homework as being a way to practice problems and learn the material by looking through solutions to try to find patterns, which implies that he values the online homework as a way to perfect his solution methods rather than a way to improve his conceptual understanding of the content.

Dan. Dan valued online homework primarily as an organizational tool. He explained, "It's like easy to study from, so you know what to study from. You don't have to like trace through notes and all that." The misalignment of the homework with the rest of the course was his main critique of his experience with online homework, "this semester it doesn't usually match with what we are doing in class and when I do it, it is just like wait, we're not doing this, it is distracting and sometimes I didn't get it done."

Dan recognized that working on problems was important for his learning, but he was critical of the types of problems presented within the online homework, saying, "some of the web work problems are a lot like more challenging than you ever get… sometimes it is just too broad. It always asks about the trig function ones, I rarely see those [on quizzes or exams]." He compared online homework problems to some optional problems assigned by his instructor, "he has a lot of conceptual ones which I think that helps a lot where a lot more whereas these are, just like, you got to learn how to plug it in and all that," which demonstrates that, after having worked through the online homework during his previous semester with calculus, he is aware of the different kinds of learning that the different types of homework problems support.

Discussion and Implications

The range of student experiences portrayed demonstrates the complexity of student interactions with online homework. Given the same homework assignment in the same class, one student might productively struggle through a 15-problem homework set prior to a quiz while another student may not even start that same assignment until after the quiz. If the average achievement (e.g., course grade) of these two students is employed as a way to understand the effect of online homework on student learning, the nuances of the students' experiences are lost and that data might tell a misleading story. To determine the effect of online homework on student learning, we must examine the mechanisms by which online homework supports learning, and we can only do that by understanding how students interact with their online homework to create learning opportunities. Once we have a better understanding of various student experiences, instructors can identify learning associated with specific experiences and can leverage teaching practices to facilitate the interactions that are most productive.

Homework Environments

The context in which online homework is completed shapes the learning opportunities afforded by that task; working on an online homework set alone in a dorm room is different than working on that same homework during office hours with a group of peers. Instructional design should draw on the strengths of online homework and should account for the shortcomings. I found that students tend to work on online homework alone and tend to complete assignments based on the deadline, regardless of how it aligns with the course schedule. Addressing those issues is one way that we might seek to improve how online homework supports learning.

One way that instructors might counteract the tendency of students to complete online homework alone is to supplement online assignments with collaborative written assignments. Students perceived optional, written homework as useful supplements to online homework both because written homework provides a space for them to express their thinking process as well as a common experience upon which to base classroom discussion and demonstration. Although interviews revealed that motivation may be an issue when the written homework is not graded, the value that students ascribed to written homework that is conceptually-based suggests that finding creative ways to assign and incentivize written homework is worthwhile. Shifting some student tasks away from online homework can also help to shift students' focus away from online homework as the only medium for studying, which is currently the case for many students as over 40% if students report spending less than an hour per week studying calculus outside of their online homework (Figure 1).

The majority of surveyed students (68.9%) reported that they complete their online homework either the day of or a couple of days before the due date. Chris and Dan both explained that they were unprepared for calculus quizzes because they completed homework assignments on the due dates that were set after the quizzes. It is no surprise that online homework that is completed following an assessment is perceived as less useful than homework completed before, so instructors should consider structuring online homework due dates in ways that facilitate the study behavior that is desired, even if the structure seems too prescriptive.

Perceptions, Strategies, and Resource Use

Student perceptions about the usefulness and purpose of online homework influenced the strategies and resources that students employed to complete their assignments, and thus affected the learning opportunities experienced. Some students viewed the completion of the online homework assignments as being important, in its own right, because of the graded component of the homework. This contrasts sharply with the perceptions of students who valued online homework as learning experience to practice the procedures and master the material. The learning opportunities shaped by the homework environments, strategies, and resource use associated with these contrasting perspectives differ substantially, and illustrate the importance of understanding online homework from the student perspective.

Brittany, Chris, and Dan all espoused perceptions about their online homework that suggested that they leaned towards valuing online homework because it was a graded component of the course. They employed strategies and resources to expedite their studying, often at the expense of deteriorating their learning opportunities. These students often turned to online forums, online calculators, the “See Similar Example” feature, and sometimes the tutoring center for assistance in performing the required procedure to calculate the correct answer to specific problems. In doing so, they essentially circumvented the experience of solving those problems on their own, diminishing their learning opportunities.

Although Brittany, Chris, and Dan mentioned the value of online homework as a learning experience, Aesha clearly explained that she valued her online homework as an important component of her learning and demonstrated a significant commitment to strategies and resources that supported her learning. When she struggled with a problem, she turned to the textbook, class notes, and instructional websites to try to understand the problem, and to make sense of the solution method as a whole, rather than seeking the solution to that specific problem. Aesha often turned to an online calculator to find an error in a solution that had already been worked out, as opposed to the strategy of employing an online calculator to simply calculate the answer to a problem, but she would turn to online forums when all else failed.

Student perceptions about the usefulness and the role of online homework are a determining factor in how students interact with online homework, and thus determine the learning opportunities that are experienced. The students that participated in my research demonstrated that a number of productive strategies exist, along with numerous strategies that degrade the quality of the learning experience. In particular, when students prioritize the credit they earn towards their grade for completing the online homework over the learning opportunity inherent in the struggle to solve a problem, they often employ strategies that degrade their learning opportunities. Nonetheless, these students perceived online homework as a useful learning tool, and likely benefited from the alignment of the online homework with the course exams. Because of this, an inquiry focused on student experiences can reveal the strengths and issues with online homework that would be overlooked by an evaluation focused on student success as measured by exam scores and course grades. Future work about online calculus homework should be directed towards the student perspective to more fully understand the ways that it can support student learning and inform instruction that facilitates productive study strategies.

Lacking confidence and resources despite having value: A potential explanation for learning goals and instructional tasks used in undergraduate mathematics courses for prospective secondary teachers

Yvonne Lai
University of Nebraska-Lincoln

In this paper, I report on an interview-based study of 9 mathematicians to investigate the process of choosing tasks for undergraduate mathematics courses for prospective secondary teachers. Participants were asked to prioritize complementary learning goals and tasks for an undergraduate mathematics course for prospective secondary teachers and to rate their confidence in their ability to teach with those tasks and goals. While the mathematicians largely valued task types and goals that mathematics education researchers have proposed to be beneficial for such courses, the mathematicians also largely expressed lack of confidence in their ability to teach with these task types and goals. Expectancy-value theory, in combination with these findings, is proposed as one account of why, despite consensus about broad aims of mathematical preparation for secondary teaching, these aims may be inconsistent with learning opportunities afforded by actual tasks and goals used.

Key words: secondary teacher education, mathematicians' instructional dispositions

Each year, many prospective secondary teachers are enrolled in undergraduate programs intended to prepare them to apply mathematical knowledge to their future teaching practice. The field has called for improving these programs, including teachers' mathematical preparation. Although effects of teacher programs have proven difficult to assess in general, there are multiple studies on secondary mathematics teacher education suggest that secondary teacher do not connect their mathematical preparation and teaching practice. Even if connections could made in theory, it seems unlikely that teachers would leverage them if they believe there is no connection.

In many institutions, mathematics departments offer courses required for these programs (Conference Board of the Mathematical Sciences, 2010). However, there are few studies of how mathematics faculty teach (Speer, Smith, & Horvath, 2010), including why mathematics faculty make the instructional priorities that they do, and what resources are available to support these priorities. In this paper, I begin with an overview of policy and textbooks that inform mathematics courses for prospective secondary teachers. Then I report on a small interview study in which 9 mathematicians were asked about their priorities for goals for these courses. The responses provide a potential explanation for why current priorities may be difficult to change, even if there is some agreement on how to change.

Background

Potential to connect mathematical preparation to teaching

Approaches to mathematical preparation for teaching. In the US, committees of the Mathematical Association of America set policy for undergraduate mathematics courses taught through mathematics departments. Policy documents for mathematics courses for prospective mathematics teachers include reports written by the Committee on the Undergraduate Program in Mathematics Panel on Teacher Training in the 1960's to 1980's and Committee on the Mathematical Education of Teachers in the 1990's. Contemporary policy documents include the *Mathematical Education of Teachers* published by the Conference Board of the Mathematical Sciences (2001, 2012).

As a set, these policies describe different approaches to designing mathematical experiences for prospective teachers: mathematics from an advanced standpoint; trajectories to disciplinary content and practices; and mathematics as it is applied to recognizing, responding, understanding mathematical issues that arise in the context of teaching.

Each of these approaches connect mathematics to teaching in different ways. Mathematics from an advanced standpoint (Klein, 1908) seeks to provide an underlying mathematical structure for school mathematics, lending mathematical coherence to K-12 mathematics. In teaching, knowledge of school mathematics from an advanced standpoint provide explanations of foundational mathematical ideas that position learners to connect the mathematics across the curriculum. Mathematics that leads to disciplinary content and practices can be used to give intellectual purpose to school mathematics because they provide potential trajectories from school mathematics to compelling problems and practices of the discipline. An example of this approach is developing the mathematics necessary to prove the impossibility of classical straight-edge and compass constructions. In teaching, knowing such trajectories may provide perspective in ways similar to the role of horizon content knowledge (Ball, Thames, & Phelps, 2008), and can inform how to portray ideas so they are consistent with generalized mathematical systems learned later.

The third approach is a “practice-based” approach because it applies mathematics to teaching practice. The phrase references Ball and Bass’s (2003) introduction to mathematical knowledge for teaching as a “practice-based theory”. It is the mathematics that teachers draw upon to carry out the work of teaching, for instance, to select mathematical tasks that are amenable to whole group discussion, recognize what students are thinking, and strategize how to respond to students’ thinking toward particular mathematical points.

There is a fourth approach represented by policy for teacher preparation, which I call mastery of conventional mathematics. By conventional mathematics, I refer to the mathematics of a conventional course of study. A common notion in the US spanning back more than a century and codified by policies such as No Child Left Behind (2002) is that the teacher should generally know mathematics that is the equivalent of one degree level higher than the level of instruction. Teachers must at least know what they will teach at the level that the students are intended to learn. In teaching, teachers at least need to solve the mathematics problems that students are assigned.

Empirical results on the effectiveness of mathematical preparation for secondary teachers. Although experiences in mathematics from an advanced standpoint and that lead to disciplinary content have been received well as professional development (e.g., Watson, 2008; Eisenbud, 2015; Educational Development Center, 2015), there are also studies suggesting that prospective teachers are dissatisfied with their mathematical preparation, do not see their preparation as connected to their teaching. In Zaskis and Leikin’s (2010) survey of 52 practicing secondary teachers, and Goulding, Hatch, and Rodd’s (2003) survey of 173 prospective teachers, many participants found their mathematical preparation disconnected to teaching. Ticknor (2012) interviewed five prospective secondary teachers and a mathematics faculty instructor, and found that instructor saw connections between abstract algebra and teaching school mathematics, the teachers were engaged with the course, and yet the teachers perceived the course as disconnected from teaching. Wasserman, Villanueva, Mejia-Ramos, and Weber (2015) interviewed 14 secondary teachers and found similar results for real analysis. Thus, though there are theoretical arguments for why experiences in mathematics from an advanced standpoint and that lead to disciplinary content are beneficial for teachers, but it is harder to establish these benefits in practice. Wasserman et al. (2015) and Ticknor

(2012) concluded that these benefits may be more likely to occur if the content taught were more explicitly and intentionally situated in teaching situations – in other words, to adopt a more practice-based approach to the content. Scholars have made the argument for a practice-based approach to teacher preparation more generally (e.g., Ball & Cohen, 1999; Stylianides & Stylianides, 2014).

Practice-based knowledge and its links to teaching quality and student outcomes. Practice-based knowledge is linked to teaching quality and student outcomes at elementary and secondary level (Hill et al., 2008; Hill, Rowan, & Ball, 2005; Baumert et al., 2010), and at least two studies have documented that practice-based knowledge is more so linked than mastery of school mathematics or mathematics from an advanced standpoint. Baumert et al. (2010) found that performance on their measure of content knowledge had less to do with teaching quality than performance on their measure of pedagogical content knowledge, and Rockoff, Jacob, Kane, & Staiger (2011) found that teachers' performance on the LMT MKT assessment (Hill, Schilling, & Ball, 2004) of practice-based mathematical knowledge related to their student achievement outcomes, whereas the relationship between teachers' performance on SAT math student achievement outcomes was positive but statistically insignificant. These results give credence to the potential value of a practice-based approach to teacher education.

Prevalence of practice-based resources for the mathematical preparation of teachers

Given the evidence for the potential of practice-based approaches to mathematical preparation of teachers, it is natural to ask to what extent existing resources, such as policy documents and textbooks, support practice-based approaches. In short, policy and texts support practice-based approaches for elementary teacher education, but not secondary teacher education, and this difference began in the 1990's and 2000's.

Surveying historical policy documents for mathematics departments, the dominant approach to secondary mathematics education is to require prospective teachers to either pursue mathematics majors or to take many courses that overlap with the requirements of mathematics majors (Ferrini-Mundy & Findell, 2004). It is striking that current policy, as codified in the *Mathematical Education of Teachers, 2* (CBMS, 2012), does not propose practice-based knowledge as an organizing principle of mathematics courses specific to secondary teacher education, despite highlighting the importance of mathematical knowledge for teaching in the introductory chapters of the document. The principles advocated are "treat high school mathematics from an advanced standpoint", "take up a particular mathematical terrain related to high school mathematics and develop it in depth", and "develop mathematics that is useful in teachers' professional lives" (p. 63). The last principle may seem practice-based, but the examples given to define it are "classical ideas that are not normally included in a mathematics major but are of special use for teachers, such as the classical theory of equations or three-dimensional Euclidean geometry" (p. 63).

Historically, policy for elementary teacher education resembles secondary teacher education in its emphasis. As the 1971 Report of the Panel on Teacher Training explained of its proposed sequence for elementary teachers, "the arithmetic of the rationals finds justification and natural applications in elementary probability theory. … Also, the algorithms of elementary arithmetic lead naturally to flowchart and to a study of the role of computers" (p. 166). Indeed, the objectives of teacher training were "understanding the concepts, structure, and style of mathematics", "facility with its applications", "ability to solve mathematical problems", and "development of computational skills" (p. 161).

In contrast, the *Mathematical Education of Teachers, 2* states for elementary teacher education, "A major advance in teacher education is the realization that teachers should study the mathematics they teach in depth, and from the perspective of a teacher. … It is also not enough for teachers just to study mathematics that is more advanced than the mathematics they will teach" (p. 23). Illustrative activities for domains to be studied in coursework include examining and critiquing student reasoning, examining common student errors, and using common classroom manipulatives to explain elementary mathematics ideas. The domains include key mathematical ideas, their general principles, and how their structures connect to the structure of ideas later in the curriculum. Contemporary policy for elementary teacher education emphasizes practice-based knowledge that draws on structure of elementary mathematics. In this sense, the approach to elementary teacher education can be interpreted as practice-based drawing upon elementary mathematics from an advanced standpoint. The change toward practice-based knowledge in policy began in the 1990s.

Textbooks for teacher education reflect the policy. Beckmann's (2003) textbook for prospective elementary mathematics teachers, a highly rated and common text (National Council on Teaching Quality, 2008), contains many examples and tasks that use representations that are typically used at the elementary level and not beyond the elementary level (e.g., Cuisenaire rods, fraction strips), ask for a student-accessible explanation, feature embedded student work or a teaching goal, or that ask for explanation or interpretation based on different ways of thinking about the same ideas. In contrast, common textbooks for prospective secondary mathematics teachers, such as Usiskin et al. (2003) and Bremigan, Bremigan, and Lorch (2011) contain some but comparatively fewer practice-based tasks, and with the majority of problems focusing on mathematics from an advanced standpoint.

Elementary and secondary teacher education paint different pictures of mathematical preparation, as evidenced by MET2 and historical changes in national policy documents for mathematics departments. This backdrop raises a question of why practice-based approaches have not taken hold of secondary teacher education, as well as whether such change would be favorable. I focus here on the first issue. To do so, I looked at expectancy-value theory, which provides one explanation for how people make decisions. This paper reports on a study addressing the questions: *What goals and tasks do mathematicians value for mathematics courses for prospective secondary teachers? What expectancy do mathematicians hold for these goals and tasks? What factors influence value and expectancy?*

Theoretical framework

Expectancy-value theory

Expectancy-value theory is a frame for understanding choices that people make. Broadly speaking, many studies have shown that a person's success in attaining a goal is strongly shaped by how much the person values the goal intrinsically, the person's confidence that they could attain the goal, and the quality of the person's ability to conceive of implementation intentions (statements of the form "If X happens, then I will do goal-attaining behavior Y"). (See Eccles and Wigfield (2002)'s review of research on the effects of motivational beliefs and values on goal attainment, and Gollwitzer and Sheeran (2006)'s review on the effect of implementation intention on goal attainment). To represent confidence, I use expectancy, that is, a person's belief about how well they will do at a task (Atkinson, 1964), as used in Eccles and colleagues' extensively validated expectancy-value theory that relative value and perceived probability of success influence achievement-related choices (e.g., Eccles, 1983; Eccles, Wigfield, Harold, & Blumenfeld, 1993). The phrasing of this study's interview questions on expectancy and value were adapted from those described in Eccles, Wigfield, Harold, and Blumenfeld (1993). Expectancy-value theory holds that a person is most likely to choose tasks for which they hold high value and expectancy. If value is high, but expectancy is low, then success may be sacrificed because a person chooses to engage in tasks that are counter to their values. A classic example of this phenomenon is quitting an addiction. Addicts may know the value of quitting, but because they do not expect to succeed at quitting, they may act in ways that enforce the addiction. Knowing the value of changing habits is not enough to support actual change.

Practice-based design

Following the conceptualizations of researchers in mathematical knowledge for teaching (Ball & Bass, 2003, Hill, Schilling, & Ball, 2004; Gitomer, et al., 2014), a task or goal is considered to follow a "practice-based" design if it intentionally and explicitly connects mathematics and teaching. That is, it applies mathematical knowledge to teaching situations, situates teachers in work of teaching, the kind of work to which the mathematics is applied is important and recurrent to teaching, and the mathematical knowledge addresses K-12 mathematics. Ball and Bass (2003) introduced mathematical knowledge for teaching as a practice-based theory, and the phrase has been subsequently codified in work that attempts to systematically catalogue the work of designing tasks that assess mathematical knowledge for teaching (e.g. Gitomer, et al., 2014).

The propositional mathematical knowledge drawn in the work of a practice-based task can include mathematics of secondary school and beyond. The Green Task gives an example of former and the Blue Task the latter. What makes them practice-based is that they both require mathematical and teaching knowledge to interact for the purpose of teaching secondary mathematics. In the Green Task, a teacher must apply knowledge of factoring to infer that discussion of different solution paths is best supported by the radicand with the most possible perfect square factors, in this case, 72. In the Blue Task, a teacher must apply knowledge of functions to a student accessible explanation.

Approaches studied

In a previous study on proofs for pedagogical purposes, some mathematicians evaluated the value of a proof differently depending on the mathematical ideas emphasized (Lai & Weber, 2014). Because the mathematical content of a practice-based task can range from secondary content to beyond, and the argument for mathematics from an advanced standpoint is that it underlies explanation of foundational ideas, I decomposed practice-based tasks into two types: practice-based drawing on strictly secondary content and from mathematics from an advanced standpoint. Thus the approaches to tasks studied were: (1) mathematics from an advanced standpoint, (2) mathematics that leads to disciplinary content, (3)(b) practice-based drawing on strictly secondary content, (3)(a) practice-based drawing on mathematics from an advanced standpoint, (4) ensuring mastery of school mathematics. Because the mathematics involved in a particular goal can vary more than it might for a specific task, I did not do a similar parsing of practice-based goals.

Study

Rationale

To examine factors influencing value and expectancy of the different approaches, mathematicians were asked to perform three card sorts using a think-aloud protocol. The card sets were statements of 4 content-specific goals, statements of 4 content-generic goals, and 6 tasks representing the different approaches to mathematics courses for prospective secondary teachers described above. Mathematicians were asked to place the cards horizontally to represent the value of the card to the mathematical preparation of secondary teachers, and then vertically to represent their expectancy in teaching the task or toward the goal.

Sorting on value was designed to simulate prioritizing. A common choice encountered in teaching is selecting among tasks and goals to accomplish in a limited amount of time. Even if many goals or tasks are valuable, it is often not possible to address all goals and tasks deemed valuable. Sorting on expectancy was meant to elicit relative confidence in ability to carry out the goals and tasks. Relative value and expectancy informs the goals and tasks that may be chosen when others must be sacrificed for the sake of time.

Card sorts with content-specific goals, content-generic goals, and tasks were used both to elicit relative value and expectancy and also to examine construct consistency among the participants. Common wisdom provided to instructors across K-16 education suggests identifying goals for the course as a whole, identifying goals for each lesson, and then selecting or constructing tasks that serve the goal. Thus one would expect consistency in how instructors perceive course-level goals, lesson-level goals, and tasks. At the same time, if inconsistencies arose, their reasons should be considered in explaining instructional choices.

Method

Participants. Mathematicians were recruited for an interview study as follows. Email invitations were sent to a list of mathematicians who had participated in workshops on teacher education discussing practice-based approaches to conceptualizing the knowledge needed for teaching. The invitation specified that the study sought mathematics faculty and mathematics graduate students who had or would, if given the opportunity, teach a course for prospective high school teachers. A total of 9 mathematicians agreed to participate. Prior to the interview, participants were asked to complete a survey about their background and experiences as mathematics instructors. The mathematicians had between 0 and 10 years experience teaching courses for prospective secondary teachers, 0 to 5 years experience teaching courses for prospective elementary teachers, 0 to 3 years experience teaching courses for practicing secondary teachers, and 0 to 3 years experience teaching courses for practicing elementary teachers. All mathematicians had at least 1 year experience teaching prospective teachers of some level. In the pre-interview survey, all mathematicians responded that, on a scale of 1 (not at all) to 7 (very much), being good at teaching courses for teachers was 5 to 7, and being good at teaching in general was either 6 or 7. The mathematicians were also asked, in comparison to other courses, how well did they think they taught courses for teachers; responses were between 3 and 7, with mostly 3's and 4's. The mathematicians taught at a variety of institutions from small liberal arts schools to research-intensive schools and ranged in appointment, including assistant professors, associate professors, full professors, and lecturers.

Materials and procedures. This interview took place in the context of a longer interview with six parts: (a) describing a favorite task used when teaching prospective teachers, its goals, and its enactment, (b) considering the appropriateness of content-specific goals for a particular task shown to participants, (c) (card sort 1) content-specific goal sort as goals independent of the task, (d) (card sort 2) task sort, (e) (card sort 3) content-generic goal sort, (f) wish list. This study focuses on the results of the three card sorts, with the responses to the wish list questions used to provide additional context for card sort comments. The card sort contents were based on existing resources for teacher education when possible. Prior to the interviews, two mathematicians and two mathematics educators independently reviewed the contents favorably for consistency with intended approach.

I now briefly describe the protocols for the three card sorts and the wish list. For each, participants were first asked to sort the cards horizontally to indicate value and then vertically to indicate expectancy. Participants were prompted to explain the relative positioning of cards for each sort.

Card Sort 1: Content-specific goals. Four content-specific goals were shown to participants representing the approaches to goals. Table 1 shows the goals.

Card Sort 2: Tasks. Six cards containing tasks were shown to participants representing the approaches. The tasks were named by colors (Pink, Orange, Yellow, Green, Blue, Purple). The cards contained tasks representing approaches to tasks, with one task (Orange) that situated the Pink Task in a teaching situation. Table 2 shows the tasks.

Card Sort 3: Content-generic goals. Four content-generic goals were shown to participants representing approaches to goals. Table 1 shows the goals.

Wish List. At the end of the interview, participants were asked: If you could make a wish list for resources for getting better at teaching math courses for teachers, what are some things that wish list would contain? What is inadequate about existing resources, such as textbooks that are already out there, or talking with other people who have taught this course before in your institution or beyond?

Analysis. For each card for each participant, cards were assigned horizontal and vertical coordinates with values between 1 and 5 based on the approximate location of the center of the card as placed by the participant where horizontal coordinates represented value and vertical represented expectancy.

Interview transcripts were chunked into statements discussing beliefs, goals, knowledge, or action plans, following Schoenfeld's (1998) theory of instructional decision making. The 9 participants made 144 statements in total during the card sorts and wish lists. Each statement was then coded for whether it discussed value or expectancy. Among these, 17 statements were coded as "neutral", meaning they did not give a specific reason (e.g., a belief statement such as "I think the orange card should be placed higher than the pink card" or "I feel confident about this"). Among the remaining, 61 statements addressed expectancy and 66 statements addressed value. The collection of statements with reasons were analyzed for themes (Strauss & Corbin, 1994). Patterns noted in card placements were triangulated with interview statements.

Results

Table 3 shows scatterplots of card sort placements. It is worth noting that generally, these participants valued practice-based tasks and goals more than they were confident in being able to carry out practice-based tasks and goals. The practice-based data points tend to fall beneath the diagonal.

We now discuss how participants' card sorts and interview responses addressed themes addressing value and expectancy, and how this might play into these participants' disposition toward practice-based tasks and goals. For brevity, we focus on only the dominant themes. We present tables summarizing all themes in the types of comments that participants provided, but give representative illustrations or only the most dominant themes for each value and expectancy. See Tables 4 and 5. The themes discussed are bolded.

Table 1. Content-specific goals, content-generic goals, and their correspondence

Content-specific goals	*Content-generic goals*
Understanding the relationship between the definition of an equation, the definition of graph, and the definition of relation.	Connecting ideas from higher mathematics to secondary mathematics
Seeing how "circles" can look very different depending on the metric used.	Experiencing secondary mathematics as a rigorous, challenging, coherent body of mathematics.
Analyzing incorrect solutions for foundational ideas that may be misunderstood.	Analyzing mathematical teaching situations
Mastery in graphing relations of two variables, especially involving absolute values.	Ensuring that teachers would be able to do the problems they are responsible for teaching K-12 students to do.

Table 2. Tasks and their correspondence to approaches

Green Task: Practice-based drawing on secondary content[1] Ms. Madison wants to pick one example from the previous day's homework on simplifying radicals to review at the beginning of today's class. Which of the following radicals is best for setting up a discussion about different solution paths for simplifying radical expressions? 1. $\sqrt{54}$ 2. $\sqrt{72}$ 3. $\sqrt{120}$ 4. $\sqrt{124}$ 5. Each of them would work equally well. Explain your reasoning.	*Yellow Task: Secondary mathematics leading to disciplinary content*[2] During a lesson on exponentiation, Ms. Waller's students came across the expression $\left((-4)^{\frac{1}{2}}\right)^2$. Two students obtained different answers when they tried to evaluate this expression. **Anna**: *I got* -4. *I started with* $(-4)^{\frac{1}{2}} = \sqrt{-4}$. *And* $\sqrt{-4} = 2i$. *So* $(2i)^2 = 4i^2 = -4$, *and so* $\left((-4)^{\frac{1}{2}}\right)^2 = -4$. **Brenda**: *My answer was* 4. *I did* $\left((-4)^{\frac{1}{2}}\right)^2 = (-4)^{\frac{1}{2}\cdot 2} = (-4)^{2\cdot\frac{1}{2}} = ((-4)^2)^{\frac{1}{2}} = 16^{\frac{1}{2}} = \sqrt{16} = 4$. Explain the apparent contradiction between Anna's and Brenda's answers in terms of a multi-valued exponential function.
Pink Task: Secondary mathematics from an advanced standpoint Suppose $x \neq 0$. Prove that $x^0 = 1$. You may use the additive law of exponents ($a^{b+c} = a^b a^c$ for all $a \in \mathbb{R}$, $b, c \geq 0$, and $b, c \in \mathbb{Z}$) and the definition that $a^1 = a$ for all $a \in \mathbb{R}$	*Purple Task: Mastery* Find three different pairs of functions g and h such that $g \circ h = (x+3)^2$.
Orange Task: Practice-based drawing on mathematics from an advanced standpoint In Ms. Swain's Algebra I class, a student says the following. *I don't know why* $x^0 = 1$. *Is it just a convention? To me, it seems like it should be 0 because anything times 0 is 0.* Write two different explanations that Ms. Swain can give to address what the student said. The explanations should address the underlying mathematics and be accessible to Algebra I students.	*Blue Task: Practice-based drawing on mathematics from an advanced standpoint* During a lesson on functions and their graphs, a student asks Mr. Loman: *The vertical line test talks about graphs and lines and points. But I thought we said that a function was something that has to do with rules about inputs and outputs. What do lines going through points have to do with rules about inputs and outputs?* Write an explanation that Mr. Loman can give to address the student's question. The explanation should address the student's concerns about the connection between the underlying mathematics.

Table 3. Scatterplots of card sort placements

		Content-Specific Sort Value vs. Expectancy	Content-Generic Sort Value vs. Expectancy	Task Sort Value vs. Expectancy

Key: Green, Orange, Blue = Practice Based, Yellow = Disciplinary Content, Pink = Advanced Standpoint, Purple = Mastery. Larger circles represent more participants placing the card in that approximate location.

Factors influencing value. The most dominant themes for determining value were importance to teaching practice, how the knowledge represented by the task or goal might enhance teaching or how well the nature of mathematics is conveyed, and proximity to secondary mathematics.

Importance to teaching practice. There were 24 statements about the value of a task or goal in terms of its importance to work that teachers do, the knowledge needed for teaching, or whether a task applied mathematics to teaching. All 9 mathematicians made statements to this effect. These statements were used to justify moving practice-based tasks and goals more to the right in the card sort, designating higher value. Typical of this reasoning was Joe's and Cantor's thinking on the content-specific goal sort as they moved the practice-based goal more to the right. As Joe commented, (italics are my emphasis):

> Because their students are going to misunderstand. There are going to be foundational ideas when they're teaching that they they'll need to convey and these ideas are often confusing. So *having them identify you know, what's wrong with this, this solution gives them experience. I guess it gives them experience teaching*.

Joe is pointing out that the work of teaching entails conveying ideas and parsing student work, and the value of the goal is that it seems close to practice. The work of teaching highlighted by participants generally concerned identifying and remedying student misconceptions and explaining mathematics. Calling out work of teaching as a reason for valuing a task or goal occurred in all three card sorts.

The potential for knowledge represented to be useful in teaching was used most typically used to justify value for the practice-based and advanced standpoint tasks and goals. As Heidi commented (italics mine), "And I did put the analyze the incorrect solutions slightly lower and then the understanding relationship and that's partially because I think *you need to understand the relationship first to really be able to analyze the incorrect pieces*." Heidi later commented that making connections between different concepts in secondary math allows a person to teach in a "flexible creative way". One participant did use application to teaching to justify the connections to disciplinary content task. However, this participant still placed the practice-based and advanced standpoint tasks higher.

Finally, the potential for a task to prompt teachers to apply mathematics to teaching was used to justify the value of practice-based tasks and goals. As Cantor reasoned (italics mine), "I guess if teachers can answer the pink one, they probably have a good answer to the orange one, but the orange one felt like more the situation a teacher would get…interact with, *that's more contextualized. So it got moved farther to the right."* All participants valued the Orange Task more than the Pink Task, although not all participants provided explicit reasoning for why. I suggest that one reason may be that, as Cantor pointed out, the Orange Task situates the mathematics of the Pink Task in a teaching situation.

Proximity to secondary mathematics. The closeness of the knowledge to secondary mathematics was generally used to justify moving cards representing advanced standpoint and practice-based with advanced standpoint cards more to the right and connections to disciplinary content more to the left, although two participants also used this to justify moving mastery cards more to the right. As Heidi commented about the connections to disciplinary content task:

> The detail needed for this particular questions is probably beyond the necessary knowledge of somebody whose teaching algebra 1 or middle school math or geometry. … so that's kind of why I put them in the middle.

Participants generally valued advanced standpoint tasks more than the connections to disciplinary content task.

Potential to enhance understanding the nature and foundation of mathematics. Whether a task or goal captured a "foundational" or "fundamental" aspect was used to justify valuing advanced standpoint and practice-based drawing on advanced standpoint, as well as to justify less value in the practice-based drawing on strictly secondary mathematics. Typical of this reasoning was Dan:

> And I feel like…the things that seem most important to me are understanding why things work the way they do and I think it might be important to have a discussion of how there are multiple ways you can come to a correct answer. And some of these problems might illustrate these better than others, but I think the other questions get at deeper foundational issues.

Dan is pointing out both that the more that a task gets at foundational mathematics, the more important it is, and the less that a task foundational mathematics, the less important it is.

Four participants pointed out the importance of connections to disciplinary content as exposure to the nature of mathematics. However, these participants did not place these cards rightmost, hedging that the content might be important, but not as important. As Jim said in the content-specific goal sort:

> I guess well you've made your horizon knowledge to understand these connections and have a deeper appreciation for what we're doing in geometry. We have to push them a little and expose them to a broader viewpoint. But what is the most important thing? Well they better know how to graph something and explain that to someone. Right?"

Two participants pointed out a "neat factor" in connections to disciplinary content, but that this might not be as important as mathematics that is more foundational.

Factors influencing expectancy. The two most dominant themes influencing expectancy were the demands of taking a practice-based approach and related past experiences.

Difficulty of taking a practice-based approach. Participants cited the demands of a practice-based approach for why they felt less confident in teaching practice-based tasks or towards practice-based goals. In particular, participants commented on the difficulty of designing good quality practice-based tasks as well as assessing solutions when the language used could not rely on the typical formal language used in the discipline.

As Cantor observed of practice-based questions, "I tend to be good at recognizing, 'This is really good, these are interesting questions.' But coming up with them, creating them myself I think I tend to struggle." Eight of the participants commented in the wish list section that they wanted "more problems like the colored tasks". That the participants had encountered difficulty in writing practice-based tasks is unsurprising. Although there is increasing knowledge in the field of how to write practice-based tasks well (Gitomer et al., 2014; Hill, Schilling, & Ball, 2004) and of how practice-based tasks function (Howell, Lai, & Phelps, 2016; Howell & Phelps, 2016; Lai, Jacobson, & Thames, 2013), the current state of the art still generally requires multiple reviews and revisions involving persons with different expertise (Gitomer et al., 2014). Combined with the lack of available examples of practice-based tasks for secondary mathematics teaching in commonly used resources, it should be expected that an individual express difficulty expressed in writing practice-based tasks.

Assessing and understanding solutions to practice-based tasks also challenged participants. As Heidi commented on the placement of a practice-based task card, "It's hard seeing inside a student's head to be absolutely sure that you're communicating correctly no matter how much assessment you do, we use words differently. So that's why it's just a little bit lower." Other participants commented that "proofs are something I can do", going on to explain that they have language for proof. I suggest that in contrast, explanations that are student accessible or that are about connections between representations may require using language that is nonstandard, and therefore should seem more difficult than language that is familiar to mathematicians because they are trained in formal language of proofs.

One participant, Margaret, also commented on the difficulty of teaching prospective teachers to see mathematics from their future students' point of view: "You have to teach them how to look … They're viewing it from the right, the student's viewing it from the left, they're seeing mirror images, they're seeing different things, and they haven't even started to think about how this student is seeing it." Margaret saw this perspective as necessary for engaging with practice-based tasks, but expressed reservation in knowing how to cultivate this perspective in prospective teachers.

Related past experiences. Participants described their experience with teaching practice-based tasks to justify expectancy for success in teaching the practice-based tasks or toward the practice-based goals shown. Participants both used positive experiences with practice-based tasks to raise their expectancy of success with these practice-based tasks, and used lack of experience as a reason for lower expectancy of success. For instance, Jim, on the content-generic goal of analyzing mathematical teaching scenarios, commented, "I think it would still be a challenge for me because of lack of experience. … I never took a course on classroom management or, or how to think about how to organize a course." On the other hand, Dan and Heidi, who had both had positive experiences teaching from Beckmann's textbooks for prospective elementary teachers featuring many practice-based tasks, expressed confidence in carrying out further practice-based tasks, even if the tasks were for a different course. As Dan reasoned, "I'm confident that I could, create situations where they could do well or learn to do well, based on having done that in other courses." Previous experience was also used to justify high expectancy on mastery tasks and goals. Although these participants generally did not value mastery tasks and goals as highly as practice-based and advanced standpoint tasks and goals, they at the same time expressed higher confidence in ability to teach for mastery because they had taught more courses with mastery goals. These comments are consistent with findings in the expectancy-value literature; previous achievement-related experience, positive and negative, have been shown to factor into a person's expectancy of future success (e.g., Eccles & Wigfield, 2002).

Table 4. Themes for how participants determined the value of a task or goal

Ways mathematicians determine value	# statements (# distinct participants)
Importance to teaching practice	**24 (9)**
• It arises in the work of teaching	8 (6)
• The work of teaching requires more math than what is being taught to students.	6 (5)
• It is important for teachers to apply content to teaching. If it does not apply as much to teaching, it is not as important.	10 (6)
Proximity to secondary mathematics	**16 (8)**
Potential to enhance teachers' understanding of the nature or foundation of mathematics	**10 (6)**
How mathematical the task or goal is	4 (4)
Not knowing it would be bad for teaching	5 (4)
Needs of particular teachers being taught	4 (3)
Priority for beginning teaching	3 (1)
Total statements	66

Table 5. Themes for factors influencing participants' expectancy

Factors influencing mathematicians' expectancy	# statements (# distinct participants)
Difficulty of taking a practice-based approach	**17 (9)**
• Coming up with practice-based problems is hard	6 (5)
• It is hard to teach prospective teachers to take a teaching viewpoint	2 (1)
• Getting away from formal language is hard	9 (4)
Lack of experience / ability to draw on experience	**27 (7)**
Difficulty of explaining complex mathematics	12 (5)
Perceptions of prospective teachers' beliefs and attitudes	5 (3)
Total statements	61

Discussion

These participants' interviews generally revealed value in practice-based approaches to mathematical preparation of teacher, as well as mixed expectancy for carrying out such approaches. Interview analysis revealed that reasons for valuing practice-based approaches included importance to teaching, proximity to secondary mathematics, and potential to enhance teachers' understanding of the nature and foundation of mathematics. Reasons for higher or lower expectancy included the demands of taking a practice-based approach as well as presence or absence of experience with a practice-based approach.

There are two limitations of the study due to the aim and scope of the study. The first is that only nine mathematicians were interviewed. This is a small sample, and although commonalities emerged from the participants, there is no warrant for sample-to-population generalizations. Nonetheless, this study does document a particular phenomenon—that practice-based tasks could be held in high value in combination with mixed expectancy, and that expectancy can be informed by previous experience. The mathematicians here all participated in workshops that emphasized the need for mathematical knowledge for teaching, so it is unsurprising that they espoused practice-based values. What is more striking in this context is the lack of expectancy. Future studies can look at the degree to which mathematics faculty hold contrasting values and expectancies for practice-based approaches and other approaches, more generally.

The second limitation of this analysis is the scope. The participants examined only a limited number of tasks designed with a particular frame of approaches. It is possible that a different set of tasks or goals would have elicited different value and expectancy ratings. The consistency of the ratings across the three card sorts is promising, although the task and content-specific card sorts could have primed the content-generic card sort that followed. It is also possible that there are approaches to the mathematical preparation of teaching that have not been documented in policy documents for mathematics departments. Yet in the current time, these approaches are the ones that are available and therefore likely the ones that instructors will select among, so understanding why they are theoretically valued as well as valued in practice, are important to understand. The current study identifies some values that may be used in prioritizing among approaches.

The literature on expectancy-value theory suggests that successful goal-oriented decision making is more likely when a person values the goal, has high expectancy at achieving that goal, and has the resources to support goals and build expectancy. When expectancy and resources are not in place, even if a person's values resonate with a goal, the person may not choose to make choices that support that goal. Mathematicians may actually share math educators' values but do not take on practice-based tasks because they lack the confidence and resources to do them.

Classifying combinations:
Do students distinguish between different categories of combination problems?

Elise Lockwood
Oregon State University

Nicholas H. Wasserman
Teachers College,
Columbia University

William McGuffey
Teachers College,
Columbia University

In this paper we report on a survey study to determine whether or not students differentiated between two different categories of problems involving combinations – problems in which combinations are used to count unordered sets of distinct objects (a natural, common way to use combinations), and problems in which combinations are used to count ordered sequences of two (or more) indistinguishable objects (a less obvious application of combinations). We hypothesized that novice students may recognize combinations as appropriate for the first category but not for the second category, and our results support this hypothesis. We briefly discuss the mathematics, share the results, and offer implications and directions for future research.

Key words: Combinatorics, Discrete mathematics, Counting

Introduction and Motivation

Discrete mathematics, with its relevance to modern day applications, is an increasingly important part of students' mathematical education, and national organizations have called for increased teaching of discrete mathematics topics in K-16 mathematics education (e.g., NCTM, 2000). Combinatorics, and the solving of counting problems, is one component of discrete mathematics that fosters deep mathematical thinking but that is the source of much difficulty for students at a variety of levels (e.g., Batanero, Navarro-Pelayo, & Godino, 1997; Eizenberg & Zaslavsky, 2004). The fact that counting problems can be easy to state but difficult to solve underscores the need need for more research about students' thinking about combinatorics.

One fundamental building block for understanding and solving combinatorial problems are combinations (i.e., C(*n,k*), also called binomial coefficients due to their role in the binomial theorem). Combinations are prominent in much of the counting and combinatorial activity with which students engage, and yet little has been explicitly studied with regard to student reasoning about combinations. This study contributes to our understanding of students' reasoning about combinations, and, in particular, beginning students' inclination to differentiate between typical combinatorics problems. This study addresses the following research question: *Do early undergraduate students use binomial coefficients to express the solution to two different categories of combination problems?*

Theoretical Perspective

Lockwood (2013; 2014) has argued for the importance of focusing on *sets of outcomes* in solving counting problems. In an initial model of students' combinatorial thinking, Lockwood (2013) proposed that there are three inter-related components that students may draw upon as they solve counting problems: formulas/expressions, counting processes, and sets of outcomes. Formulas/expressions are terms involving numbers or variables that reflect the answer to a counting problem. Counting processes are the series of procedures, either mental or physical, in which one engages as they solve a counting problem. Sets of outcomes are the complete set of objects that are being counted in the problem, and the cardinality of the set of outcomes gives the answer to the counting problem (Lockwood, 2013). Lockwood also pointed out that a given expression might reflect a counting process, and that various counting processes may impose different respective structures on the set of outcomes. For example, consider solving a problem like *How many arrangements are there of the letters A, B, C, and D?* A 4-stage counting process to solve this problem is to first place one of the four letters in the first position (there are 4 choices), then to place one of the three remaining letters in the second position (3 choices), then to place one of the two remaining letters in the third position (2 choices), and finally to place the last remaining letter in the last position (1 choice). Because at each of these stages the number of choices is the same and is independent of the result of the previous stages, we can multiply the number of options at each stage.[1] This counting process thus yields an expression of 4•3•2•1, which is 24. Note that this counting process also imposes a structure on the set of outcomes, namely organizing them according to first, then second, then third, then fourth letter. The lexicographic listing of the set of outcomes in Figure 1 demonstrates the set of outcomes that might be associated with the specific counting process.

ABCD	BACD	CABD	DABC
ABDC	BADC	CADB	DACB
ACBD	BCAD	CBAD	DBAC
ACDB	BCDA	CBDA	DBCA
ADBC	BDAC	CDAB	DCAB
ADCB	BDCA	CDBA	DCBA

Figure 1 – A lexicographic listing of arrangements of A, B, C, and D

The point of this example is that a given formula or expression (4•3•2•1) may have a combinatorial process that underlies it (the 4-stage process described above), which in turn structures the set of outcomes in some specific way. Lockwood (2013) argued that it would behoove students to have flexibility in their counting, especially in understanding that different counting processes may organize the sets of outcomes in different ways, and vice versa.

Lockwood (2014) emphasized the importance of sets of outcomes, and argues for a set-oriented perspective toward counting. In this perspective, counting "involves attending to sets of outcomes as an intrinsic component of solving counting problems" (p. 31). In this paper, we frame our work from this perspective, namely that *sets of outcomes* are the key factor in determining what counting situation one is in, and thus what counting process and formula may be appropriate. That is, as we discuss "combination problems," we consider a problem to be a combination problem if the set of outcomes can be appropriately modeled in a particular way (specifically, as sets of distinct objects), as opposed to being attuned to problem features like particular key words or contexts.

The nature of our data is such that we are, at times, only able to examine a student's written expression and must make inferences about their counting process based on that expression. In this way, we draw on Lockwood's (2013) model and its position that counting processes can and do underlie formulas and expressions. Those underlying processes can suggest how students might be conceiving of the set of outcomes, if at all.

[1] This is due to the multiplication principle, which is a fundamental yet subtle combinatorial idea. See Tucker (2002) for a statement of the principle and Lockwood, Reed, & Caughman (2015) for a more in-depth discussion of its mathematical subtleties.

Literature

Combinations as a Unifying Combinatorial Topic

Combinations, or binomial coefficients, are one of those unifying topics that connect a variety of combinatorial contexts and ideas. They are commonly used to count particular kinds of objects, namely k-element subsets of n-element sets, or, equivalently, the number of ways of selecting k elements from an n-element set. But this fact is applied meaningfully in a variety of important combinatorial settings, establishing combinations as a foundational "big idea" in combinatorics. Specifically, in addition to solving counting problems, these binomial coefficients also show up as entries in the rows of Pascal's Triangle as a model for solving multichoose problems, and as the coefficients in the binomial theorem, $(x+y)^n = \sum_{k=0}^{n} C(n,k)x^n y^{n-k}$, because to find the coefficient of a given x^k term we simply choose which k of the n binomials will contribute an x term. Because of this important relationship, combinations are known as binomial coefficients and arise in a number of mathematical domains. Finally, combinations appear in many combinatorial identities, and they necessitate combinatorial proof, which is another key topic in combinatorics. The variety of contexts in which combinations naturally arise points to the invaluable role that they play in the domain of combinatorics. Given how pervasive and fundamental they are, we were motivated to better understand how students might reason about and learn this foundational combinatorial idea.

Combinations in Mathematics Education Literature

There is much documented evidence for the fact that students struggle with solving counting problems correctly. Some reasons for such difficulty are that counting problems are difficult to verify (Eizenberg & Zaslavsky, 2004) and that it can be difficult to effectively encode outcomes in terms of objects one knows how to count (e.g., Lockwood, Swinyard, & Caughman, 2015b). We seek to address potential difficulties by focusing on better understanding students' application and use of combinations – which are fundamental in enumeration. Piaget & Inhelder (1957) studied students' mental processes as they solved arrangement and selection problems, and they took a special interest in determining whether permutations, arrangements, or combinations would be most difficult for students. Dubois (1984), Fischbein and Gazit (1988), and Batanero, et al. (1997) have also investigated the effects of both implicit combinatorial models and particular combinatorial operations on students' counting, again considering differences in reasoning about particular problem types such as permutations and combinations. We extend existing work that focuses on students' mental processes of foundational combinatorial ideas, seeking specifically to explore the extent to which undergraduate students appear to distinguish between two categories of combination problems (we define these two categories in the following section).

Other researchers have looked at students as they explore the variety of settings in which binomial coefficients arise. For example, Maher, Powell, and Uptegrove (2011) documented several episodes in which students of their longitudinal study make meaningful connections between binomial coefficients, certain counting problems, and Pascal's Triangle. More specifically, Speiser (2011) documented one 8th grade student's reasoning about problems involving block towers, which can be solved as combination problems, and connections she made to the formula C(n,r). In a similar vein, Tarlow (2011) reported on eight 11th grade students who could make sense of a well-known binomial identity using both pizza and towers contexts. These studies highlight the many connections that binomial coefficients afford in combinatorial settings, suggesting that it may be beneficial for students to have a sophisticated understanding of binomial coefficients that could facilitate these kinds of valuable connections. We build upon this work by Maher et al., (2011) by focusing on whether or not students see two distinct settings as both involving combinations.

Our work also builds on a recent study by Lockwood, Swinyard, & Caughman (2015a) in which two undergraduate students reinvented basic counting formulas, including the formula for combinations. Based on the students' work on combination problems, Lockwood, et al., (2015b) suggested the importance of being able to correctly encode outcomes combinatorially (by which they mean the act of articulating the nature of what is being counted by associating each outcome with a mathematical entity such as a set or a sequence). More specifically, the students could solve combination problems but not others, which was curious given their overwhelming success overall. In our current study, we were able to mathematically characterize a fundamental difference between some common combination problems based on characterizing a difference in their sets of outcomes. We wanted to explore further whether, for novice students, this distinction in the set of outcomes would pose a significant hurdle to their ability to recognize binomial coefficients as equally useful in the solutions to both situations. This resulted in us differentiating two different, different "categories" of combination problems and speculating about whether or not, for students, this difference matched their reality. We introduce and explore this distinction in the next section.

Mathematical Discussion – Classifying Two Categories of Combination Problems

In this section we outline mathematical details of combinations, and we highlight a distinction between two "categories" of combination problems based on their sets of outcomes that is the focus of our investigation. A combination is a set of distinct objects (as opposed to a permutation, which is an arrangement of distinct objects). Combinations can also be described as the solution to counting problems that count "distinguishable objects" (i.e., without repetition), where "order *does not* matter." The total number of combinations of size k from a set of n distinct objects is denoted C(n,k) and is verbalized as "n choose k."[2] So, the binomial coefficient C(n,k) represents the set of all combinations of k objects from n distinct objects. As an example, combinations can be used to select, from eight (distinguishable) books, three books to take on a trip (order does not matter) – the solution is C(8,3), or 56 possible combinations. In contrast, other combinatorial problems and solution methods, such as permutations, are frequently organized in relation to the different possible constraints – see Table 1.

Table 1: Selecting *k* objects from *n* distinct objects

	Ordered	**Unordered**
Distinguishable Objects (without repetition)	Permutations $\frac{n!}{(n-k)!} = n\cdot(n-1)\cdot(n-2)\cdot\ldots\cdot(n-k+1)$	Combinations $\binom{n}{k} = \frac{n!}{k!(n-k)!}$
Indistinguishable Objects (with repetition)	Sequences $n^k = \underbrace{n\cdot n\cdot n\cdot\ldots\cdot n}_{k}$	Multicombinations $\left(\binom{n}{k}\right) = \binom{k+n-1}{n-1}$

In this paper we refer to *combination problems* as problems that can be solved using binomial coefficients, in the sense that parts of their outcomes can be appropriately encoded as *sets* of distinct objects. Sometimes this encoding is fairly straightforward, as the outcomes are very apparently sets of distinct objects. For instance, in the above problem of selecting three books from eight books to take on a trip, the books could be encoded as the numbers 1 through 8

[2] The derivation of the formula for $C(n,k)$ as $n!/((n-k)!k!)$ is not pertinent to the study; Tucker (2002) provides a thorough explanation.

(because they are different books), and the outcomes are fairly naturally modeled as 3-element sets taken from the set of 8 distinct books. Any such set is in direct correspondence with a desired outcome; there are C(8,3) of these sets. We call such problems Category I problems.

In other situations, fairly typical combination problems may still appropriately be solved using a binomial coefficient, but recognizing how to encode the outcomes as sets of distinct objects is less clear. For example, consider the Coin Flips problem (stated in Table 2). A natural way to model an outcome in this problem is as an ordered sequence of length 5 consisting of 3 (identical) Hs and 2 (identical) Ts, such as HHTHT. Solving the problem then becomes a matter of counting such sequences. One way to count the number of such sequences is to arrange all of the five letters (in 5! ways), and then divide out the repetitive outcomes based on the fact that there are three identical Hs (3!) and two identical Ts (2!) – a solution of 5!/(3!2!). One could think of first treating all five of the letters as distinct and then "un-labeling" identical Hs and Ts. However, we note that the problem also can be (and frequently is) solved using a binomial coefficient – but, in order to do this, the outcomes must be encoded appropriately as a set of distinct positions in which the Hs are placed. Given the five possible distinct positions (i.e., the set: {1, 2, 3, 4, 5}), the outcome HHTHT would be encoded as the set {1, 2, 4}. This sufficiently establishes a bijection between outcomes (sequences of Hs and Ts) and sets of the numbers 1 through 5 because every outcome has a unique placement for the Hs (the Ts must go in the remaining positions). In this way, the answer to the Coin Flips problem is simply the number of 3-element subsets from 5 distinct objects (i.e., positions 1 to 5), which is C(5,3). This gives an identical formula of 5!/(3!2!) and it is another way of solving the problem.[3] We call these problems, which can naturally be modeled as *sequences* of *identical* objects, but which can be encoded so as to be solved via a binomial coefficient, Category II problems (See Table 2).

Table 2: Characterizing two different categories of fairly standard combination problems

	Description	Example problem	Natural Model for Outcomes
Category I	*An unordered selection of distinguishable objects*	*Basketball Problem.* There are 12 athletes who try out for the basketball team – which can take exactly 7 players. How many different basketball team rosters could there be?	{(1,2,3,4,5,6,7), (1,3,5,7,9,11,12), …}
Category II	*An ordered sequence of two (or more) indistinguishable objects*	*Coin Flips Problem.* Fred flipped a coin 5 times, recording the result (Head or Tail) each time. In how many different ways could Fred get a sequence of 5 flips with exactly 3 Heads?	{(HHTTH), (HTHHT), (TTHHH), …}

In light of various ways of encoding outcomes that facilitates the use of combinations, we point out that it may *seem* that combinations are actually being used to solve two very different kinds of problems. The outcomes in the Books problem are clearly unordered sets of distinct objects, but the outcomes in the Coin Flips problem are actually *ordered* sequences (not unordered) of two kinds of *indistinguishable* (not distinct) objects (Hs and Ts). Combinations are

[3] We can use Lockwood's (2013) language to describe this phenomenon, in which two different counting processes might yield the same expression. Indeed, the point is that just by looking at a particular formula or expression that a student writes for a problem, it may require some interpretation as to what their underlying counting process to solve the problem might have been. We can hypothesize and look for supportive evidence, but it is possible for multiple counting processes to yield identical expressions.

applicable in both situations, but we argue that there could be a difference for students in identifying both problems as counting combinations. Indeed, although both categories can be, and frequently are, thought of in terms of counting (choosing) sets, using combinations to solve Category II problems involves an additional step of properly encoding the outcomes with a corresponding set of distinct objects. We thus posit that Category I problems may be more natural for novice students, more clearly representative of combination problems than Category II problems. In spite of the widespread applicability of combinations, we posit that students may not recognize both categories of combination problems as problems involving combinations. This may be due in part to the fact that students tend not to reason carefully about outcomes (e.g., Lockwood, et al., 2015b), and because "distinguishable" and "unordered" are not always natural or clear descriptions of the situation or outcomes.

However, we note that it is important and useful for students to be able to solve these Category II problems (and use combinations to do so) because combinations often arise as a *stage* in the counting process. Furthermore, using combinations in this way can facilitate productive and efficient solutions. For example, consider a problem such as *Passwords consist of 8 upper-case letters. How many such passwords contain exactly 3 Es?*. This problem can be solved by using combinations as a stage in the counting process – first we select 3 of the 8 positions in which to place Es (there are C(8,3) ways to do this), and then we fill in the remaining position with any of the 25 non-E letters (there are 25^5 ways to do this). Thus, the two-stage process yields an answer of $C(8,3)*25^5$. Here, we recognize that a Category II combination problem can help us complete the first stage of the counting problem. Importantly, realizing that a combination is useful in the first step makes the problem much easier than if one were to try to only to use permutations to do so. If we tried to answer the Passwords problem without first selecting places for the Es, and instead took a permutation approach, it would be possible, but it would require a large number of complex case breakdowns.[4] Thus, we argue that being able to solve Category II problems by using combinations demonstrates the utility of combinations as a powerful tool, and yet it also represents a sophisticated understanding of what combinations count, because it involves encoding the set of outcomes in a particular way. Given that the ability to solve Category II combination problems may allow students to solve a wide range of problems, and that it can reinforce a more complete understanding of what binomial coefficients can do, we are motivated us to investigate whether or not students actually respond differently to the two different problem categories.

Methodology

We designed two versions of a survey, and although the surveys contained a number of elements, we focus in particular on features of the survey that serve to answer the research question stated above. Each survey consisted of 11 combinatorics problems, and each problem was designed with categories in mind that included problem category (I or II) and complexity (Simple, Multistep, or Dummy).[5] *Simple* combination problems refer to those that can be solved using a single binomial coefficient, in the sense that their outcomes can be appropriately encoded as sets of distinct objects; *multistep* combination problems would require multiple binomial

[4] For example, we would have to consider how many of the non-Es are distinct and then arrange them. So we would have to account for cases in which a) all of the non-E letters are identical, b) exactly one of the non-E letters is identical (and the rest are distinct), c) exactly two of the non-E letters are identical (and the rest distinct), there are exactly two pairs of identical non-E letters, and so on. This process can generate the right answer, but it is complex.

[5] We also coded the tasks according to other criteria that we do not report on in this paper, such as: sense of choosing (Active or Passive), and whether an object or process is to be counted (Structural or Operational).

coefficients in the solution (see Table 3 for problems in Survey 1 and the Appendix for Survey 2). The authors coded the problems independently before finalizing the coding for each problem. Each version of the survey contained the same number of problems of each category and complexity, as well as the same two "Dummy" problems to discourage students from assuming that every problem could be solved with a combination. Each problem was selected for one version of the survey with a companion problem in mind for the other version in order to compare responses with respect to the various coding categories. In this report, however, we primarily use the two surveys as additional support that the phenomenon observed is not limited to particular problems on one survey, but is consistent across a larger variety of these different categories of problems.

Table 3: Survey 1

Description		Problem
Category I	**Simple**	*There are 12 athletes who try out for the basketball team – which can take exactly 7 players. How many different basketball team rosters could there be?*
Category I	**Simple**	*There are 8 children, and there are 3 identical lollipops to give to the children. How many ways could we distribute the lollipops if no child can have more than one lollipop?*
Category II	**Simple**	*There are 3 green cubes and 4 red cubes. Sam is making "towers" using all of the 7 blocks by stacking the cubes on top of each other. How many different "towers" could Sam make?*
Category II	**Simple**	*Computers store data using binary notation - an ordered sequence of 0s and 1s. A particular piece of computer data is 95 digits in length, and it has exactly 12 1s. How many possible sequences fit this constraint?*
Category II	**Multistep**	*Stella is stacking ice cream scoops onto a cone. She has 3 scoops of chocolate, 5 of vanilla, 2 of pistachio, and 6 of strawberry. How many different ways can she stack all of the ice cream scoops onto the cone?*
Dummy		*In Montana, a license plate consists of a sequence of 3 letters (A-Z), followed by 3 numbers (0-9). How many different possible license plates are there in Montana?*
Category I	**Simple**	*There are 12 points, all different colors, drawn on a sheet of paper (and no three points are on a line). How many different possible triangles can be made from these 12 points?*
Category I	**Simple**	*Bob got a new job and is at a store looking for new ties. The tie rack has 196 different ties to choose from. In how many ways can Bob select 10 ties to buy?*
Category II	**Simple**	*Fred flipped a coin 25 times, recording the result (Head or Tail) each time. In how many different ways could Fred get a sequence of 25 flips with exactly 11 Heads?*
Category I	**Multistep**	*There are 8 females and 10 males who would like to be on a committee. How many different committees of 6 people could there be if there need to be exactly 2 females on the committee?*
Dummy		*From an Olympic field of 15 athletes competing in the 100-meter race, how many different possible results could there be for gold, silver, and bronze medals?*

We targeted Calculus students because they were believed to have been likely to have encountered combinations at some point in their mathematical careers (perhaps in middle or high school) without having studied them in detail, making them informed but novice counters. Although we collected some additional demographic information about their previous mathematics courses and experiences with combinatorics, we have yet to incorporate this into our analysis. Overall, 281 people started the survey; however, many of these did not answer a single question on the survey, leaving n=126 people (65 for Survey 1, 61 for Survey 2), who responded to at least one of the combination questions. We included a reminder in the beginning of the survey that offered a brief standard overview of combinations and permutations. The goal was for students to be reminded of the formulas and notation for combinations and permutations that they likely had encountered previously at some point in their education.

The prompt for the combination problems asked participants to use notation that would suggest their approaches, rather than just numerical values. We gave this prompt because we wanted to be able to know what the student's counting process was, and so we would not have to make inferences based only on numerical responses. Specifically, the prompt was:

> Read each problem and input your solution in the text box. **Please write a solution to the problem that indicates your approach.** If you're not sure, input your best guess. NOTE: Appropriate notation includes: 9+20, C(5,2), 5C2, 21*9*3, 5*5*5*5=5^4, 8!, 8!/5! = 8*7*6 = P(8,3), C(10,2)*3, Sum(i,i,1,10), 12!/(5!*7!), etc. *Only* if you individually count *all* of the outcomes should you input a numerical answer, such as 35.

In addition, for three of the problems, participants were prompted to expand particularly on how they understood the set of outcomes they were counting (see Appendix for this prompt.) The intent was to provide further evidence from the students about their counting process and the set of outcomes. Notably, however, many students had difficulties with these instructions, frequently providing numerical answers in their initial responses. We discuss further our analysis approach.

In general, to investigate the research question we wanted to compare their solutions to the different categories of combination problems. Thus, we coded each response in three different ways. First, we coded whether the response was "correct" or "incorrect." In this case, *any* problem the participants answered was determined to be correct or incorrect (with two exceptions: if the notation they used was not standard, e.g., "C(3,5,2,6)," – which happened four times – or their answer was unclear, e.g., "a small fraction of 95^{95}," to where we could not judge correctness – which happened five times). Importantly, *many* of the participants only included numerical answers, for which we could just confirm correctness, but not process. Therefore, secondly, for those participants that wrote a solution indicating their approach (i.e., followed the instructions) we coded the "definite" method that characterized their solution. If they used a combination, we coded whether they used the combination correctly (CC) or incorrectly (CI); if their answer involved a permutation, we coded it a P; if their answer was essentially multiplying numbers, we coded it M; if it only involved factorials that were not in a permutation or combination formula, we coded it F; if it involved exponents, we coded it E, if they just summed numbers, we coded it S; if they just used a single number from the problem, we coded it N; and if it was did not fall into any of the previous categories, we coded it O.

Notably, for three of the problems, participants had an opportunity to explain more in relation to the sets of outcomes. For some participants who wrote numerical expressions, it was here that they explained their process. Therefore, when the numerical answer and their process matched up in these cases, we included a "definite" method based on their explanation. As mentioned previously, from some solution responses the method would not be completely clear. Particularly considering combinations, we had to determine the meaning of a response such as: "8!/(5!3!)." Thankfully, there were not many such instances. For participants who appeared to be using the verbatim combination formula, such as "8!/(5!(8-5)!)," we coded this as a combination; however, for participants who wrote "8!/(5!3!)," if there was a clear indication from the set of outcomes responses or if they had used combination notation on other problems, e.g., C(20,10), we presumed their response to be indicative of a permutation approach.[6] Thirdly, if numerical answers seemed to have a clear process – such as the problem including the numbers 8 and 5, and participants answering 40 – we coded the "probable" method that characterized their response.

We consider this last coding involving "probable" codes as the best set of codes for our analysis for two reasons. First, some students gave correct numerical responses, such as 4,457,400, which we viewed as most likely indicative of using C(25,11), because coming up with this answer in some other way would be very difficult. This allowed us to include C(25,11) as their probable method – to the extent possible, we wanted to give students the benefit of the doubt. Second, because so many responses were only numerical, this also allowed us to include some more responses in the analysis for which we could be fairly sure of their method.

For the purposes of this paper, we limit our analysis only to the most basic combination questions – the four *simple* Category I problems and the three *simple* Category II problems on each survey. These seven problems provide us with the most basic comparison between their responses to these two categories of problems. So, using the third coding ("probable" method), first we computed the proportion of instances on which participants used a combination approach at all for Category I problems, and the proportion of instances on which participants used a combination approach at all for Category II problems, and compared these two proportions. We also computed the proportion of these responses that were correct uses of a combination approach. Notably, however, each individual participant answered up to seven such questions. Thus, for each individual, we secondly computed whether or not that individual had used a combination approach at all on at least one Category I problem, and whether they had used a combination approach at all on at least one Category II problem. We also computed the proportion of participants that had used the combination approach correctly on at least one of each category of problem. This allowed us the ability to compare the proportion of distinct participants (not distinct problems) who had used a combination approach correctly on the differing problem categories. Thirdly, given that many participants' methods were significantly off track – i.e., many simply multiplied numbers in the problem without ever using a different method – we limited our participants to only those that had used a combination approach on at least one problem. This allowed us to probe further whether participants that at least found a combination approach useful on one problem were differentiating between the two problem categories. For each proportion, we used a proportion *t*-test to determine whether the proportions were significantly different, and then used Cohen's *h* to determine the relative effect size of the differences. (We used standard cutoffs from Cohen (1988) of: 0.2, small effect; 0.5, medium; and 0.8, large.) Notably, when separating the analysis by survey, the results in every analysis were similar, and so we present the combined analysis across both surveys.

Findings

In this section we present the different analyses of our data, which all support the singular finding that students do indeed use a combination approach more regularly on Category I problems than they do on Category II problems. We regard this result as indicating that from a

[6] Indeed, one participant (1009), had correctly responded "20C4" to one problem, explaining it as, "You choose any 4 out of 20. Order is irrelevant," and had responded "8!/((5!)*(3!))" on another problem, explaining it as, "It's like having five dots and placing 3 dots in between the five. This is similar to arranging them in any way but not caring how they are arranged among themselves."

learners' perspective there is a meaningful difference between these two categories of basic combination problems.

Overall Participant Responses. Of the 126 participants, there were 117 of which we were able to give a "probable" approach code on at least one Category I problem that they answered, yielding 380 total responses to Category I problems for which we probably knew the participants' approach. There were 116 participants for which we were able to give a "probable" approach code on at least one Category II problem, yielding 261 total responses to Category II problems for us to consider. Table 4 indicates the results. The data show that about 24% of the responses to Category I problems used a combination approach, whereas only 16% of responses to Category II problems did – a significant difference, but with a small effect size. Interestingly, most of the combination approaches to Category I problems were correct (only 2/90 were incorrect), whereas about one-quarter of the combination approaches to Category II problems were incorrect (11/43 were incorrect). We see this as another indication that even if a student attempts to use a combination approach on Category II problems, they are doing so in ways that are, in fact, incorrect. Similarly, when isolating unique participants, we also find a statistically significant difference, with relatively small effect size, between the proportion of participants that were using a combination approach on Category I compared to Category II problems.

Table 4. Comparison of Overall Participant Responses

	Category I Simple		**Category II Simple**		***p*-value**	**Cohen's *h***
On what proportion of **responses** is a combination approach **used at all**?	90/380	~24%	40/261	~15%	p<0.01	0.212 (Small)
On what proportion of **responses** is a combination approach used **correctly**?	88/380	~23%	29/261	~11%	p<0.001	0.324 (Small)
What proportion of **participants** used a combination approach **at all** on at least one problem?	38/117	~32%	24/116	~21%	p<0.05	0.268 (Small)
What proportion of **participants** used a combination approach **correctly** on at least one problem?	37/117	~32%	18/116	~16%	p<0.01	0.385 (Small)

Reduced Participant Responses. Since many participants never used a combination approach on any problem in the survey, as is evident from the overwhelmingly small proportions in Table 4, we reduced our participants to only those 42 who had used a combination approach on at least one problem – either Category I or Category II. These 42 participants yielded 153 responses to Category I problems, and 114 responses to Category II problems. Table 2 indicates the results. Notably, for even these seemingly more knowledgeable participants there is a significant difference in the use of a combination approach to these two categories of problems. In fact, by reducing our population to only those who at least appear to have some idea that a combination might be a useful approach to solve a counting problem, we see larger effects in the differences. Given that these participants most closely match our desired population of participants – students who had likely been introduced to combinations but not studied them extensively, and who can use combinations appropriately in some settings – we see these results as the most telling.

Table 5. Comparison of Reduced Participant Responses

	Category I Simple		Category II Simple		*p*-value	Cohen's *h*
On what proportion of **responses** is a combination approach used **correctly**?	88/153	~58%	29/114	~25%	$p<0.001$	0.664 (Medium)
What proportion of **participants** used a combination approach **correctly** on at least one problem?	37/42	~88%	18/42	~43%	$p<0.001$	1.009 (Large)

Discussion

Despite the fact that both Category I and Category II problems could be naturally encoded as combination problems, our findings suggest that the participants do not view the problems in this way. We found statistically significant differences in students' use of combinations to solve Category I versus Category II problems. In this way, our study offers quantitative evidence of what had been an anecdotally observed phenomenon.

In terms of the model of students' combinatorial thinking (Lockwood, 2013) and the set-oriented perspective toward counting (Lockwood, 2014), this study suggests that students are not recognizing that outcomes of Category II problems can be appropriately encoded as *sets* of objects. That is, even though natural bijections exists that would allow students to leverage binomial coefficients in a variety of contexts, our research suggests that students are either not aware of this fact or are not able to use that bijection to encode outcomes effectively. Indeed, a large majority of students were simply not able to answer Category II questions in a correct manner, regardless of the method – there were no other correct non-combination responses to the Category II questions, except one participant who correctly solved three Category II questions in a permutation manner. However, we want to acknowledge that it is not necessarily surprising that students would struggle to see this distinction. Indeed, familiar descriptions of "unordered" and "distinct" do not seem to apply – at least in the most natural way to model the outcomes. Students can tend to associate counting with key words, specific contexts, and mantras like "order doesn't matter," and they tend not to think about counting in terms of the outcomes they are trying to count (Lockwood, 2014). If this is a student's perspective on counting, it would follow that they would not be attuned to the importance of encoding outcomes and might not realize that they have the flexibility to encode outcomes in creative ways. Our study thus offers further evidence that students would benefit from focusing on the nature of the outcomes as the determining factor in what counting processes (and, ultimately, formulas) are most appropriate in a given situation.

Conclusions, and Implications

In sum, students may need additional exposure to combinations and may benefit from explicit instruction about how Category II problems can be encoded in a way that is consistent with Category I problems. Generally, this point underscores a need for students to become more adept at combinatorial encoding (Lockwood, et al., 2015b). Encoding outcomes as sets is an inherent part of the field of combinatorics, but students may need particular help in making this connection explicit. Also, these findings provide evidence for the fact that it may not be productive for students to be exposed to formulas initially if they are not pushed to understand those formulas.

In terms of implications for instruction, then, we feel that teachers should explicitly direct students toward focusing on what they are trying to count. This means thinking of combination problems not exclusively as those problems whose outcomes can be encoded as sets of objects. Given how difficult (and seemingly unnatural) it is for students to encode outcomes of Category II problems, instructors may need to give examples of ways to encode outcomes of Category II problems and to clearly establish relevant bijections. Discussing the relationship between how one models the set of outcomes and the pertinent solution approach may also be particularly meaningful in this context. For example, listing outcomes as 5 Hs and 3 Ts might lead to a permutation approach of 8!/(5!3!), whereas further encoding the outcomes in terms of the 5 distinct positions, for which three will be heads, might lead to C(5,3) as the natural solution approach. This is not to claim one approach as preferential over another, but we regard having both the flexibility to see different solution approaches as viable in this situation, as well as connecting sets of outcomes with particular solution methods, as highly important in developing an understanding of combinatorics. This might mean that instructors should first familiarize themselves with this distinction and to be able to understand and articulate what the distinction is between these two categories and why students might perceive them as different. Being able to use binomial coefficients flexibly and in a variety of settings can be a powerful tool for solving enumeration problems, but without a robust understanding – including how and why Category II problems can be solved using them – students may possess a tool they do not really understand how to use. As instructors, we should invest time and energy in helping students to understand this tool and the various ways in which it can be effectively used.

There are natural next steps and avenues for further research. We plan to investigate more questions and hypotheses with the data we have, such as analyzing effects of demographic data and investigating other relationships and potentially contributing factors in students' responses. We also want to explore the multistep problems more, and we wonder if perhaps the multistep problems might be similar in some way to the Category II problems, because both of these use a binomial coefficient as part of a process as opposed to the complete set of solutions. We could also see investigating similar kids of questions with counters with more experience than the novice calculus students, such as discrete mathematics or probability students. Our findings also indicate that further investigating students' reasoning about encoding with combinations through in-depth interviews may give insight into the development of more robust understandings.

Appendix

Prompt 2: "On the previous page, you entered your solution to different combinatorics problems. **On this page, we would like you to expand upon how your solution is related to the "set of outcomes" for a few of the problems.** That is, we want you to list **some (but not necessarily all)** of the outcomes that you are counting. Explain your thinking for your solution and its relation to what is being counted.

For example, for the problem, "If we have four distinct toy cars (Red (R), Blue (B), Green (G), and Yellow (Y)), how many different subsets of 2 of them are there?", your solution to the problem might have been: C(4,2). On this page, the intent is to expand on how that solution, C(4,2), relates to the set of outcomes. You might write something like, "The set of outcomes includes the following pairs of cars: BR, RG, GY, BG. I used the combination C(4,2) because the outcomes were "pairs" (2) from the 4 different colored toy cars. I did not include RB because this would be the same as BR in this case."

Table: Survey 2

Description		Problem
Category I	**Simple**	*You are packing for a trip. Of the 20 different books you consider packing, you are going to select 4 of them to take with you. How many different possible combinations of books could you pack?*
Category I	**Simple**	*There are 9 justices on the Supreme Court. In theory, how many different ways could the nine justices come to a 7:2 vote in favor of the defendant?*
Category II	**Simple**	*Stella is ordering an ice cream cone that is 8 scoops tall. She orders 5 chocolate scoops and the rest vanilla. How many different ways can the employee stack the ice cream scoops?*
Category II	**Simple**	*There are 55 elementary students standing in a line. The teacher has 35 identical red balloons and 20 identical blue balloons, and gives each student either a red or a blue balloon. How many different outcomes are possible in this process?*
Category II	**Multistep**	*Sam is making "towers" from 3 green, 4 red, 2 yellow, and 8 orange blocks. Using all 17 blocks, how many different "towers" could Sam make?*
Dummy		*In Montana, a license plate consists of a sequence of 3 letters (A-Z), followed by 3 numbers (0-9). How many different possible license plates are there in Montana?*
Category I	**Simple**	*There are 15 people in a room. Everyone shakes hands with everyone else. How many different handshakes take place?*
Category I	**Simple**	*There are 250 kittens at a shelter. Sally is adopting 6 of them. In how many ways could she adopt 6 kittens?*
Category II	**Simple**	*A professor writes a 40-question True/False test. If 17 of the questions are true and 23 are false, how many possible T/F answer keys are possible?*
Category I	**Multistep**	*There are 19 students in your class. How many ways are there to split the class into 3 different groups - one group of size 5, another of size 6, and another of size 8?*
Dummy		*From an Olympic field of 15 athletes competing in the 100-meter race, how many different possible results could there be for gold, silver, and bronze medals?*

When we grade students' proofs, do they understand our feedback?

Robert C. Moore

Earlham College

Sarah Hanusch
Texas State University

Tim Fukawa-Connelly
Temple University

Instructors often write feedback on students' proofs even if there is no expectation for the students to revise and resubmit the work. It is not known, however, what students do with that feedback or if they understand the professor's intentions. To this end, we asked eight advanced mathematics undergraduates to respond to professor comments on four written proofs by interpreting and implementing the comments. We analyzed the student's responses using the categories of corrective feedback for language acquisition, viewing the language of mathematical proof as a register of academic English.

Keywords: Proof Writing, Proof Grading, Proof Instruction, Proof Revision, Student Thinking

Introduction and Research Questions

Rav (1999) claimed that proofs "are the heart of mathematics" and they play an "intricate role […] in generating mathematical knowledge and understanding" (p. 6), and multiple authors have claimed that proof is how the discipline grows (cf., Lakatos, 1976; de Villiers, 2003). Consequently, proof is perhaps the dominant feature of the advanced undergraduate mathematics curriculum. For example, Mills (2011) estimated that approximately half of all class time consists of instructors presenting proofs at the board while the presentation of definitions, examples, algorithms and theorems (as well as explanations of the same) together constitute less than half of class time. Similarly, student homework and exams in advanced mathematics classes generally include a number of prompts asking them to produce written proofs of given claims (cf., Fukawa-Connelly, 2015). That is, as Weber stated, developing proof proficiency "is often the primary goal of advanced mathematics courses and typically the only means of assessing students' performance" (2001, p. 101).

While proof proficiency may be the primary goal of advanced undergraduate mathematics courses, a significant body of research has demonstrated that students have great difficulty writing proofs, and a body of writing about mathematicians' personal teaching experiences supports this claim as well. For example, Epp (2003) claimed:

> Often their efforts consisted of little more than a few disconnected calculations and imprecisely or incorrectly used words and phrases that did not even advance the substance of their cases. My students seemed to live in a different logical and linguistic world from the one I inhabited, a world that made it very difficult for them to engage in the kind of abstract mathematical thinking I was trying to help them learn. (886)

Due to space constraints, we do not report all of this research here, rather we note that there are multiple handbook chapters (e.g., Harel and Sowder, 2007) describing the literature, and a comprehensive summary of undergraduate mathematics majors' difficulties with proof is given in Selden and Selden (2008). This difficulty is further illustrated by the emphasis on reforming proof instruction as evidenced by the large number of "how-to" textbooks on proofs (e.g., Chartrand, Polimeni, & Zhang, 2012; Franklin & Daoud, 2011; Smith, Eggen & St. Andre, 2014), and practitioner articles about improving student proof writing (e.g., Strickland & Rand, in press; Zerr & Zerr, 2011). Of particular importance to the present study is Moore's (1994) claim that students are unfamiliar with the language of mathematical proof. Yet, the language of proof writing is largely unstudied, and thus, there is little information about how mathematicians understand this language; instead, we rely on individual reflections and theoretical analyses.

We argue that the language of proof is a particular academic register of English. A register is a variety of language used for a particular purpose or within a particular social context. Specifically, it "is the set of meanings, the configuration of semantic patterns, that are typically drawn upon under the specific conditions, along with the words and structures that are used in the realization of these meanings" (Halliday, 1978, p. 23).To support our claim that the language of mathematical proof constitutes a register, we note that Scarcella (2003) claimed that academic English was a particular register "used in professional books and characterized by the specific linguistic features associated with academic disciplines" (p. 9) and that each academic discipline had its own particular subregister. Halliday (1978), Pimm (1987) and Moschkovich (1999) have similarly argued that the language of mathematics constitutes a particular register. Thus, "we can refer to a 'mathematics register,' in the sense of the meanings that belong to the language of mathematics [...], and that a language must express if it is being used for mathematical purpose" (Halliday, 1978, p.195).

When considering how students might learn and use this register, exposure and practice is certainly important (Pinker, 2009). Yet, without feedback on this practice, students are unlikely to improve their proof writing. Moreover, mathematicians act on the belief that giving students feedback is critical to their learning by making marks and notes on student proof productions (e.g., Hattie & Timperley, 2007; Moore, 2016). Yet, this feedback improves student learning only if students read, make sense of, and incorporate it into their future work. Few, if any, studies have explored students' understanding of this process of giving feedback as a means to improve their proficiency. Thus, in this study we investigate the following questions:

1. What do students claim to do with the professor's feedback on their proofs?
2. How do students interpret and explain the rationale for the professor's marks and comments on student-written proofs?
3. How do students' responses to the professor's comments align with the way that is normative in the discipline, as described by mathematically enculturated individuals?

Literature and Theory

Theoretical orientation

The theoretical orientation for this study is acquisition of language through which we consider the register of mathematical proof. In the case of proof in an advanced undergraduate mathematics classroom, there is an interesting duality: there are the proofs that the professors present and those that the students produce. Professors report that they often present proofs with small gaps in them; giving multiple reasons for doing so, such as not allowing technical details to obscure the big ideas, conserving limited class time, and providing the gaps as learning opportunities for students to help them better understand the content and support their proof writing (Lai & Weber, 2014; Lai, Weber, & Mejia-Ramos, 2012).

Language acquisition

While there is little research on how students learn formal mathematical language, there is a significant body of research on language acquisition (both first and second language acquisition) which has relevance to the acquisition of a register. Pinker (2009) described four criteria for a language, or in this case, a register, to be learnable:

1. From among the class of all possible languages, the target needs to be identified.
2. Learners need an environment in which to learn it.
3. Learners need a learning strategy, meaning a learner-created algorithm that uses information in the environment to create "hypotheses" about the target language, and then to determine whether they are consistent with the input information from the environment.
4. Learners determine a success criterion, meaning the hypotheses are related in some systematic way to the target language. A learner may waver among a set of hypotheses, one of which is correct. They may arrive at a hypothesis identical to the target language, or they may arrive at an approximation to it.

All of these are fulfilled by the advanced mathematics classroom: there is a particular register to be acquired, an environment in which to learn it, means for trying out usages of the language (proof writing), and a success criterion (sufficient fluency to earn passing marks).

Pinker continued by noting that language learning was a case of induction—developing uncertain generalizations from the observed instances of the language used in the environment. In the case of the formal mathematical register, students often get specific instruction describing the use of some phrases as well as the syntax, and they observe their professors using the register, although mixed with colloquial mathematics (Lew, et a., 2016). Moreover, professors frequently write only the algebraic steps of a proof on the board while saying aloud many of the connecting phrases and logical underpinnings (Fukawa-Connelly, 2012). In contrast, when reading proofs the professors focus on the phrases and logical descriptions in the written language, acting as if the algebraic manipulations are of secondary importance (Hodds, Alcock, & Inglis, 2014). Thus, the sample of the register on which the students are inducting is problematic and suggests an over-importance of the symbolic argument, thus increasing the number of generalizations likely to be present in the superset of the language that the students might develop. It is from these uses that students must develop hypotheses about the symbols, phrases and syntax, and yet as noted above, unlike in colloquial language, formal mathematical language must be unambiguous and correct, thus increasing the challenge for students.

Most important, language acquisition research suggests vital roles for learners' language production, including that learners "try out new language forms and structures as they stretch their interlanguage to meet communicative needs; they may use output to see what works and what does not" (Swain, 1998, p. 68). That is, students learning the mathematical register will write proofs in which they will commonly use correct grammar and syntax but also incorrect grammar and syntax, and they do this, partially, in order to try to learn the language and solicit feedback. This testing of language is not typically a conscious goal, rather we appear to be biologically disposed to do so. While to a mathematical expert, novice proof productions are filled with errors of logic, grammar, syntax and more, under the lens of language learning we instead view them as attempts to communicate in the style of the community where the rules are, at best, partially mastered and often tacit. On the basis of this research, we assert that professors' feedback on student proof productions has perhaps an unparalleled role in students' learning to produce proofs.

The role of feedback in language acquisition

We adopt Leeman's (2007) definition of feedback, meaning a mechanism that provides a learner with information regarding the success or failure of a given production, such as a written proof. Much research has focused on negative feedback, which is feedback that in some way indicates an error or issue with the production (Gass, 2008; Herschensohn & Young-Scholten, 2013). In particular, Lyster and Ranta (1997) described six types of corrective feedback, each of which can also be seen as indicating issues with the learner's production. Their types of feedback included:

1. Explicit correction: the teacher indicates that the utterance is incorrect and provides the correct form.
2. Recast: the teacher reformulates the student's production and remediates the error or provides the correction, such as writing out the correct sentence, without specifically indicating the error in the student's work.
3. Clarification request: the teacher asks the student to reformulate their production without specifically indicating what the error is.
4. Metalinguistic clues: the teacher poses questions, typically with a yes/no answer, or gives comments related to the student's production but does not provide the correct form or specifically indicate the error (e.g., Do we use this symbol here?").
5. Elicitation: the teacher directly elicits the correct form from the student by asking questions or starting the phrase. These questions typically expect more than a yes/no answer, such as, "Where do we use this hypothesis?"
6. Repetition: the teacher repeats the student production but highlights the error in the delivery (e.g., highlighting).

Lyster and Ranta found that recasts and explicit corrections did not result in subsequent improvement in student productions and hypothesized that it was because students are then limited to repeating the correct form the teacher provided (Tedick & de Gortari, 1998). Gass (2008) argued that explicit negative feedback can only teach about surface-level phenomena and cannot teach abstraction. Consequently, students may use the correct grammar and syntax in the future but without developing reasons to support their choices. The other five types of responses do not provide learners with the correct form and require that the learners provide it. Lyster and Ranta claim that when learners must restate, they are having to actively engage with the feedback, which is a critical feature in learning from feedback.

Student and mathematician misunderstandings

While we argue that professor comments on student proof productions have a significant role in students' learning to produce proofs, we also have reason to believe that students are likely to misinterpret them. Research on student understanding of lectures suggests that students sometimes develop significantly different understandings of the presented material and meaning for professor actions than the professor intends (cf. Lew, et al., 2016; Weinberg, Weisner, & Fukawa-Connelly, 2014). The work of Ko and Knuth (2013) and Selden and Selden (2003) has shown that students often fixate on the form, such as the presence of mathematical symbols, rather than the content of the proof, when reading mathematical arguments.

We use this prior research on misunderstandings and “misses of understanding” to form hypotheses about how students are likely to interpret a professor’s comments on proof productions. (To learn about the kinds of comments professors leave on proofs, see Moore, 2016). In particular, we hypothesize that they are likely to:

- not apprehend some feedback,
- develop only a surface-level understanding of some feedback, and
- interpret feedback in ways that differ from what mathematical experts would do.

Moreover, we argue that the latter two of these hypotheses are supported by the language acquisition literature described above.

Methods

Participant selection

The participants were 8 students, 4 men and 4 women, with advanced undergraduate standing at two institutions, four from each institution. Each participant had taken at least two proof-based undergraduate mathematics classes, including a transition-to-proof course. We purposely selected participants who had experience with writing proofs and receiving feedback from their professors so as to give the best possible chances for their success in understanding the proofs and interpreting the professor’s comments in this study.

Data collection

We engaged each participant in a 90-minute task-based interview where the primary task was to describe and interpret a professor’s comments about proofs. The interviews were audio-recorded and pencast with Livescribe pens. Each interview began with basic demographic questions and reflective questions about the participant’s typical use of their professors’ feedback, as follows:

1. What is your major(s) and which college-level math courses have you taken? Which math courses have emphasized proof writing?
2. When a professor returned homework papers, how often were you asked to revise and resubmit your work?
3. When you were not asked to revise and resubmit, what did you do with the feedback your professors gave you? Can you provide a specific example?
4. If you were asked to revise and resubmit, what did you do with the feedback?
5. Do you think it is important to read the comments on your proofs? Why or why not?

Subsequently, the main part of the interview consisted of a sequence of three or four proofs, as time allowed. We ensured that each proof had a mix of professor marks and comments related to notation and presentation, and logical issues. The proofs and professor comments were taken from a previous research project exploring four mathematics professors’ proof grading practices (Moore, 2016). From among the various marks and comments that the professors in Moore’s study wrote on the proofs, we selected the ones that appeared on the proofs in the present study. An example proof, Proof A, with comments, is shown in Figure 1. (Note that the participants did not see the numbers beside the comments; we inserted them later for our convenience in referring to the comments).

First, we handed a proof to the participant, told her it had been written by a student, and asked her to read and understand it as best she could. Next, we presented a marked proof to the participant with a professor’s feedback written in red ink. To determine whether the participant’s interpretation of the mark or comment matched our own, we asked the participant to explain why the professor had written each individual mark or comment and what changes she thought the professor wanted. Finally, we asked the participant to rewrite the proof in order to allow us to further explore her interpretation of the comments and see how she implemented the professor's recommendations.

Theorem A. Transitive Relation

Define a relation R on the set of real numbers by $x\ R\ y$ if and only if $x - y$ is an integer, that is, two real numbers are related if and only if they differ by an integer. Prove that R is transitive.

Proof A.

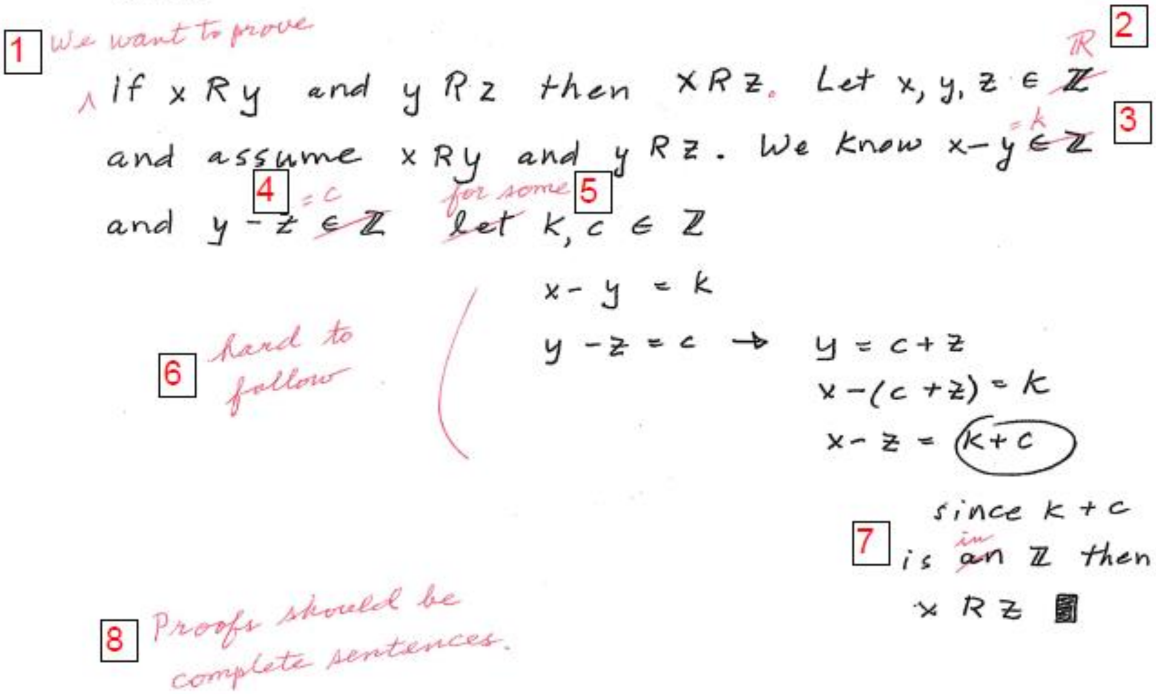

Figure 1. Proof A with the professor's comments.

Data analysis

For each comment in each proof, each of the researchers wrote a description of what change he or she believed the professor wanted and a rationale for the change. Based on these individual notes, we created a consensus description of what each mark and comment was asking the participant to change and the reason for the change. We also classified each comment using Lyster and Ranta's (1997) types of corrective feedback. Thus, each comment was classified along three dimensions: what change was requested, the reason for the change, and the type of corrective feedback.

We transcribed each interview and then chunked it at a number of levels. We parsed the demographic and reflective questions in one piece and the participant's discussion of each proof in additional pieces. We partitioned the discussion of each proof by identifying the participant's initial reading of the proof as a whole, and then her conversations about the individual comments. In cases where participants discussed multiple comments in the same utterance, we looked across interviews, and when it was common, we treated the comments as a single unit to parse all interviews similarly. We made a final block of the talk-aloud proof-writing process, for which we chunked the participant's utterances around the comments and linked those to what she wrote when she revised the proof.

To code the participant's utterances about each comment we first wrote a brief holistic summary, and then we developed a more detailed coding sheet that recorded:

- what the participant identified as the part of the proof the comment addressed,
- what the participant's response suggested should change in the proof,
- any reason the participant gave to explain the intended change and the underlying logic,
- a summary of what the participant changed in her revised proof,
- a comparison of each of the above points to our consensus expert interpretation, and
- an explanation of how an unanticipated change exhibited during the proof writing could be understood as a logical interpretation of the professor's comments.

We then created summaries, first by looking at individual proof comments across participants, and then by looking across the different categorizations of comments. For example, in the case of explicit corrections we described how the participants interpreted the requested changes, the kinds of reasons the participants provided for them, and the changes the participants included in their revised proofs. Similarly, we aggregated all of the changes that, according to our expert consensus, were recommended by the professor for a particular reason, such as "cultural convention," described the kinds of reasons the participants provided for them, and noted the changes the participants included in their revised proofs.

Results

Overall, the participants were very successful at interpreting what a professor wanted them to do in response to the comments. For example, for each of the eight comments on Proof A, 100% of participants correctly identified an acceptable part of the proof to be changed, and they all executed a change in a manner logically consistent with our understanding of the comment. However, their explanations of the rationale for the comments were not always consistent with our expert understanding. In the sections that follow, we explore the participants' work and thinking about the professor's comments on Proofs A and B.

Explicit corrections and recasts: feedback that specified the change

When the professor's comment specified a change to make to the proof, such as in an explicit correction or recast, the participants were consistently able to identify and state the change the professor wanted, and in the case of explicit corrections, what the professor considered incorrect. In their revised proofs, all of the participants consistently adopted the professor's suggested changes. For example, six of the professor's eight comments on Proof A (see Figure 1) were explicit corrections or recasts. Five of them indicated that something in the proof should be crossed out and replaced. In these instances, the participants always identified what they believed the professor wanted them to revise and implemented the revisions in a way that conformed with expert understanding.

Comment 1, the only recast comment on Proof A, was also specific but suggested the addition of new text, namely, the phrase "We want to prove," rather than the replacement of existing text. Seven participants added the recommended phrase, and one participant, Adam, showed some individuality by assuming that *xRy* and *yRz* and then writing, “We will prove that *xRz*,” which we judged to be consistent with our understanding of the professor’s comment.

In summary, when the professor’s comment was an explicit change of or an addition to the proof-text, the participants’ identification and implementations of the recommended changes were largely consistent with the expert consensus, or made a related change that addressed the intent of the comment. Thus, it appears that the participants demonstrated that they could appropriately identify and use explicit corrections and recasts on proofs.

Elicitations and clarification requests: feedback that did not specify the change

The professor’s comments on the four proofs included eleven elicitations and clarification requests. None of these comments gave specific directions about how to revise the proof. For example, comment 6 on Proof A, which says “hard to follow,” was a clarification request that did not indicate how to revise the proof. The participants generally interpreted this comment to mean that the algebraic steps lacked readability. Adam said about this comment:

> When I was reading the original proof, I guess it took me a little bit of time to follow how they laid it out, and maybe the layout could have been a little bit easier to follow. So maybe we should change some of this so it’s a little bit easier to get from certain points to certain points.

Our interpretation of Adam’s statement is that the comment asked for a change in layout in order to help a reader understand how the proof flows from point to point.

Bella and Don interpreted comment 6 differently and focused on the idea that the professor was asking for more detail. Bella focused on adding algebraic steps, whereas Don suggested clarifying and justifying the steps: “I would take that to mean use more detail, I suppose, describing what I’m actually doing at each step, even it were just to label, you know, 1, 2, 3, and then preferably say why 1, why 2, why 3.”

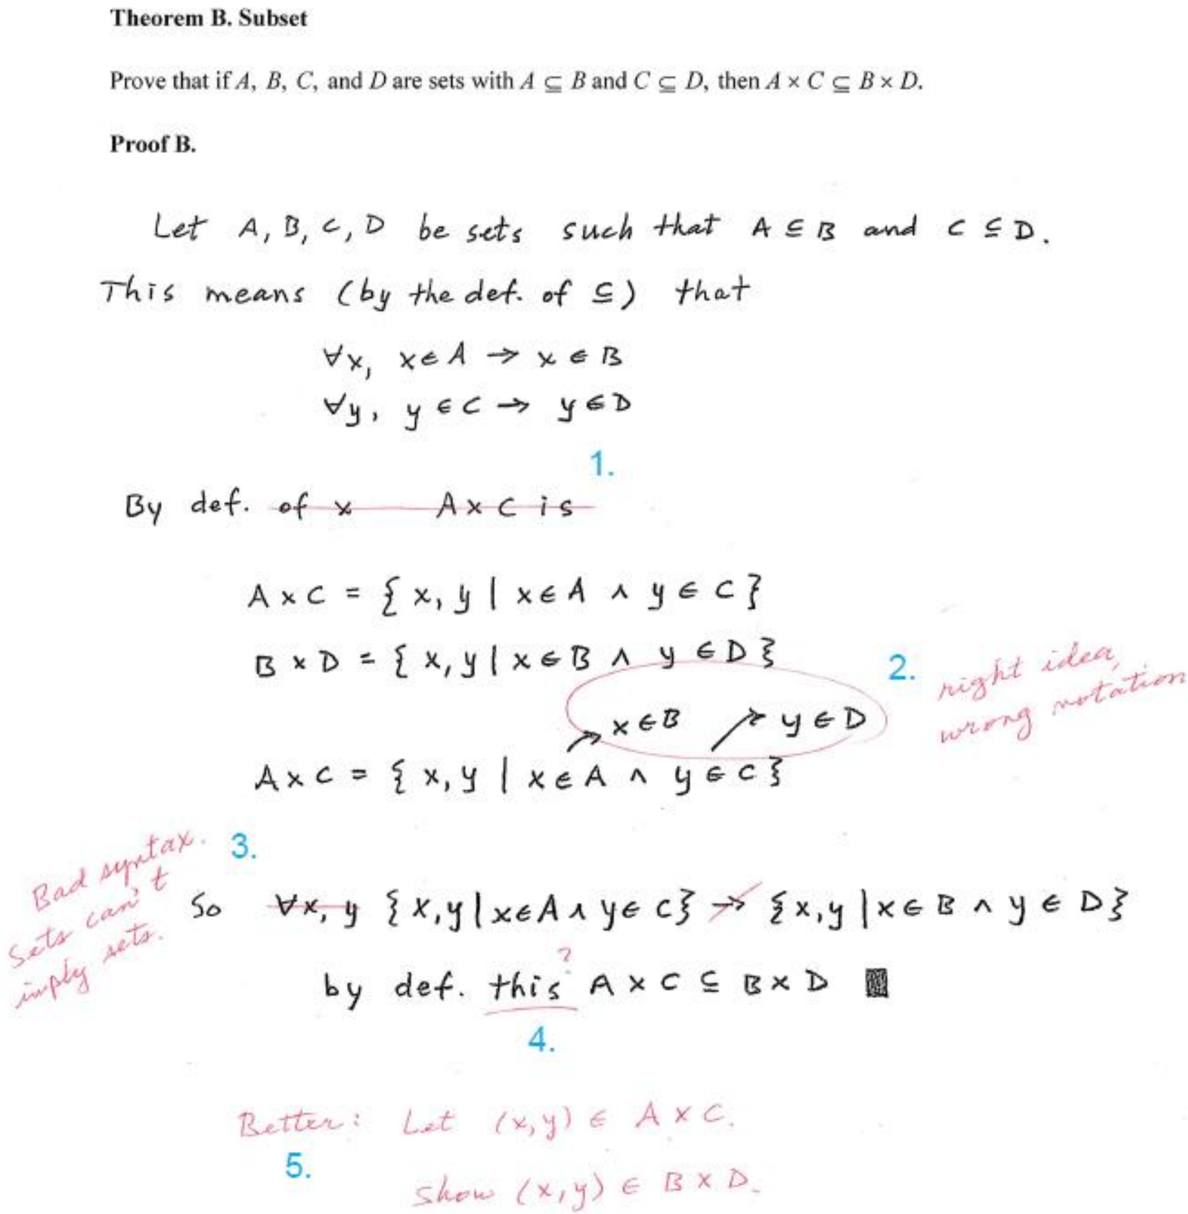
Two participants, Ruby and Nancy, noted specific changes that they would make to the proof. Ruby suggested that, “If there were sentences there, it wouldn’t be as hard to follow.” Nancy explained how she would add transition phrases and justifications, when she said:

> Normally you say more instead of just writing a bunch of random equations. ... You could say like “using substitution, we know this part” ... instead of just writing down random arrows and saying “Ha, ha! We got it!” … You can figure out what it’s trying to say, it’s not hard to follow in that sense, but it’s hard to follow in the sense of formal proof writing. It doesn’t have the normal, yeah, words, English.

Nancy has claimed that text is a “normal” part of proofs and a “bunch of random equations” is not appropriate, and her interpretation of the comment appears to be influenced by this belief.

On Proof B, shown in Figure 2, we classified comments 2 and 3 as clarification requests. For comment 2, the professor circled a part of the student’s work and wrote, “right idea, bad notation.” For comment 3, the professor crossed out two parts of the student’s proof and wrote, “Bad syntax. Sets can’t imply sets.” Note that in comment 2, the professor did not specify the error in what was written, and for neither of these two comments did the professor indicate how to revise the proof, which is consistent with the definition of a clarification request.

When the participants read comment 2, “right idea, bad notation,” all but one were able to identify that the professor was indicating that the student’s arrow notation was incorrect and needed to be changed, but most of them had difficulty articulating exactly what was incorrect and how to correct it. For example, Charles said, “I suppose this tells me they did it wrong. I would have to look up to see what the proper notation was, if I didn’t know what it was off hand.”



Theorem B. Subset

Prove that if A, B, C, and D are sets with $A \subseteq B$ and $C \subseteq D$, then $A \times C \subseteq B \times D$.

Proof B.

Let A, B, C, D be sets such that $A \subseteq B$ and $C \subseteq D$.

This means (by the def. of $\subseteq$) that

$\forall x,\ x \in A \rightarrow x \in B$

$\forall y,\ y \in C \rightarrow y \in D$

1.

By def. ~~of $\times$ $A \times C$ is~~

$A \times C = \{x, y \mid x \in A \wedge y \in C\}$

$B \times D = \{x, y \mid x \in B \wedge y \in D\}$

2. right idea, wrong notation

$\rightarrow x \in B \quad \rightarrow y \in D$

$A \times C = \{x, y \mid x \in A \wedge y \in C\}$

Bad syntax. Sets can't imply sets.

3.

So $\cancel{\forall x, y}$ $\{x, y \mid x \in A \wedge y \in C\} \cancel{\rightarrow} \{x, y \mid x \in B \wedge y \in D\}$

by def. this? $A \times C \subseteq B \times D$ ■

4.

Better: Let $(x, y) \in A \times C$.

5.

Show $(x, y) \in B \times D$.

Figure 2. Proof B with the professor’s comments.

Two participants suggested a means to deal with the comment by changing everything into written language without using symbols. Genevieve claimed, “that should be sentences instead of arrows.” Nancy noted that the text is “not written in a mathematically formalized way. It’s more written in a shorthand of reminding yourself” and suggested “actually writing it out in a way that says ... it in a mathematical proof kind of way.” Nancy’s response provided insufficient evidence to determine what she thought would make the argument more formal, but when asked, suggested writing out the inclusions in words: "Here I might write, 'by definition of subset,' and then write, 'x is in B and y is in D,' or something like that."

The participants' responses to comment 3 were similar to those for comment 2. They recognized the arrow between the two sets as problematic but did not give much more information. Bella stated, "It's not something you can do, it's not like, it's just maybe a rule." Multiple participants commented that the arrow indicated implication, such as Adam, "Yeah, the arrow means implies. Syntax. … you have to make sure you're using the right ones to mean what you want it to mean. And implies doesn't work for sets. You just don't do that." Genevieve said, "It's not grammatical when you substitute implies in place of arrow." Thus, although the participants generally recognized the problematic usage of the arrow, their verbal explanations of their interpretations of this comment offered little insight into what was wrong about the arrow and what they would change. Moreover, all of the participants avoided the problematic arrow usage in their revised proofs, typically by writing the inclusion in sentence form, often significantly restructuring the last few lines of text.

Participants' descriptions of the logic of specified changes

The participants were also asked to describe why they thought the professor had specified each of the changes to the proof text, and their answers revealed a variety of ways of thinking about the language of formal mathematics. For most of the comments, some participants were able to express the logic supporting the comment and some were not, and this was consistent across comment types.

With regard to the "We want to prove" recast comment at the beginning of Proof A, the expert consensus was that a proof should not begin with the conclusion that is to be proved, and the correction indicates that the first sentence expresses the goal of the proof. Two participants clearly articulated the logical issues with first line of the proof. Here is Adam's response:

> I think what the professor meant by this is you want to make a statement saying this is what we are going to prove or trying to prove.... They didn't say we're trying to prove this or this is the conclusion we're going to come to. And you want to make that clear.

In contrast, Bella explained that she understood the reason for the comment as "that's just one of the proper ways to start a proof, that from what I've learned, yeah, it's just the way to start a proof." That is, her thinking appeared to focus on the form of proofs, rather than on the logical function of the statement. The other five participants described the added phrase as clarifying the presentation, but they did not clearly articulate the logical issue. For example, Don said, "This is just to me good syntax. It's a way of setting it up to be understand better and to be read more easily." Thus, we suggest that the logic the professor intended to motivate by this comment was not successfully communicated to six of the participants.

The participants also initially showed mixed understanding of the reasons for the professor's explicit corrections on Proof A (Figure 1). For comment 2, which specified changing $\boldsymbol{Z}$ to $\boldsymbol{R}$, the experts agreed that the change was logically necessary because the relation R is defined on the set of real number. Six of the participants gave an explanation that approached that of the experts, including Genevieve who said, "there is no reason to believe that x, y, z are in the integers. The theorem never states that they are in the integers. [The theorem states] on the set of real numbers." Don gave a mixed explanation, initially saying "they [$\boldsymbol{Z}$ and $\boldsymbol{R}$] are both correct but the real numbers are more applicable, in most cases," but later in the interview noted that the theorem specifies that x, y, z are real numbers. Don's explanation for the requested change did not reject the original statement as inappropriate for the proof.

In reference to comment 5, only two participants, Don and Nancy, articulated the distinction between *let* and *for some,* whereas the other participants said little about this comment or gave explanations that did not fully align with the expert consensus. For instance, Charles said: "... when you make the mark *for some k, c,* that's traditional writing. But it also helps clarify how k and c are related to the two previous corrections. Um, whereas the student seems to be setting it up as its own separate idea, it's important to clarify that k and c are related to x, y, and z." Charles's comment about "traditional writing" suggests that he viewed the explicit correction as stylistic, i.e., to bring the writing into alignment with writing norms, although he also noted the logical issue.

The participants' interpretations of the clarification requests were similarly met with mixed success. Consider comment 2 on Proof B (Figure 2). The participants generally did not know the correct notation, and as a result, gave only an explanation about the importance of correct notation. For example, Adam said, "Wrong notation. Let me think here. (pause) I don't necessarily know if I know the right notation to put this in now (laughs), but I knew that wasn't the right notation." Genevieve, on the other hand, was able to articulate the notational issues with this part of the proof by saying "The arrows are sort of sometimes ambiguous with people because it generally means implies, but sometimes people use arrows in different ways, and so I think to actually put it in a sentence and make it clearer would be a lot better."

Similarly, for comment 3 on Proof B the participants agreed that "sets can't imply sets" but struggled to articulate the reason. Nancy and Ruby attempted to give a rationale in terms of *if-then* statements but had difficulty expressing themselves clearly and succinctly.

The participants' revisions of the proofs

When the professor gave an explicit correction or recast comment, the participants always incorporated it, or revised the proof in such a way as to avoid the problem. When the professor used an elicitation or a clarification request, the participants had to develop their own change. One such comment was "proofs should be complete sentences," which is somewhat directive in that it suggested a course of action. Four of the participants rewrote the entire proof in paragraph form, eschewing the string of equations, while the other four displayed the string of equations and wrote the concluding part of the proof in complete sentences. Both are reasonable interpretations of the professor's note, and either is stylistically acceptable.

In sum, the participants were generally quite capable of writing revised proofs that remediated the issues indicated by the professor's marks and comments, even when they could not fully explain the rationale for the comments.

What the participants claimed to do with professor feedback

To begin the interview, we asked the participants to describe what they typically did with the professors' comments on their graded proofs. Generally, they claimed to make relatively little use of them. Bella noted that she did not consistently read the comments, noting that "sometimes it would just go on the pile of homework, to be honest." Five more claimed to consistently read them. Nancy claimed to do more than simply read the comments:

> I would read through it, um, and I would try to kind of make mental notes. I would often not try to go back and rewrite it, but if I then did another proof that was similar, I would ... try to

make a mental note of it and use that. I did try to use it in other proofs. I wouldn't always redo those, but I definitely would use that information the next time that I wrote a proof. And I would actually get it out and look at it the next time I was writing a proof and try to see what did I do, what could I do differently to make this better.

Adam, too, talked about making additional use of the comments, and in his case it was in the context of his abstract algebra course. During this course, the teacher would sometimes return proof papers in class and go over them, and in that case Adam would write notes on his proofs for later reference. Adam claimed that he would use the written and oral comments to help him prepare to rewrite the same proofs during exams. But it seemed that without that motivation, he would normally do no more than read the comments.

Six of the participants claimed to make use of their professors' comments when they were asked to revise and resubmit proofs, but they all noted that they were seldom asked for revisions. This evidence suggests that students generally do not meaningfully engage with the comments on their graded proofs unless required to do so. The language acquisition literature (e.g., Lyster & Ranta, 1997) and composition research (e.g., Bean, 2011) argue that such engagement is critical for learning from feedback.

Conclusion

This study contributes to undergraduate mathematics education in that it is the first study to describe and analyze how students interpret and respond to their graded proof papers. Given that mathematicians consider proof grading to be an important means of teaching students to write proofs (Moore, 2016), the study opens a new line of research on the teaching and learning of mathematical proof at the undergraduate level.

We report three principal findings in response to the research questions. The first important finding is that when the professor wrote an explicit correction or a recast comment on a proof, the participants correctly identified the changes recommended and generally, but not always, could provide some rationale for the changes, including what was incorrect about the original proof. We suggest that the participants were able to invent reasons by comparing the original text and the corrected text; that is, they were able to develop a hypothesis about usage via induction (Swain, 1998). In contrast, when the professor's comment was a clarification request or an elicitation and did not provide new text, the participants struggled to provide a rationale for the change and fell back to more general claims that did not explicitly identify what was incorrect about the original proof. We note that the literature on second language acquisition suggests that cognitive engagement with the feedback is important for the students to incorporate the new information, and that clarification requests and elicitations promote cognitive engagement better than explicit corrections and recasts (Lyster & Ranta, 1997). Yet in this study, when the professor wrote clarification requests and elicitations, our participants were not reliably successful in responding to the comments because they did not appear to fully understand the comment and the mathematical language to correct the problem. Instead, they relied on general claims that are insufficient to support future proof-writing attempts. On the other hand, in the context of an actual course, if the professor requires students to revise their work, clarification requests and elicitations may promote cognitive engagement by directing students to use available resources to learn how to address the issues raised by the comments on their proofs.

The second important finding is that, regardless of the type of feedback the professor offered, the participants could not reliably describe normatively correct logic for the changes and why the original proof production was incorrect or problematic. While explicit corrections and recasts gave the participants a means to develop hypotheses by contrasting the two proofs, their inferences were sometimes incorrect or incomplete. It appeared that, generally, the participants could only explain the logic for requested changes when they already could identify the issue prior to reading the professor's comments. Moreover, it appears that they would often fall back to claiming that a requested change was "cultural" or "how you do it in formal mathematics." This observation suggests that the way professors currently write comments is not an effective way to communicate the reasons underlying the comments, which they often claim is the most important thing they are attempting to convey in their instruction (Lew, et al., 2016). Our data suggests that professors should write more about the logic that they are attempting to convey to the students, as well as distinguish between logical errors and readability concerns. What form such feedback might take to be most effective and efficient, whether direct statements, clarification requests, or elicitations, is a productive direction for future research.

A third finding is that students' written proofs are insufficient to distinguish between those who have some level of conceptual understanding and those who work only procedurally. When they revised the proofs, the participants successfully implemented the suggested changes in nearly all instances, regardless of the type of comment, even when they did not fully understand the rationale for the changes. This ability to write a correct proof without an understanding of the underlying logic is problematic for the teacher who may conclude that students understand more than they actually do. This potential mismatch suggests that perhaps professors have good reason to focus on teaching students the important mathematical logic and let the language, symbols, and grammar sort themselves out over time.

We recognize that this is a single, exploratory study with a small number of elementary proofs, a small number of participants, and only analytical generalizations. Moreover, we note three significant limitations of this study that suggest the need for further work. First, the participants were reading and writing proofs on mathematical topics that most of them had not worked with in some time, possibly since their introduction to proof class. Second, we asked the participants to interpret comments on proofs they had not written, thus imposing a need to make sense of another student's proof attempt prior to interpreting the comments. More research is needed to explore students' ability to interpret feedback in the context of their own proof writing. This first exploratory study provides a body of empirical evidence for future directions and more theoretical work. We note a third limitation: initially the four experts did not always agree on the reasons for the changes. While we could come to a consensus interpretation, there were significant differences in our initial interpretations, which means that different researchers, or a different mix of researchers, might have arrived at a different consensus interpretation of the professor's comments. This limitation of the study suggests an avenue for future research, motivated by Weber's (2014) argument that proof is a cluster concept. We hypothesize that while professors might share instructional goals about proof and use similar notes and language to communicate with students, in reality they may be attempting to convey very different content via the same notes, which has significant implications for students.

Students' symmetric ability in relation to their use and preference for symmetric heuristics in problem solving

Meredith Muller Eric Pandiscio
University of Maine

Advanced mathematical problem solving is marked by efficient and fluid use of multiple solution strategies. Symmetric arguments are apt heuristics and eminently useful in mathematics and science fields. Research suggests that mathematics proficiency is correlated with spatial reasoning. We define symmetric ability as fluency with mentally visualizing, manipulating, and making comparisons among 2D objects under rotation and reflection. We hypothesize that symmetric ability is a distinct sub-ability of spatial reasoning which is more accessible to students due to inherent cultural biases for symmetric balance. Do students with varying levels of symmetric ability use or prefer symmetric arguments in problem solving? How does symmetric ability relate to insight in problem solving? Results from initial analysis indicate that, among mathematics undergraduates, there is variation in symmetric ability. Methods, future research, and implications are discussed.

Key words: [Symmetry, Problem Solving, Heuristics, Cognitive Spatial Reasoning]

Context

Geometry is the branch of mathematics most connected to the world as humans experience it; geometry is the math we see in the natural and manufactured structures around us. Cultures around the world have used geometry to build, navigate, make art, and predict motion. It is how we measure the earth and space. Shapes and angles provide the vocabulary we use to describe our surroundings and communicate about them with others. The utility of geometry to students is as plain as a line they draw and the plane in which they draw it. A traditional geometry curriculum in the United States is capped around age 16 with proof-based construction geometry and the introduction of trigonometry. Broadly speaking, visualizing in mathematics is one of the most important tools we have to offer students to help them better understand the application of mathematics to the physical world around them. Wai, Lubinski, and Benbow (2009) found that spatial ability was a key factor in determining success of students in advanced STEM education and career paths. Others have found that spatial skills can be taught and retained, which may increase participation in STEM fields (Uttal et al., 2013). Unfortunately, robust visual geometric understanding is often not the outcome of a standard mathematics education. Undergraduate students have trouble with geometric transformations, including symmetrical relationships (Rizzo, 2013). The 2011 TIMSS survey found that only half of United States 4th graders could complete a shape to have line symmetry. Further, in both 4th and 8th grades in the content area of geometry and measurement, American students underperformed in comparison to their overall mathematics achievement (Mullis, Martin, Foy, & Arora, 2011).

Symmetry. It has been frequently suggested, to the point of inclusion in both NCTM and CCSS standards (Common Core State Standards Initiative, 2012; National Council of Teachers of Mathematics, 2000), that studying symmetry is an important part of a well rounded mathematics education. Mathematicians have long noted symmetry as a major convergence point of mathematics and beauty (Drefus, T., Eisenberg, 1990). Symmetry is a persistent part of visual language worldwide (Dreyfus & Eisenburg, 2000; Hargittai & Hargittai, 1994; Shaw, 1990). Molecules, gems, butterflies, flowers, human faces, sculpture, architecture, musical notation, and even galaxies exhibit symmetry in both generation and propagation. Many cultures use and have used symmetry in their creative expressions. Classifying and decoding the meaning of symmetry in historical artifacts is an important endeavor to sociologists (Washburn & Crowe, 1987). Further, symmetry has great sway in terms of value judgments of mathematical, musical, literary, scientific, and aesthetic objects (Weyl, 1952). Symmetry is relevant in all branches of school mathematics. While most apparent in geometry and its study of transformations on Euclidian spaces, topics in algebra like symmetric functions, symmetric systems of equations, and symmetric graphs also rely on this construct (Hilton & Pedersen, 1986). In calculus, there is symmetry in integral construction. In statistics and probability, there is symmetry in distributions. And in trigonometry, there is symmetry in the identities (Dreyfus, T., Eisenberg, 1990). Symmetry has great importance to life and earth sciences, and it has served as a strong basis for investigation since the early geometers. The relatively new field of group theory in mathematics is based in large part on notions of symmetry and has been applied to the study of crystals, particle physics, and phyllotaxis (the study of branching in plants) (Dreyfus, T., Eisenberg, 1990). For these reasons, fluency in symmetry not only taps into an innate part of the human experience, but also can provide rich opportunities for engagement across academic disciplines.

Spatial Ability. There are many forms of spatial ability and reasoning, as well as tests and probing research on this aptitude. Spatial ability, the precision and robustness of visual perception, correlates positively with mathematical achievement (Battista, 1990). Spatial ability includes skills like differentiating foreground and background, performing mental shifts of orientation, seeing the effects of single and multiple reflections, identifying rotationally symmetric objects in two- and three-dimensions, correlating elevational and cross-sectional plans, mentally rearranging objects, and recreating visual patterns. Clements and Battista (1992) define spatial reasoning as “the set of cognitive processes by which mental representations for spatial objects, relationships, and transformations are constructed and manipulated.” Spatial reasoning is further split by some psychometricians into several factors like spatial orientation: “The ability to perceive spatial patterns or to maintain orientation with respect to objects in space,” and spatial visualization: “The ability to manipulate or transform the image of spatial patterns into other visual arrangements” (French, Ekstrom, & Price, 1963). The primary difference between these two constructs being the active or passive nature of the observer. These definitional distinctions are hotly debated and other such terms have been proposed and defended. Many facets of spatial ability have been studied in contexts such as gender differences and mathematical achievement (Battista, 1990; E. H. Fennema & Sherman, 1978; E. Fennema & Sherman, 1977; Harris, 1981), problem solving (Tartre, 1990), implications for instruction (Bruce & Hawes, 2014; Ferrini-Mundy, 1987) with the aid of engineering drawings (Olkun, 2003), learning disabilities (Garderen, 2006), and relationship to fields such as: chemistry (Bodner & Guay, 1997), geology (Orion, Nir, Ben-Chaim, David, Kali, 1997), kinematics (Kozhevnikov, Motes, & Hegarty, 2007), and music and sport (Pietsch & Jansen, 2012). Evidence suggests that spatial ability peaks in humans during preadolescence, further justifying inclusion and serious treatment of symmetry in middle and high school curricula (Ben-Chaim, Lappan, & Houang, 1988). Overall, spatial ability is an important cognitive function that strongly correlates (.30-.60 (Battista, 1990)) with mathematical achievement. This correlation becomes more pronounced as task difficulty increases and is of approximately equal weight to that of verbal reasoning (E. Fennema & Sherman, 1977). The perception of symmetry is an unknown portion of spatial ability.

Problem Solving. Problem-solving and critical thinking are main pillars of reformed K-12 curricula (Common Core State Standards Initiative, 2012; National Council of Teachers of

Mathematics, 2000) and are pervasive in PCAST reports (Holdren & Lander, 2012). Schoenfeld (1987) demonstrates that metacognitively aware problem solvers read, analyze, explore, plan, implement, and verify during their problem solving process. The "analyze" phase involves creating hypotheses of how a problem can be solved – i.e. the generation and recall of solution strategies. Polya (1957) offered up some of the first solution strategies for devising a plan of mathematical action: use a related problem or alter the problem to make it easier. Since then, more and more solution strategies have been named and studied as they relate to specific mathematical problem areas, many of them algorithmic. Multiple solution tasks are those that can have many solution paths. Almost all mathematics problems can be solved more than one way. A simple example might be the different algorithms one can use to add three-digit numbers. A more complex task might be to prove that a parallelogram with congruent diagonals is a rectangle (Levav-Waynberg & Leikin, 2012). Some research on problem solving focuses on flexibility which is, "knowledge of multiple solutions as well as the ability and tendency to selectively choose the most appropriate ones for a given problem and a particular problem-solving goal" (Star & Newton, 2009). This research shows that flexibility can be trained for and that contrasting cases are particularly useful in this endeavor (Rittle-Johnson & Star, 2007). The skilled mathematician is fluid in their use of solution strategies.

Symmetric Heuristics. Symmetry is often an easy path in problem solving and may have broad appeal to students and mathematicians alike. Goldin & McClintock (1980) call the application of symmetry in problem solving insight and enumerate several kinds of symmetry in problem solving: overt, construction, representational alteration, and hidden. They make recommendations for teaching to exploit symmetry. Drefus & Eisenberg (1990; 2000) emphasize that for symmetry to cut through the restrictions of a problem, like a hot knife through butter, it must first be seen and imposed, a challenging task. The utility of symmetry as heuristic has applications in multivariate calculus, organic chemistry, applied engineering and design, and physics (Hilton & Pedersen, 1986). Previous research with in-service teachers shows that they generally do not use symmetric solution strategies, and are skeptical of the mathematical validity or sufficiency of such solution strategies when working on multiple solution tasks (Leikin, Berman, & Zaslavsky, 2000; Leikin, 2003). Similarly they believe that conventional solution strategies (relying on calculus, algebra, or geometric definitions) are more trustworthy and they have more confidence in teaching them. The insightful recognition of when to use symmetric arguments, and preference for/against symmetric arguments has not been investigated with students before. The terms Goldin & McClintock offered for categorizing symmetric heuristics have not been observed in practice and cataloged as of yet.

Mathematics attitude. Research indicates that affective/attitudinal factors greatly influence mathematical achievement (E. Fennema & Sherman, 1977) as well as selective processes like choosing a career (Betz & Hackett, 1983). Put differently, one's attitudes about mathematics influence one's mathematics performance as well as one's decisions having to do with mathematics. We propose to look at mathematics attitude in relation to how one ranks solution strategies in order of preference. Having some measure of self-conception is important when trying to form a well-rounded picture of ability level. Bandura (1993) posits that a students' self-efficacy is composed of several factors, one of them being selective processes. Choice as mediated by ability is a new avenue in mathematics research.

Research Questions and Goals

In this research we propose to investigate the relationship between students' symmetric spatial abilities, their attitudes toward mathematics, and their use and preference for symmetric heuristics. We define symmetric ability as: a student's ability to mentally visualize, manipulate, and make comparisons among 2D geometric objects and as applied to cultural material in terms of reflectional and rotational symmetry. A research instrument was developed for the purpose of measuring this sub-ability of spatial reasoning. In response to the research context and instructional significance presented here, this research project is designed to answer the following research questions:

1. How does students' symmetric ability relate to their use and preference for symmetric heuristics in problem solving?
2. How does students' symmetric ability track with confidence and self-efficacy in mathematics learning?

The conclusions of this research could serve as a basis for the continued curricular expansion of treatments of symmetry within geometry and other mathematics curricula, and provide insight into how students currently think about symmetry as a heuristic. Future research might seek to find out how one's symmetric ability can be built upon in challenging problem solving situations as we know that spatial ability can be refined through training (Uttal et al., 2013). This research was undertaken from a cognitivist theoretical framework, meaning that the perspectives and views of subjects were assumed to be accessible through verbal and visual communication with them. This framework is appropriate because subjects' conception of validity and justification of symmetry as heuristic is the focus of this study.

Research Methods

Two research instruments were developed for this investigation: a survey and an interview protocol.

Symmetric Ability Survey. A survey was developed to provide a quantitative measure of symmetric ability. Our definition of symmetric ability mimics those that Olkun (2003) summarizes: spatial ability in reasoning, relations, and visualizations with an added cultural component influenced by research on ethnomathematics (Abas, 2004; D'Ambrosio, 2001; Eglash, Bennett, O'Donnell, Jennings, & Cintorino, 2006). Therefore this survey has three sections (based on our definition of symmetric ability and our research goals dealing with mathematics attitude): cultural, mathematical, and attitudinal. Sample items can be seen in Figures 1-4. For both the cultural and mathematical symmetry sections, detailed written instructions and worked examples were part of the survey.

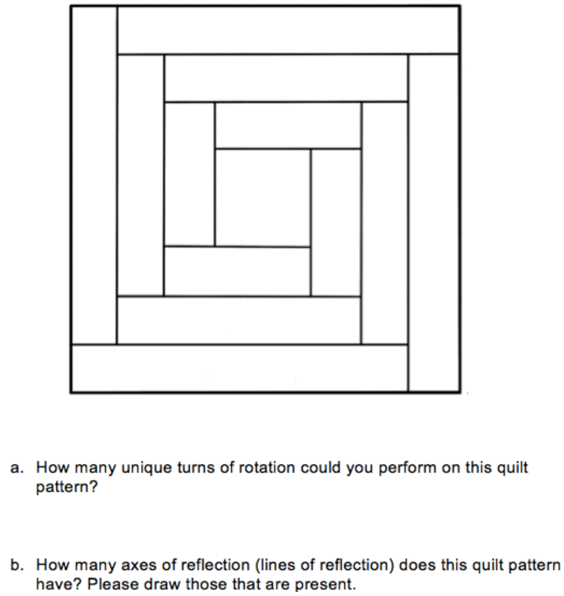

Figure 1. Cultural item from symmetric ability survey, one of five. All items used the same questions (a.,b., and implied c. - drawing)

The cultural symmetry section of this survey was developed through both informal (research workshop) and formal (pilot sample) validity measures. Cultural objects were drawn from traditional northeastern art and design while question vocabulary was drawn from school-aged curricula.

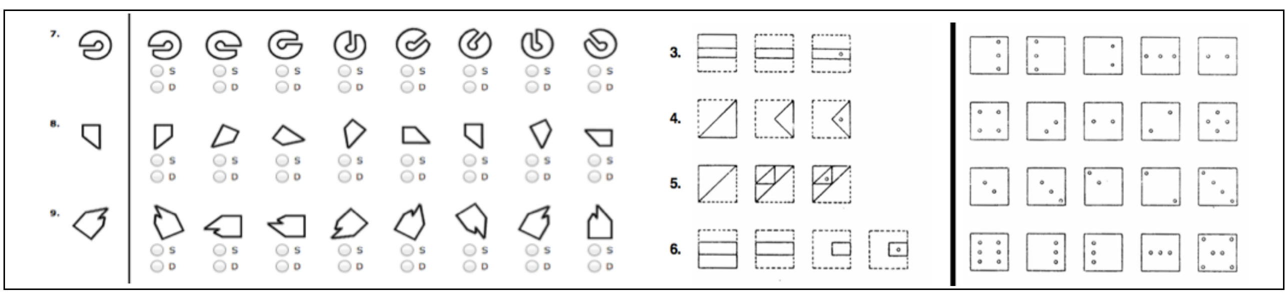

Figure 2. (left) Geometric 2D items from symmetric ability survey, tests rotational ability. Students mark whether the eight images are rotationally symmetric (S) or different (D) from the leftmost image. Three of ten.

Figure 3. (right) Geometric 2D items from symmetric ability survey, tests reflectional ability. Images to the left of the bold line show a series of folds and hole punches done on a square piece of paper. Students choose the image to the right that corresponds to the correct pattern of holes when the paper is unfolded in place. Four of ten.

The mathematical symmetry section was composed of two factor analysis tests taken from the literature. An exhaustive search was performed to catalog all the research-validated tests of spatial ability. The Card Rotations Test and Paper Folding Test (Ekstrom, French, Harman, & Derman, 1976) were chosen as they highly correspond to the tasks of mental rotation and mental reflection in two dimensions. This portion of the survey was timed in accordance with the Educational Testing Service's administration protocol (Ekstrom et al., 1976).

I am challenged by math problems I can't understand immediately.

Disagree				Agree
1	2	3	4	5

I study mathematics because I know how useful it is.

Disagree				Agree
1	2	3	4	5

I don't think I could do advanced mathematics.

Disagree				Agree
1	2	3	4	5

Generally I feel secure about attempting to learn mathematics.

Disagree				Agree
1	2	3	4	5

Figure 4. Attitudinal items from the symmetric ability survey. Four of twenty-five.

The attitudinal section of the survey was composed of the confidence and self-efficacy sub-scales of the Fennema-Sherman attitudinal scales (Fennema & Sherman, 1976), Figure 4.

Symmetric Heuristics Interview. An interview protocol to qualitatively describe use and preference for symmetric arguments was developed. This interview protocol centered on four problems. Sample problems can be seen in Figures 5-6.

You are programming a robot to transport items across a warehouse. Your robot starts at point A, moves to a moveable point P on line segment $\overline{CD}$ to pick up a box of cereal. It then delivers this box to point B. What is the shortest distance you can have this robot travel?

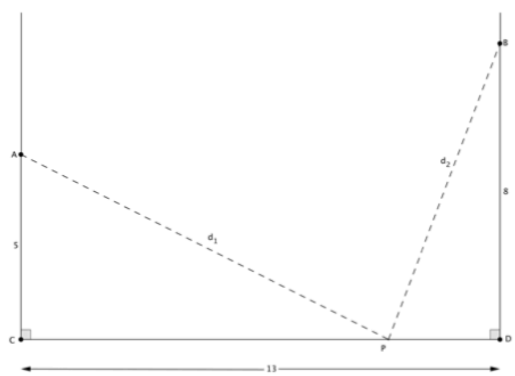

Figure 5. Students may respond to this open-ended question with several solution strategies. Expected solutions include parameterization and minimization, guess and check, reflection of B through CD to form the straight path AB' and application of the Pythagorean theorem, and using proportional reasoning from the related case of AC=DB. Problem statement modified from Goldin & McClintock (1980).

Which solution to the following system of equations do you prefer?

$$\begin{cases} 3x + 2y + z = 30 \\ x + 3y + 2z = 30 \\ 2x + y + 3z = 30 \end{cases}$$

1. To solve a system of three equations with three variables we can solve by pairs of equations. Taking the first and second equations together and the second and third equations together we can remove z from both by multiplying out the z coefficient and subtracting equations as shown.

$$\begin{array}{cc} 3x + 2y + z = 30 & x + 3y + 2z = 30 \\ x + 3y + 2z = 30 & 2x + y + 3z = 30 \\ & \\ 2(3x + 2y + z) = (30)2 & 3(x + 3y + 2z) = (30)3 \\ 1(x + 3y + 2z) = (30)1 & 2(2x + y + 3z) = (30)2 \\ & \\ 6x + 4y + 2z = 60 & 4x + 2y + 6z = 60 \\ -1x + 3y + 2z = 30 & -3x + 9y + 6z = 90 \\ \hline 5x + y = 60 & x - 7y = -30 \end{array}$$

We now have a system of two equations in two variables. Solving for x or y in either and substituting will yield an answer of $x = 5, y = 5$, and $z = 5$.

2. Notice that the coefficients of x, y, z cycle through the equations: $\{3, 2, 1\}, \{1, 3, 2\}, \{2, 1, 3\}$. For all of these equations to equal 30 at the same time, $x = y = z$. The first equation can be rewritten:

$$3x + 2x + x = 30$$
$$6x = 30$$

Therefore, $x = 5, y = 5$, and $z = 5$.

3. Use a software program like Mathematica, MATLAB, or WolframAlpha to solve. Finding that $x = 5, y = 5$, and $z = 5$.

Figure 6. Students respond by ranking their preferred solution strategy. Problem statement from Leikin et al. (2000).

These problems were taken from various sources: the literature, an undergraduate physics text, and the mathematics cannon. Two of the problems were open-ended and could be solved in multiple ways, for example: algebraically, with calculus, by guess and check, or with symmetry. These problems were intended to gauge native use of symmetry as heuristic (Fig. 5). The remaining two problems presented students with three worked solutions that they were asked to rank. Criteria for this ranking were not specified. Instead, students were asked to reflect on the reasoning behind their selections, and further to hypothesize on how expert mathematicians would rank the solution strategies. These problems were intended to gauge students' preference for symmetric heuristics and identify reasoning for these preferences (Fig. 6). One of each type of problem, open-ended or ranked solution, had a symmetric solution strategy relying on reflection and one of each type of problem had a symmetric solution based on rotation. Sample cognitive interview prompts can be seen in Figure 7.

Use:
1. Can you explain why you decided to try solving the problem this way?
2. Can you think of any other ways to solve this problem?
3. How might a mathematician approach this problem?
4. What are you studying in math class right now?

Preference:
1. Can you rephrase this solution strategy in your own words?
2. Why do you prefer this strategy to others?
3. Can you think of any other ways to solve this problem?
4. Which would a mathematician prefer?

Figure 7. Sample prompts from the problem solving interview protocol.

Primary data collection occurred during the 2015-16 academic year at a large northeastern university. The symmetric ability survey (Fig. 1-4) was administered to n=95 students concurrently enrolled in integral (39%) or multivariable (61%) calculus courses. The majority of students (78%) were engineering majors (mechanical, chemical, electrical & computer), 4% were math majors, and 14% were women. A subsample, currently n=5, was selected to take part in the symmetric heuristics interview (which was designed as a think-aloud, problem solving format). Calculus students were chosen as an audience to ensure that calculus solution strategies would be available to students.

Data Analysis

Symmetric Ability Survey. The three sections of the symmetric ability survey were scored separately. A rubric was developed to establish the cultural section as a quantitative measure. Cultural symmetry questions (Fig. 1) were scored in a binary fashion for each of the three problem parts: the number of possible rotations, the number of reflectional axes, and the correct drawing of axes on the image. To establish inter-rater reliability of this rubric, three raters reviewed overlapping portions of the data set. We found agreement > 95% of the time. Card rotation items (Fig. 2) and Paper folding items (Fig. 3) were scored following the guidelines provided by the distributors (Ekstrom et al., 1976). Likert scale attitudinal data (Fig. 4) were scored using the reverse coding method (Field, 2009). This method calls for Likert data to be coded against the response pattern of an ideal subject, thus giving a measure of confidence and self-efficacy as compared to a responder with perfect self-image of confidence and efficacy. All measures were scaled for comparison purposes. In future data analysis we hope to search for trends within the card rotations and paper folding test having to do with angular difference (Cooper, 1975) and fold complexity. Further, we intend to catalog the persistence and variety of misconceptions students have with using school language symmetry with the cultural items.

Symmetric Heuristics Interview. Survey participants were invited to participate in the think-aloud symmetric heuristics interview. We used high and low symmetric ability and high and low attitude as selection criteria for the interview. Students whose scores were $\pm$ 1 standard deviation from the mean in any of two symmetric ability scales and on either of the attitudinal scales were contacted for participation. The matrix in Figure 8 describes the distribution of interview participants.

Figure 8. Distribution of symmetric ability survey participants based on $\pm$ 1 standard deviation performance on multiple measures of symmetric ability and at least one measure of mathematic attitude. Darkened circles indicate current interview sample, effort was made to interview high and low performance students.

In addition to these subjects, we conducted a pilot interview with a small group of mathematics graduate students in order to solicit broader idea generation and to practice fruitful questioning tactics. Inclusion of one or more expert (professorial) interviews is expected. Transcription of these interviews is in process. We will undertake a grounded theory reading of the interviews searching for trends in student reasoning (Corbin & Strauss, 2008).

Preliminary Results

Symmetric Ability Survey. In the survey sample population we see some variation in symmetric ability (Fig. 9), indicating that this instrument can parse differences in student performance. However, we noted that on all measures members of the inter and upper quartile performed very well, getting more than half of all questions correct. This contrasts with previous findings from a pilot study (n=11) of undergraduate 'exploratory mathematics' students (Fig. 10). Further, there seems to be a positive correlation between symmetric ability and mathematics attitude (Fig. 11), though this correlation is weak and not statistically significant (r^2 = .11).

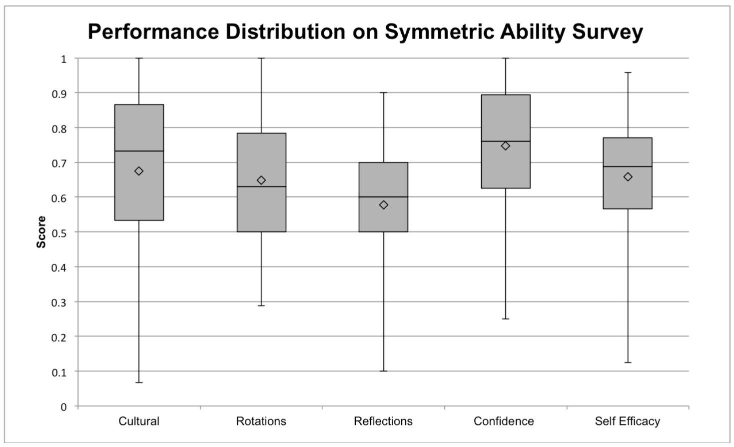

Figure 9. Summary statistics for each section of the symmetric ability survey.

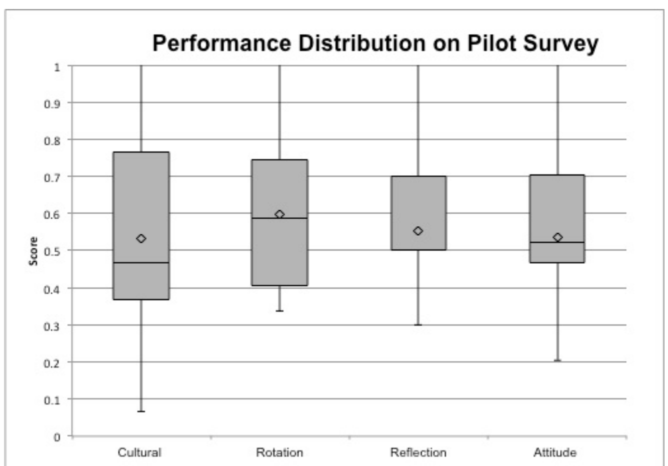

Figure 10. Summary statistics for each section of the symmetric ability survey, pilot population. Note: In a previous version of the survey the attitude item scales were incomplete. Cultural, rotational, and reflectional sections did not undergo revision and are cross-comparable.

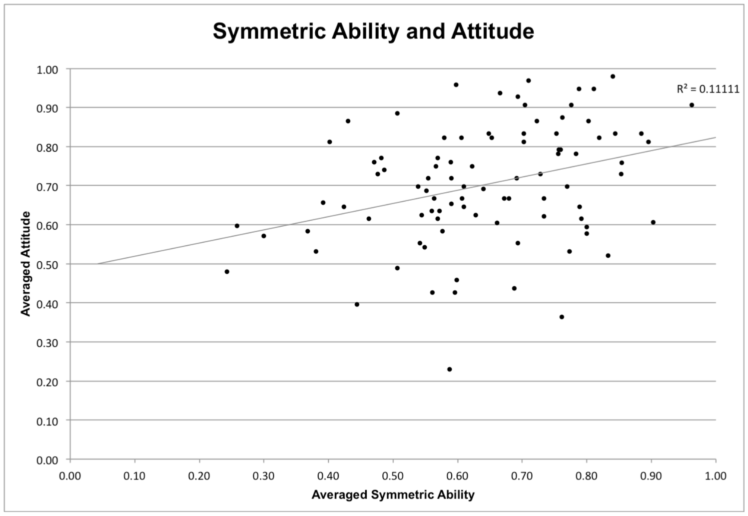

Figure 11. All three measures of symmetric ability weighted equally in comparison to an equal weighting of attitudinal scales.

Symmetric Heuristics Interview. Initial investigation revealed a few avenues for further inquiry. Students displayed expected conventional solution strategies as seen in Figures 12-13 but there was more of a mix of preference when ranking traditional and symmetric solution strategies both personally and when projecting on to experts.

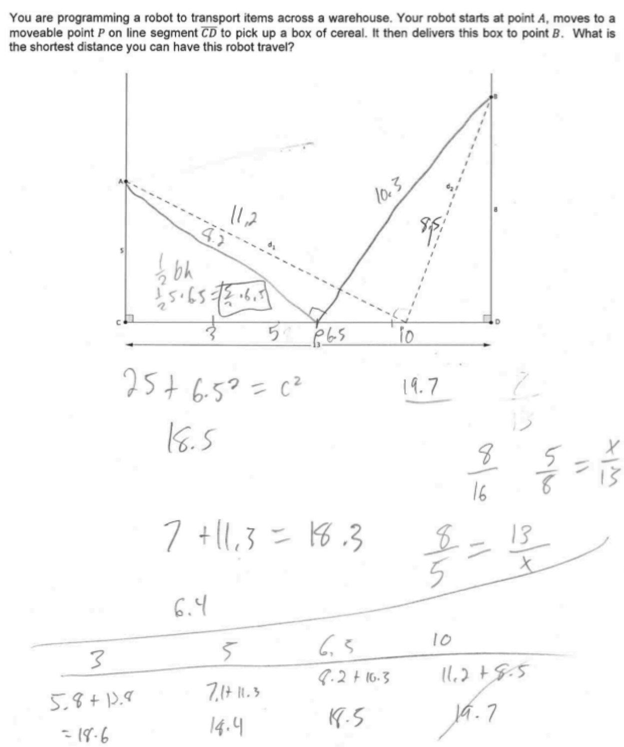

Figure 12. Example of expected 'guess and check' solution strategy.

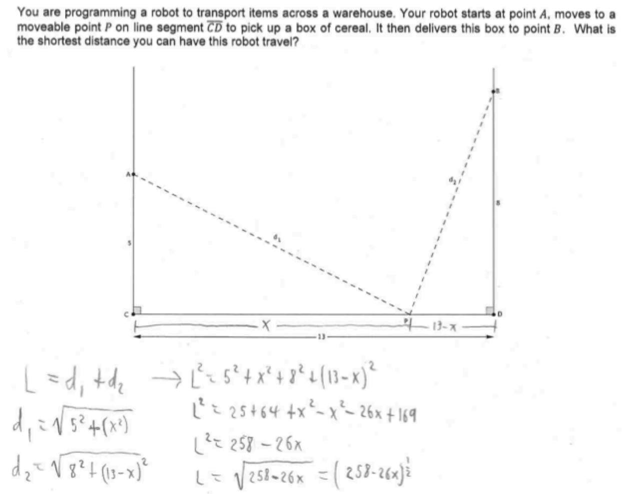

Figure 13. Example of expected calculus minimization solution strategy.

The student who successfully applied calculus (Fig. 13) later expressed preference for a traditional solution strategy while working on the system of equations problem (Fig. 6).

> *"I'd like to think that my professor would choose the first solution, but I do know some professors that would be just like, oh yea, that (the second solution strategy) is how equations work. My professor definitely sees patterns in the numbers a lot better than I do sometimes. I'd like to think they would use the first one just because it is a good rote way to do it, showing us how to do it. But if they were to do it off the top of their head, I think they might have been able to do the second one."*

This preference for the traditional solution strategy extends beyond personal to include a preference for how this student thinks the content should be taught, recognizing that the symmetric strategy requires a certain level of intuition which causes some self doubt. This might support the findings of Leikin (2003) that there is appreciation for symmetric heuristics but qualities like validity and perceived ease detract from overall preference and use.

Implications and Future Inquiry

Based on preliminary findings it seems that this population does not exhibit, with this measure, a meaningfully varied range of symmetric abilities. While there is a statistically insignificant positive correlation between symmetric ability and mathematics attitude, students performed very highly on both. It could be that a sample of quite advanced mathematics students would have previously self-selected to continue in mathematics based on good symmetric ability and/or mathematics attitude. This hypothesis suggests that differences may exist between students with high or low symmetric ability, but our research population was not suited to find this. Future research plans include expanding symmetric ability survey sample size to less proficient mathematics students. Possible further interview findings include: high symmetric ability students prefer but do not natively use symmetric heuristics, low symmetric ability students do not prefer and do not natively use symmetric heuristics, or any combination therein. Further, this line of inquiry will provide a characterization of how students think about symmetry as a heuristic.

Research has shown that it is possible to train and develop varieties of spatial ability (Uttal et al., 2013) and that using symmetric heuristics can enhance one's problem-solving endeavors (Ho, Ho, & Jaguthsing, 2012). We share the perspective of others that symmetry is a powerful and yet lightweight tool that could be used as a vehicle for inspiring deeper mathematical learning. We sought to find a connection between symmetric ability and symmetric heuristic use and preference which would be an important finding for the continuing efforts of establishing curricular recommendations that align with this perspective.

Understanding and advancing graduate teaching assistants' mathematical knowledge for teaching

Stacy Musgrave
California State Polytechnic University, Pomona

Marilyn Carlson
Arizona State University

Graduate student teaching assistants (GTAs) usually teach introductory level courses at the undergraduate level. Since GTAs constitute the majority of future mathematics faculty, their image of effective teaching and preparedness to lead instructional improvements will impact future directions in undergraduate mathematics curriculum and instruction. Yet GTA training, when offered, tends to focus on the practice of teaching rather than the mathematics being taught. In this paper, we argue for the need to support GTAs' in improving their mathematical meanings of foundational ideas and their ability to support productive student thinking. By investigating GTAs' meanings for average rate of change, a key content area in precalculus and calculus, we found evidence that even mathematically sophisticated GTAs possess impoverished meanings of this key idea. We argue for the need, and highlight one approach, for supporting GTAs' to improve their understanding of foundational mathematical ideas and how these ideas are learned.

Key words: graduate student teaching assistant, mathematical meanings, average rate of change, precalculus

Many mathematicians believe that undergraduate curriculum and teaching is unproblematic. After all, it worked for them! However, evidence exists to suggest otherwise (Bressoud, et al., 2012; Seymour, 2006). As universities continue to explore how to improve the mathematical success of their students, we propose that consideration for the preparation of future faculty be a central component of shifting introductory university level instruction. Graduate student teaching assistants (GTAs), namely, those individuals who constitute future faculty, teach many of the courses that undergraduate students first encounter in college (i.e., courses up to and including calculus). As such, GTAs who offer high quality instructional experiences for their students can impact a large number of students early in their studies. Yet GTA instructional support and professional development, when offered, frequently focuses on general discussion of best practices in pedagogy and specific logistical and student issues for a given institution. As novice instructors, this information is important in supporting GTAs' development of facility with the day-to-day practices of teaching, but it does little to support them in engaging deeply with the mathematical content in a way that will translate to meaningful mathematical discussions in their classrooms.

As other researchers have noted, having completed many mathematics courses, as most GTAs have, does not necessarily improve a teacher's understandings and teaching practices (Speer, 2008; Speer, Gutmann, & Murphy, 2005). Speer and Wagner (2009) further argue that the work done by mathematics instructors in providing analytic scaffolding, which entails recognizing and figuring out the ideas expressed by students to build upon and push the mathematical discussion forward, involves *mathematical* work. Instructors with impoverished or strictly procedural meanings for the mathematical content of a lesson will struggle to engage their students in conceptually oriented discussions around this lesson. Thompson, Carlson & Silverman (2007) claim that:

> If a teacher's conceptual structures comprise disconnected facts and procedures, their instruction is likely to focus on disconnected facts and procedures. In contrast, if a teacher's conceptual structures comprise a web of

> mathematical ideas and compatible ways of thinking, it will at least be possible that she attempts to develop these same conceptual structures in her students. We believe that it is mathematical understandings of the latter type that serve as a necessary condition for teachers to teach for students' high-quality understanding (pp. 416-417).

The possible attempts to support student learning are revealed in the nature of the instructor's questions, her questioning patterns and the quality of the discussion she leads. All of these activities are built from how the teacher makes sense of her students' thinking, which itself is done through the lens of the teacher's own mathematical meanings (Teuscher, Moore & Carlson, 2015).

In this paper, we argue the need for attention to the GTAs' mathematical meanings, fostering attentiveness to student thinking, and supporting GTAs to *speak with meaning* during their training (Clark, Moore, & Carlson, 2008). In the context of an intervention to support mathematics GTAs to act in productive pedagogical ways, we investigated GTAs' meanings for average rate of change (AROC), a key content area in precalculus and calculus. We found evidence that even mathematically sophisticated GTAs possess meanings that vary widely in productivity for teaching prior to our intervention, and that shifts in meanings required prolonged engagement in professional development focused on making meaning, building coherence and communicating with precision.

We provide an expanded description of our goals for high quality instruction, how the intervention supports GTAs in making progress towards those goals, and describe what research has reported to be a productive meaning for the idea of AROC (Thompson, 1994). We then report on results that reveal the varied fluency among participants in speaking with meaning about AROC when probed before, during and after the intervention. We conclude with a discussion about the impact of the intervention and implications for other GTA training and professional development for undergraduate mathematics instructors.

Theoretical Framework

We provide a brief explanation of our theoretical perspective on mathematical meanings and say what we mean by high quality instruction. We also include a detailed description of the intervention used to support GTAs in developing more robust meanings of the concepts of AROC.

Researchers have proposed *mathematical meanings* as the organization of an individual's experiences with an idea, also referred to as a scheme (Thompson, 1994). It is through repeated reasoning and reconstruction that an individual constructs schemes to organize experiences in an internally consistent way (Piaget & Garcia, 1991; Thompson, 2013; Thompson, Carlson, Byerley, & Hatfield, 2013). For example, an individual's meaning for the idea of *average rate of change* might consist of the calculation for the slope of a secant line, or simply $\Delta y/\Delta x$. An individual who has committed to memory that the average rate of change is the slope of a secant line does not possess the same meaning as someone who sees the slope of a secant line as the constant rate of change that yields the same change in the dependent quantity (as some original non-linear relationship) over the interval of the independent quantity that is of interest. These two individuals hold different meanings for the same idea, and the consequences of such differences can be profound. For instance, the former individual may or may not have an understanding of AROC as a *rate of change*, but instead conceptualizes AROC as the numerical output of a computation. This individual will struggle to generate problem solving strategies relying on AROC, for instance, in situations where linear approximations could help generate characterizations for how two quantities covary over a given interval.

In studying individuals' meanings for various mathematical constructs, researchers are at a disadvantage – we cannot *see* schemes. Rather, we only have access to what an individual says, writes and gestures when engaging in mathematical activity. In our research and in the intervention, we focus on an individual's *expressed meaning of an idea*, or the spontaneous utterances that an individual conveys about an idea. From these utterances we can make inferences about how an individual has organized her experiences with the idea. We find the expressed meanings of particular interest in studying instructors' mathematical meanings because it is these spontaneous verbalizations that emerge during class instruction when students ask questions or pose solutions that deviate from what the instructor had prepared. What the instructors say *in the moment*, in turn, affects the ways of thinking their students develop about the mathematical idea(s) central to the discussion. We further propose that these expressed meanings provide insight into an instructor's meanings, which influence nearly all instructional activities, including: how the instructor interprets and responds to students' utterances and written products, the nature of the questions the instructor poses to students, and the selection and implementation of curricular tasks during class meetings.

We further note that an individual's meanings can be more or less productive for teaching. By more productive for teaching, we intend to describe those meanings that would support the individual in constructing new mathematical ideas and connections to other ideas, and correspondingly create the possibility for the individual to foster those connections within her students. An individual's meaning for specific ideas can be further developed through reflection, which occurs when the individual is faced with perturbations to her current meanings for those ideas (Dewey, 1910). With this perspective in mind, the intervention for GTAs is designed, in part, to perturb the GTAs' thinking about mathematical content areas specific to the courses they teach, namely precalculus and beginning calculus.

High quality instruction

For the purposes of this paper and the intervention being discussed, we delineate some of the characteristics we take as essential components of high quality instruction. A teacher is engaging in high quality instructional practices when she

- Supports students in constructing deep understandings and rich connections among central ideas of a course,
- Supports students in developing flexible problem solving abilities that enable them to solve problems that are novel to them and require that they apply their understandings
- Interprets and acts on student thinking when teaching, and
- Reflects on student thinking and learning to improve teaching.

One of the behaviors that might indicate high quality instruction to an observer is that the instructor is speaking precisely and meaningfully about mathematical ideas (Clark, Moore, & Carlson, 2008). Another indicator is that the instructor asks questions that elicit student thinking and then interprets, analyzes, clarifies and, whenever possible uses students' contributions to push forward the mathematical activity in the classroom (Johnson, 2013; Steffe & Thompson, 2000). A teacher's ability to engage in these practices depends heavily on the teacher's mathematical meanings and her mathematical knowledge for teaching (Ball & Bass, 2003; Ball, Hill, & Bass, 2004; Silverman & Thompson, 2008).

The intervention

The graduate students involved in the intervention volunteered to participate in the program and were compensated for their participation. All but one had met their respective university requirements to teach and agreed to further engage in a yearlong professional development program, which we call *the intervention*. The GTAs participated in a 2-3 day workshop before the start of their first semester of teaching with research-based, *Pathways Precalculus* curriculum materials (Carlson, Oehrtman, & Moore, 2015). During this intensive workshop, the GTAs completed mathematical tasks that were designed and sequenced to support graduate students in constructing a productive meaning for the key ideas in the precalculus curriculum, including the ideas of constant rate of change, AROC, exponential growth, angle measure, and the sine and cosine functions[1]. The graduate students confronted problems and questions designed to perturb their meanings for these topics. Sometimes these questions were as simple as "Explain the meaning of _____." Other times, the workshop tasks were more advanced mathematical problems that could be solved with precalculus tools, provided the individual had a deep understanding of the mathematical ideas central to the lesson. Still other intervention tasks were situated in the act of teaching, requiring participants to respond to hypothetical student questions and responses. The intent of these questions and tasks was to prompt reflection and subsequent shifts in the GTAs' meanings for the mathematical ideas that were the focus of their instruction.

The intervention leaders conducted workshops in a manner to encourage the participants to speak with meaning about the ideas. This meant GTAs were encouraged to avoid using vague language (e.g., use the quantity descriptions instead of pronouns, as in "The distance increases" instead of "It goes up.") and to explain basic vocabulary (e.g., *proportional*) instead of taking terms as understood. As this type of communication is new to most of the participants, this focus on speaking with meaning about the mathematics continued during the intervention. During the fall and spring semesters, the GTAs attended weekly 90-minute seminars concurrent with teaching a course using *Pathways Precalculus* materials, instructional resources designed using research on student thinking (e.g., Carlson, 1998; Carlson et al., 2002; Moore, 2012; Strom, 2008; Smith, 2008; Engelke, 2007) and scaffolded to support students' construction of key ideas of precalculus that are foundational for calculus.

The primary goals of the weekly seminars were to support the graduate students in developing more productive meanings of the key ideas to be taught during the upcoming week, and to support them in clearly explaining their meanings for those ideas to others. As part of the intervention to support them in achieving these goals, each of the graduate students reviewed the course materials prior to the weekly seminar and came prepared to discuss what is involved in understanding and learning the ideas central to the lesson for the subsequent week. They also came prepared to give presentations to their peers about how they intended to support their students' learning of these ideas. During the seminars, participants frequently worked in small groups to develop mini-presentations focused on implementing the most conceptually challenging tasks to be used in the lessons for the upcoming week. At some universities, GTAs were further asked to videotape their instruction and write reflections on their instruction with respect to the ways of thinking they supported during that class, the types of questions they posed to students, and how they might have responded differently taking student thinking into account.

The intervention had a primary focus on the mathematical content and what was entailed in understanding and learning key ideas of each lesson. Student thinking was discussed and described using constructs from relevant research literature and the GTAs' classroom experiences. Student thinking was analyzed for the purpose of describing student reasoning and understanding, and identifying productive ways for advancing students' learning. To

[1] The idea of *average rate of change* is the culminating idea of the first instructional unit of the

achieve the goal of improving the GTA's ability to make sense of and advance student thinking, the intervention leaders and accompanying instructor materials had a primary focus on supporting the GTAs in developing rich and well-connected meanings for the mathematical ideas that were the focus of each lesson.

The content for the course began with a focus on developing students' ability to conceptualize quantities in a problem context and consider how pairs of varying quantities change together—these reasoning abilities have been identified to be necessary for constructing meaningful formulas and graphs (Moore & Carlson, 2012) to define functional relationships in applied contexts. As students explore the patterns of change for non-linear functions, such as exponential, quadratic, polynomial, rational, and trigonometric functions, they use the idea of *average rate of change* to characterize and compare function behavior over intervals of a function's domain. Since the idea of *average rate of change* is an important cross cutting idea that is challenging to teach with a conceptual focus, we selected this idea for studying the GTAs' mathematical meanings.

A productive meaning for the idea of average rate of change

Constructing a rich meaning of *average rate of change* entails conceptualizing a hypothetical relationship between two varying quantities in a dynamic situation. Given a relationship between the independent quantity A and the dependent quantity B, and a fixed interval of measure of quantity A, the *average rate of change* of quantity B with respect to quantity A is the *constant rate of change* that yields the same change in quantity B as the original relationship over the given interval. In order to understand this complex idea meaningfully, an individual must first conceptualize the idea of *quantity* as a measurable attribute of an object (e.g., the distance a car travels from home, number of minutes elapsed since noon). Next, provided a situation in which two quantities vary in tandem, an individual must develop an understanding for what it means to describe the *rate of chang*e of one quantity relative to the other. Namely, the individual must conceptualize the multiplicative comparison of changes in the two quantities (the change in the output quantity is always some amount times as large as the change in the input quantity). In the special case that the relative size of changes in one quantity relative to the other remains constant, we say the quantities vary with a constant rate of change (CROC) (see Figure 1 for the mental actions involved in constructing the idea of CROC). Individuals with a robust meaning will draw connections between AROC and CROC and view those two connected ideas as a means for approximating values of varying quantities in dynamic scenarios.

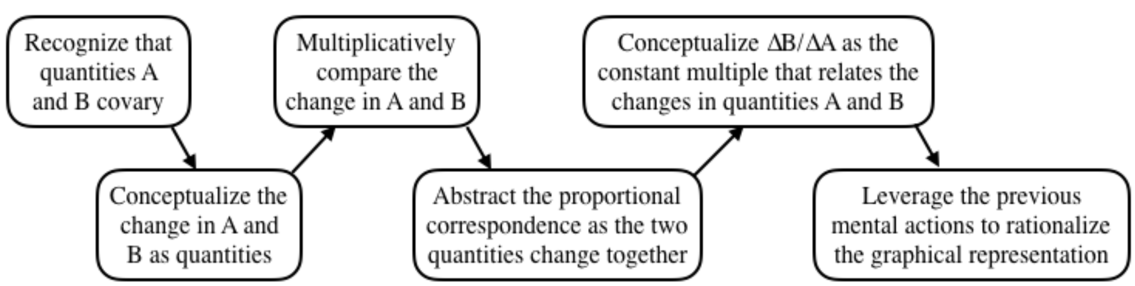

Figure 1. Mental actions involved in understanding constant rate of change

Methods

We collected data from mathematics graduate students and instructors at three large, public, PhD-granting universities in the United States. Participants' teaching experience varied between zero and 11 years, at both the K-12 and tertiary level. We conducted semi-structured clinical interviews with 19 graduate teaching assistants, all of whom had at least one semester experience teaching a small section or acting as the recitation leader for a Precalculus course that used the *Pathways Precalculus* materials (Clement, 2000). The lead author conducted interviews to probe shifts in their beliefs about the roles of students and teachers in teaching and learning mathematics, and gain insights about their understandings of mathematical ideas, teaching practices and goals for student learning. Interviews were recorded using both a video camera and Livescribe technology to capture audio-matched written responses to sample teaching scenarios provided during the interviews. Interviews lasted 1-2 hours, and were transcribed and coded by three members of the research team. Members of our team analyzed videos in pairs at first, identifying themes of interest relative to our conception of a productive expressed meaning for AROC before working individually to continue coding and reconvening as a group to discuss our findings (Strauss & Corbin, 1990).

Results

We first share data that reveals the expressed meanings that the graduate students conveyed for the idea of AROC when entering the program. We then illustrate their varied fluency in describing their meaning for AROC by sharing excerpts from clinical interviews with experienced participants. This is followed by our contrasting this data with their written descriptions of participants' meaning for AROC provided the week after they had completed teaching the investigations on AROC in a precalculus course using the Pathways materials for the first time. Collectively, our data reveals that the meanings for AROC conveyed by the novice and experienced GTAs differ in terms of the level to which they are able to spontaneously provide a meaningful description of what is involved in understanding AROC; however, it is noteworthy that even after completing the intervention, some GTAs in our study did not shift to speak fluently about the idea of AROC.

Pre-Intervention Meanings for AROC

As a warm-up activity for the start of a Summer 2015 teaching assistant workshop, we asked seven math graduate students to describe the meaning of "average rate of change." Each participant's response is recorded in Figure 2, in the order in which they verbalized their meaning to the group. Their responses align with the authors' prior experiences with both students and teachers at the secondary and tertiary levels; most of the participants provided computational or geometric interpretations based on imagining a secant line between two points on the graph of a function. In particular, we see that Alan[2] described AROC both computationally (i.e., $\Delta y/\Delta x$) and geometrically as a line, instead of highlighting the key attribute of the line—its slope. Another student, Frank, provided two equivalent descriptions of how to *compute* the AROC over a given interval, but did not convey what the result of those computations represent. When prompted by the workshop leader to explain the meaning of the result of the described computations, Frank struggled to communicate his thinking beyond referencing speed, saying, "[The result] represents how fast you're moving in effect. I always think of it as distance and time. It's difficult when you don't know what the quantities are." This issues of describing a meaning for AROC devoid of context arises repeatedly, even among the most experienced GTAs.

---

[2] Psuedonyms are used throughout the reporting to protect the identity of participants.

Responses to the question: What does "average rate of change" mean to you?	
Alan:	Delta *y* over delta *x*. A straight line between two points on a graph
Edgar:	Rate of change over an interval and talk about interval as a whole. Describe the rate of change.
Frank:	The amount the dependent variable changes divided by the amount the independent variable changes. Delta *y* divided by delta *x*.
Cassie:	Steepness of a graph, like how steep or how flat it is.
Diane:	Steepness of a graph. […] Uh, I don't have actual words.[…] Slope or derivative.
Brian:	As one variable changes for every one unit, how much is the other variable changing. Slope. Speed.
Greg:	I lost all the words…It's the predictive effect of changing one variable and the amount and how it's going to affect the other variable. One quantity affecting change in another quantity.

Figure 2. Pre-intervention participant descriptions of AROC

Cassie and Diane spoke explicitly about a graph's steepness, a visual aspect of a graph that is simultaneously restricted to the Cartesian coordinate system and, in that setting, is potentially misleading when the coordinate axes do not have the same scale (see Figure 3). Another GTA, Brian, also mentioned slope, though he did so while conveying the idea that slope is an amount of change in the dependent quantity for each unit change in the independent quantity, a restrictive meaning for slope as it fails to support reasoning about variation when changes in the independent quantity have magnitude other than 1. His mention of speed suggests he might have been imagining more than he communicated, but his inability, or perceived lack of need, to coherently communicate with precision about his thinking is exactly one of the characteristic behaviors of the novice GTAs the intervention aims to transform.

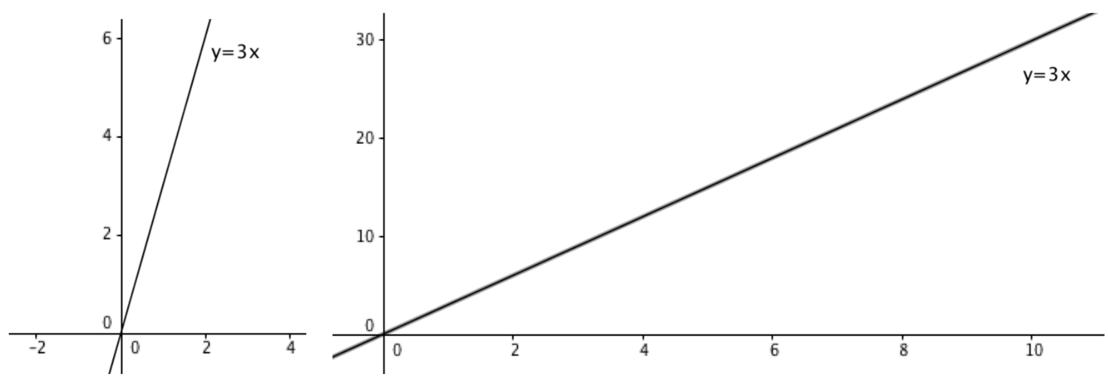

Figure 3. Same relationship but different visual "steepness"

Edgar's description of average rate of change as the rate of change over a whole interval lacks specificity and fails to communicate new information to the label of "average rate of change" beyond involving an interval. Taken literally, saying the AROC describes the rate of change loses all nuances about the possibility of a situation involving a varying rate of change and how AROC allows one to capture information about a dynamic situation even in the absence of information about the actual rate of change. Greg commented on the "predictive" quality of AROC, making him the only participant to explicitly highlight the idea that AROC provides an alternate means for characterizing how two quantities change together. This thinking, however, is missing many elements of what we have previously characterized as a productive meaning for AROC.

The pre-intervention participants' expressed meanings were predominantly geometric, computational, or restricted to particular representation formats (i.e., a graphical representation of a function in the Cartesian coordinate system); moreover, only one of the seven participants spontaneously hinted at the idea that the AROC serves as a tool for characterizing a function's change over some interval of its domain.

Post-Intervention Meanings for AROC

We analyzed 19 clinical interviews with participants who experienced at least one summer workshop and one semester of our intervention. In contrast to the predominantly geometric and computational descriptions of AROC from our pre-intervention participants, 15 of the 19 participants attempted to describe a meaning for AROC that conveyed some significance of the concept beyond a computation to perform (i.e., $\Delta y/\Delta x$) or an image to consider of a particular representation (i.e., secant line connecting two points). These descriptions can be classified as: the productive, general meaning described in our theoretical framework; a special case of that meaning for average speed; or, in one instance, a distinct interpretation the participant called "linearization." The other four participants offered explanations that fall strictly into the last four categories described in Table 1.

Table 1. Experienced participant descriptions of AROC

Expressed Meaning Category	*Sample Excerpts from Clinical Interviews*	*Number of Instances**
Productive – General	[Students] have to understand constant rate of change because the average rate of change is the constant rate of change someone else would have to go, and I'm talking about average speed now, to achieve the same change in output for a given change in input. So, if you don't have meaning for constant rate of change, well, then average rate of change is just this number.	9
Average Speed	[AROC] is a constant rate of change for that specific time and distance, or uh, you know how I mean…	8
Conceptual Other	I would like to say linearization. Right, this idea of approximating something that isn't linear in a linear fashion.	1
Computational	… this final minus initial over the outputs and this final minus initial over the inputs and that's a rate.	4
Geometric	Average rate of change is the constant rate of change to go between two points.	2
Incorrect	I want my students to understand that constant rate of change is a special case, I guess of average rate of change. It's this special case that exists when the corresponding changes in our two quantities are proportional.	3
None		1

* Total exceeds 19 because some interviewees conveyed more than one expressed meaning.

The excerpts in Table 1 highlight the fact that the impact of the intervention on participants is far from uniform. One participant failed to provide a clear statement of a meaning for AROC as he talked around the issue for 14 minutes during his interview. We found this surprising in light of the fact that this participant had four semesters of experience teaching the idea of AROC using curriculum materials designed to support the productive meaning described above. Of the 9 people who conveyed the productive meaning for AROC, four started with the more specific version of average speed and then generalized to a description in terms of general quantities. The other five produced explanations with various degrees of fluency, taking one participant almost 4 minutes to construct his explanation. Four of the eight participants who conveyed a meaning tied to average speed did not convey a meaning for AROC beyond the context of comparing distance and time. In fact, two of those four GTAs only discussed average speed when prompted from the interviewer following their initial response of describing a computation.

The sample excerpt for an incorrect meaning suggests that the participant developed a meaning for AROC linked to CROC in a non-standard way; conventional treatment of the two ideas typically describes AROC as a CROC approximation instead of viewing CROC as a special case of AROC. Another GTA stated that an average rate of change can be found by adding up and dividing, conveying a meaning for AROC that is conventionally identified as an arithmetic mean. Yet another participant proclaimed, "I will forever think of average rate of change as the slope of the secant line." The fact that some of these GTAs did not immediately produce the meaning for AROC supported both by the intervention and the curriculum materials points to the complexity of the idea of AROC and the difficulty that even graduate students had in modifying their strongly held geometric and computational images of the idea of AROC to a more robust scheme with connections that are rooted in a quantitative meaning that can be expressed in multiple representational contexts.

Nonetheless, many participants' expressed meanings did align with our productive meaning for AROC as a way to describe a characteristic of a relationship between varying quantities, even if only in the special case of average speed. Recall that during the intervention, leaders encouraged participants to *speak with meaning* as a tool to support their students in reasoning about quantities. Participants were asked to use appropriate language, describe the underlying meanings of specialized vocabulary (e.g., reference quantities instead of using pronouns like "it", explain "proportional" instead of just using that word), and offer multiple ways of explaining a concept. We see evidence of this practice in the "Productive Meaning" excerpt from Table 1 that was conveyed by a participant with 3 years of experience with the intervention, first as a participant and more recently as a leader. Not only did she express a productive meaning for AROC, using appropriate descriptions that highlighted *changes* in quantities as opposed to *values* of quantities, she further made explicit the connection between CROC and AROC and described the mental imagery she hopes her students develop. She later elaborated the importance of students imagining a second object or scenario that displays a CROC relationship that would yield the same change in output over the given interval of the input quantity.

Similarly, Hannah stumbled slightly, but ultimately described AROC in terms of changes in quantities, as seen in the following interview excerpt:

> *I think one needs to understand that average rate of change means that […] two quantities are varying but not necessarily at a constant rate of change—like the output quantity can, umm, not have a constant factor with respect to the input quantity. But the average rate of change of that relationship would be like if the…if there was a constant rate of change, the same output would be covered for a given amount of input. I think the easiest one for students to*

understand with that is the example of like distance and speed. So if you're driving your car at a constant speed and I am stopping and going and slowing down and speeding up, we will cover the same amount of distance in the same amount of time. And your—the constant rate that you go—is the same with my average rate. But I find that with that example it's really […] hard for students to talk about things not in terms of time. I also find that using the word "average" is confusing to students.

She continued to reflect on a driving context as a familiar example to support students' reasoning about AROC, but demonstrated an awareness of student thinking by highlighting that particular example as potentially problematic for students to generalize beyond contexts dependent on time. She also expressed an awareness of student difficulties with the multiple meanings of the word "average" appearing in the phrase *average rate of change*.

Interestingly, though Hannah demonstrated a relatively high level of fluency in speaking with meaning about AROC, she pointed out that this particular idea is usually difficult for her to discuss with her students, saying:

I was struggling with it, and […] it's just hard to word it in terms of input and output and varying quantities without having a concrete example. And so, to me I'm not even sure that [students are] not getting it so much as that they're not able to articulate it.

Other GTAs expressed similar difficulties in discussing the idea, both during the interview and while teaching. For those GTAs who were not actively involved in the intervention and were also not the lead course instructor (they led the break-out recitation sections while a professor or lecturer provided the lecture and assigned student grades), their discomfort in expressing their meaning for AROC appeared to be more severe; not only were they unable to verbalize a coherent meaning for AROC, but they appeared more uncomfortable in being asked to do so. Examination of the video data revealed that they were more likely to squirm in their chairs, cross their arms, or move away from the interview desk. After the interviewer asked one GTA to describe his meaning for CROC, the GTA first explained how many months it had been since he taught that idea. As the interview progressed and he was asked to explain his meaning for AROC, he stumbled through saying:

The average rate of change is…um…rather than having a, a, um, ok. So the average rate of change is the, um, is again, the relation of two quantities…[explanation omitted]…ahhh…blah. You understand what I'm getting at, I hope. I'm just putting it into words poorly.

Another GTA paused for several seconds as she debated how specific to be in her response and if she would "mess up writing it or verbally saying it." Both of these participants eventually conveyed the productive meaning for AROC, but not without discomfort, lengthy periods of reflection and scratch paper.

Mid-Intervention Meanings for AROC

Because of the extreme difficulty some of the GTAs had in describing a meaning for AROC, we gathered written data from six GTAs at one university while they were actively engaged in the intervention. Participants wrote responses to several tasks asking about their meanings for CROC and AROC during the week after they taught the idea in their respective classes, either as lead instructor or as recitation leader. We attribute some of the variation in productivity of responses to whether or not the GTA was lead instructor or recitation leader (see Table 2). All but one of the GTAs wrote a description of AROC as a CROC satisfying some condition. The first GTA produced a written description of AROC that conveys the productive meaning for AROC *and* uses the same level of precision in language supported in the intervention and curriculum materials. This GTA had extensive experience studying student thinking around the idea of AROC outside of her participation in the intervention and had been selected to help lead the weekly meetings of the intervention during the academic year.

In sharp contrast to the pre-intervention computational and geometric expressed meanings, GTAs 2-6 all refer to the CROC needed to achieve the "same" or "given" change in one quantity relative to the "same" change in the other quantity. At this stage of the intervention, the sharpest criticism of these responses is that they neglect to clarify what these changes are the same *as* (i.e., a mention of an existing relationship between two quantities and the corresponding changes under inspection). In the same set of tasks, the GTAs were further prompted to construct new problem scenarios that would require a student to use the idea of AROC to understand. All five of these GTAs produced coherent problems that did, in fact, rely on the productive meaning of AROC in the context of distance and time. Interestingly, GTA 1 was the only GTA to construct a problem involving two *non*-time quantities, with her example asking a student to determine a vehicle's average rate of change of miles traveled with respect to gallons used based on an odometer reading and information about number of gallons purchased at a gas pump.

Table 2. Written responses to the question "What is *your* meaning for 'average rate of change'?"

<table>
<tr><th>GTA #</th><th>Type of GTA</th><th>Written response</th><th>Meaning Category</th></tr>
<tr><td>1</td><td>Lead instructor</td><td>I imagine 2 quantities x and y changing together, not necessarily at a constant rate of change. As x changes from x_1 to x_2, I imagine that y changes from y_1 to y_2. x_1 and y_1 stand for an arbitrary ordered pair that is fixed. The average rate of change of y with respect to x over the interval (x_1, x_2) is the constant rate of change needed to have the same change in x (that is $x_2 - x_1$) and the same change in y (that is $y_2 - y_1$) as the original function.</td><td rowspan="5">Productive - General</td></tr>
<tr><td>2</td><td>Lead instructor</td><td>The constant rate of change needed to cover the change in the output given the change in input.</td></tr>
<tr><td>3</td><td>Recitation Leader</td><td>The constant rate of change needed to produce the same change in output given the same change in input.</td></tr>
<tr><td>4</td><td>Recitation leader</td><td>AROC is the constant rate of change required to cover the same change in the dependent variable over the same change in the independent variable.</td></tr>
<tr><td>5</td><td>Recitation leader</td><td>It is the constant rate of change that you have to apply to your variable to get a fixed value of your answer. For example, if it is speed: it is the value of speed that you should pick to get a given distance in a given amount of time.</td></tr>
<tr><td>6</td><td>Recitation Leader</td><td>It is the constant rate of change to have traveled the same amount distance in the same amount of time.</td><td>Average Speed</td></tr>
<tr><td>7</td><td>Not teaching</td><td>Sum all the rate of change, the divide by the total number.</td><td>Incorrect</td></tr>
</table>

Surprisingly, GTA 7, who participated in the intervention by attending the summer workshop and the weekly seminar, in hopes of getting a teaching assignment during the subsequent semester, again gave a response highlighting the stability of a meaning for AROC as the arithmetic mean by describing AROC as the arithmetic mean of rates of change. Even more than the interview setting, getting this type of response from a GTA in writing points to the difficulties of getting individuals, even those with sophisticated mathematical backgrounds, to shift their thinking and communication about the idea of AROC.

Discussion

The vast majority of participants held impoverished meanings for the idea of AROC at the beginning of the study, primarily focused on computation or a geometric interpretation restricted to graphical representations of function relationships in the Cartesian coordinate system. Once the GTAs participated in a summer workshop and taught using Pathways research-based curriculum designed to support the productive meaning for AROC, the meanings GTAs conveyed in written responses more closely matched the meaning supported by the intervention. Our interviews with participants who were no longer attending the weekly seminars revealed that these GTAs had retained aspects of the productive meanings for the idea of AROC that we desired. In particular, the majority of post-intervention interviewees attempted to give a meaning for AROC that went beyond a computational or geometric meaning for the idea. What remained variable, however, was the fluency with which they conveyed these somewhat more productive, albeit unstable, meanings.

The initial impoverished meanings expressed by graduate students were widespread across all three institutions, suggesting that that the relatively impoverished meanings expressed by mathematics graduate students' prior to the intervention is likely a widespread phenomena and is in need of further investigation. Moreover, it bears noting that some of these graduate students had prior teaching experience, typically as recitation leader for a range of calculus classes. Yet their experiences in teaching these classes did not support them in building strong, connected meanings for ideas of slope, rate of change, constant rate of change and average rate of change. These findings challenge the assumptions that graduate students in mathematics have strong meanings of fundamental ideas of mathematics, and further, that having taught a course guarantees such meanings will be constructed. In fact, when asked what it means to talk about "rate of change," one GTA responded by saying, "Actually, I've taught calculus before, like Calc 1. Usually in that class, I don't talk about rate of change to them. So I haven't thought about that before." Such a statement suggests that interventions such as what we have described are necessary in fostering reflective teaching practices among future faculty that might lead to more productive and coherent mathematics instruction. Failure to take action to debunk these faulty assumptions by supporting GTAs' development of conceptually coherent and meaningful conceptions of key mathematical ideas may have severe consequences for improving the predominantly procedural focus that exists in many introductory undergraduate courses in colleges and universities across the United States of America (e.g., Tallman & Carlson, 2012).

Graduate mathematics students who hold a meaning for AROC that is strictly geometric (i.e., slope of secant line) will be unable to support their students in developing a quantitative meaning for AROC. It is the quantitative meaning for AROC that an individual leverages to build connections between accumulation functions and rate of change functions, an activity foundational to applying the tools of calculus in contextualized problem scenarios. In particular, those bound by a geometric meaning for AROC are similarly limited to thinking about derivatives in a calculus class as the result of some limiting process for slopes of secant lines. Individuals with this meaning will be hard pressed to make connections between this slope-of-tangent-line meaning and, say, using the derivative to predict population values given a model of population relative to time.

Though not the focus of this research, there was mention during some of the interviews of how the Pathways materials exposed the participants to new ways of thinking about the mathematical ideas. As one GTA said, her participation in the intervention gave her the experience of "living conceptual learning…all of a sudden [she] was being asked questions about linear functions [she] couldn't answer and that really transformed [her] image of what precalculus was and the math that [she] was teaching." Other GTAs emphasized that their new ways of thinking further had positive effects on their own performance as mathematics PhD students. Interestingly, however, these new ways of thinking did not necessarily translate to what the participants had as goals for their students' learning. There was evidence of tension between what the GTAs had experienced as undergraduate students and what they were being asked to do as instructors with regards to discussing mathematics meaningfully.

On a similar note, experiences in working with the graduate students during the interventions produced encouraging anecdotal evidence that the opportunity to reconceptualize fundamental ideas may have a lasting impact on their image of what effective mathematics teaching entails. GTAs with prolonged exposure to the intervention (more than one year, and sometimes in conjunction with a leadership role within the intervention) more frequently commented on both wanting students to develop a more coherent view of the mathematics and the role of understanding their students' thinking in helping them become more effective instructors. One GTA even suggested that, depending on the level of influence his future position will offer, he could envision leading a similar type of program for instructors of a common course to provide a space for discussing the mathematics, student thinking and ways of supporting student learning. This leaves us optimistic that ours and other similar efforts might motivate mathematicians to engage in work to make undergraduate mathematics instruction more meaningful for students.

Changes in Assessment Practices of Calculus Instructors while Piloting Research-Based Curricular Activities

Michael Oehrtman	Matthew Wilson	Michael Tallman	Jason Martin
Oklahoma State University	Oklahoma State University	Oklahoma State University	Oklahoma State University

We report our analysis of changes in assessment practices of introductory calculus instructors piloting weekly labs designed to enhance the coherence, rigor, and accessibility of central concepts in their classroom activity. Our analysis compared all items on midterm and final exams created by seven instructors prior to their participation in the program (386 items) with those they created during their participation (495 items). Prior exams of the seven instructors were similar to the national profile, but during the pilot program increased from 12.4% of items requiring demonstration of understanding to 33.5%. Their questions involving representations other than symbolic expressions changed from 37.0% to 59.8% of the items. The frequency of exam questions requiring explanations grew from 5.2% to 18.0%, and they shifted from 1.0% to 5.1% of items requiring an open-ended response. We examine qualitative data to explore instructors' attributions for these changes.

Key words: [Calculus, Assessment, Cognitive Level, Representations, Problem-Solving]

One component of the recent national study of calculus programs in the United States (Bressoud, Mesa, & Rasmussen, 2015) examined the assessment practices of instructors of these courses. Tallman et al. (2016) analyzed the content of 150 Calculus 1 final exams sampled from a variety of post-secondary institutions in the larger study. Using their Exam Characterization Framework (ECF), Tallman et al. described the cognitive orientation, mathematical representations, and answer format of each item in their sample. The study demonstrated that few final exam items required a demonstration or application of understanding of the material, primarily involved only symbolic representations, and rarely required explanation or involved open-ended responses. One explanation of these results may be that faculty assessment practices simply reflect the expectations of institutionally adopted curricula. Lithner (2004), for example, found that a majority of exercises in calculus textbooks could be solved by choosing examples or theorems elsewhere in the text based on surface-level features and mimicking the demonstrated procedures.

We examined the assessment practices of pilot instructors implementing activities in their calculus courses designed to simultaneously enhance the coherence, rigor, and accessibility of student learning throughout the course. Project CLEAR Calculus provided weekly labs in which students participated in group problem-solving activities to scaffold the development of central concepts in the course along with instructor training and support to implement the labs. While the project did not address student assessment through exams, we hypothesized the conceptual focus in the labs and requirements of student write-ups would impact the instructors' assessment practices. Our study was guided by the following research questions:

1. How do the pilot instructors' exam questions compare to their previous exams along the three ECF dimensions (cognitive orientation, mathematical representation, and answer format)?
2. What factors do the pilot instructors attribute for any shifts in their assessment practices?

Background

Limit concepts are at the core of mathematics curriculum for STEM majors, but decades of research have revealed numerous misconceptions and barriers to students' understanding. Building off of work by Williams (1991, 2001), Oehrtman (2009) identified several cognitive models employed by students that met criteria for emphasis across limit concepts and for sufficient depth to influence students' reasoning. Williams noted that students frequently attempt to reason about limits using intuitive ideas associated with boundaries, motion, and approximation. Oehrtman found that, unlike most other cognitive models employed by students, the structure of students' spontaneous reasoning about approximations shares significant parallels with the logic of formal limit definitions while being simultaneously conceptually accessible and supporting students' productive exploration of concepts in calculus defined in terms of limits. These findings suggest the commonly presumed dichotomy between a formally sound, structurally robust treatment of calculus on the one hand and a conceptually accessible and applicable approach on the other (Tucker, 1986) is false. By adopting an instructional framework utilizing approximation and error analyses, we designed labs based on criteria listed in Figure 1 intended for weekly use in an introductory calculus sequence.

Design Criteria 1.	Language, notation, and constructs used in the labs should be conceptually accessible to introductory calculus students.
Design Criteria 2.	The structure of students' activity should reflect rigorous limit definitions and arguments without the language and symbolism of formal ε-δ and ε-N notation that is a barrier to most calculus students' understanding.
Design Criteria 3.	The labs should present a coherent approach across all concepts defined in terms of limits and effectively support students' exploration into these concepts.
Design Criteria 4.	The central quantities and relationships developed in all labs should be coherent across representational systems (especially contextual, graphical, algebraic, and numerical representations)
Design Criteria 5.	All labs should foster quantitative reasoning and modeling skills required for STEM fields.
Design Criteria 6.	The sequence of labs should establish a strong conceptual foundation for subsequent rigorous development of real analysis.
Design Criteria 7.	All labs should be implemented following instructional techniques based on a constructivist theory of concept development.

Figure 1. Design criteria for the CLEAR Calculus labs.

When left unguided, students' applications of intuitive ideas about approximations are highly idiosyncratic (Martin & Oehrtman, 2010a, 2010b; Oehrtman, 2009). To systematize students' reasoning concerning approximation ideas and support an accessible yet rigorous approach to calculus instruction, students engage in labs that contain contextualized versions of the questions in Figure 2. These questions develop coherence between structural components, reveal operations performed on these components, and highlight relationships among the operations, all of which is foundational for the generation of new understandings (e.g., Piaget, 1970; von Glasersfeld, 1995; Ernest, 1998).

Question 1.	Explain why the unknown quantity cannot be computed directly.
Question 2.	Approximate the unknown quantity and determine, if possible, whether your approximation is an underestimate or overestimate
Question 3.	Represent the error in your approximation and determine if there is a way to make the error smaller.
Question 4.	Given an approximation, find a useful bound on the error.
Question 5.	Given an error bound, find a sufficiently accurate approximation.
Question 6.	Explain how to find an approximation within any predetermined bound.

Figure 2. Approximation questions consistent across most labs.

Exam Characterization Framework

Tallman et al. (2016) developed a three-dimensional framework to analyze a sample of post-secondary calculus I final exams to get a snapshot of the skills and understandings that are currently being emphasized in college calculus. Their *Exam Characterization Framework* (ECF) characterizes exam items according to three distinct item attributes: (a) *item orientation*, (b) *item representation*, and (c) *item format*.

Item Orientation

Tallman et al. adapted the six intellectual behaviors in the conceptual knowledge dimension of a modification of Bloom's taxonomy (Anderson & Krathwohl, 2001) to characterize the cognitive demand of exam items. The six categories of item orientation are hierarchical with the lowest level requiring students to remember information and the highest level requiring students to make connections (see Table 1).

Table 1
Item orientation codes (Tallman et al., 2016, p. 113)

Cognitive Behavior	**Description**
Remember	Students are prompted to retrieve knowledge from long-term memory.
Recall and apply procedure	Students must recognize what procedures to recall and apply when directly prompted to do so.
Understand	Students are prompted to make interpretations, provide explanations, make comparisons or make inferences that require an understanding of a mathematics concept.
Apply understanding	Students must recognize the need to use a concept and apply it in a way that requires an understanding of the concept.
Analyze	Students are prompted to break material into constituent parts and determine how parts relate to one another and to an overall structure or purpose.
Evaluate	Students are prompted to make judgments based on criteria and standards.

Create	Students are prompted to put elements together to form a coherent or functional whole; reorganize elements into a new pattern or structure.

Item Representation

The item representation domain of the ECF involves classification of both the representation of mathematical information in the task as well as the representation the task solicits in a solution (see Table 2). A task statement or solution may involve multiple representations. Since many tasks can be solved in a variety of ways and with consideration of multiple representations, we observed Tallman et al.'s recommendation of considering only the representation the task requires.

Table 2
Item representation codes (Tallman et al., 2016, p. 116)

Representation	Task statement	Solicited solution
Applied/ modeling	The task presents a physical or contextual situation.	The task requires students to define relationships between quantities or use a mathematical model to describe a physical or contextual situation.
Symbolic	The task conveys information in the form of symbols.	The task requires the manipulation, interpretation, or representation of symbols.
Tabular	The task provides information in the form of a table.	The task requires students to organize data in a table.
Graphical	The task presents a graph.	The task requires students to generate a graph or illustrate a concept graphically.
Definition/ theorem	The task asks the student to state or interpret a definition or theorem.	The task requires a statement or interpretation of a definition or theorem.
Proof	The task presents a conjecture or proposition.	The task requires students to demonstrate the truth of a conjecture or proposition by reasoning deductively.
Example/ counterexample	The task presents a proposition or statement.	The task requires students to produce an example or counterexample.
Explanation	Not applicable.	The task requires students to explain the meaning of a statement.

Item Format

The third and final dimension of the ECF is item format. The most general distinction of an item's format is whether it is multiple-choice or open-ended. However, there is variation in how open-ended tasks are posed. For this reason, Tallman et al. define three subcategories of open-ended tasks: short answer, broad open-ended, and word problem. A short answer item is similar in form to a multiple-choice item, but without the choices. A student can anticipate the form of the solution of a short answer item upon reading the item. In contrast, the form of the solution of a broad open-ended item is not recognizable upon immediate inspection of the item. Broad open-ended items therefore elicit various responses, with each response typically supported by some explanation. Word problems can be of a short answer or broad open-ended format, but prompt students to create an algebraic, tabular and/or graphical model to relate specified quantities in the problem, and may also prompt students to make inferences about the quantities in the context using the model. Also, tasks that require students to explain their reasoning or justify their solution can be supplements of short answer or broad open-ended items.

Exam Characterization Results of the National Sample

Tallman et al. only coded 14.83% of items in their randomly-selected sample of 150 post-secondary calculus I final exams, collectively containing 3,735 items, at the "Understand" level of the item orientation taxonomy or higher. Their coding also revealed that 34.55% of items in their sample involved representations other than symbolic in either the problem statement or solution. Additionally, Tallman et al. found that only 2.4% of the items required explanations from students and just 1.34% of items in their sample were broad open-ended questions.

Methods

Twelve instructors piloted up to 30 labs in 24 different first and second semester calculus classrooms at eight different institutions from Fall 2013 to Spring 2015. Training began with in-person and online meetings with pilot instructors before the start of the fall semesters, and most of the instructors attended a three-day workshop outlining the goals, strategies, and activities of the project. We supported their implementation of the labs throughout the fall and spring semesters with online meetings with project personnel. The project website (http://clearcalculus.okstate.edu) provided instructors with student materials, instructor notes for each lab, solutions, grading rubrics, supporting handouts, and virtual manipulatives. Support meetings frequently included discussions of assessing lab write-ups but did not include discussions of creating or grading exams.

To document changes in the pilot instructors' assessment practices, we collected mid-term and final exams from the calculus classes the instructors taught prior to implementing CLEAR Calculus labs and from the classes in which they were implementing the labs. Five of the instructors either had not previously taught calculus or were required to give exams that were created by other faculty, so exams from these instructors were removed from the comparative sample.

A lead researcher in the development of the ECF and its application in the national study trained two members of our team to code with the framework resulting in 89% agreement between coding the training sample. Subsequent training focused on discrepancies. One member of our team has coded 386 items from 24 exams given by seven instructors prior to using CLEAR Calculus labs and 495 items from 27 exams given by the same instructors while implementing the labs. A random sample of 13% of the items was coded by the second member resulting in 92% agreement.

We also collected self-reported characterizations on the impact of pilot instructors' teaching and exams through their implementation of CLEAR Calculus labs.

Results

Our analysis of exams given by our pilot instructors prior to participating in the project revealed a pattern very similar to the national profile found by Tallman et al. (2016) as shown in Table 3. In contrast, while implementing the labs the instructors nearly tripled the frequency at which they asked questions requiring a demonstration or application of understanding (from 12.4% to 33.5%) and included representations other than symbolic expressions at over 1.5 times the previous frequency (37.0% to 59.8%). They asked for explanations nearly 4 times as often (5.2% to 18.0%) and included broad open-ended items over 5 times as often (1.0% to 5.1%).

Table 3
Shifts in CLEAR Calculus pilot instructor's assessment practices

	Tallman et al. National Sample (3735 items)	Pilot instructors prior to CLEAR Calculus (355 items)	Pilot instructors with CLEAR Calculus (417 items)
Items requiring understanding or higher level reasoning	14.8%	12.4%	33.5%
Items involving representations other than symbolic	34.6%	37.0%	59.8%
Items requiring explanation	2.4%	5.2%	18.0%
Broad open-ended items	1.3%	1.0%	5.1%

Items Requiring Understanding or Higher Level Reasoning

When looking at the individual instructors, five out of seven instructors were below the national average prior to CLEAR Calculus. However, with CLEAR Calculus all seven were above the nation average, which is shown in Figure 5. Moreover, the degree of the shifts in particular is noteworthy.

As an example of the types of shifts we observed, we compare an exam question from one pilot instructor's prior exam in Figure 3, to an exam question from the same pilot instructor while using the labs in Figure 4.

1. Use implicit differentiation to find $\frac{dy}{dx}$ for $3xy - 4 = y^2 + 2x$.
2. Use your answer to question 1 above to find the equation of line tangent to the curve $3xy - 4 = y^2 + 2x$ at the point (2, 4).

Figure 3. Question from a pilot instructor's exam prior to CLEAR Calculus.

Consider the function $f(x) = \arctan(x)$ a) Find the tangent line approximation to $f(x)$ near $x = 1$. (Hint: $\arctan(1) = \frac{\pi}{4}$.) b) Use the equation you found above to approximate $\arctan(1.1)$. c) Is you approximation of $\arctan(1.1)$ an overestimate or an underestimate? Explain how you know.

Figure 4. Question from the same pilot instructor's exam with CLEAR Calculus.

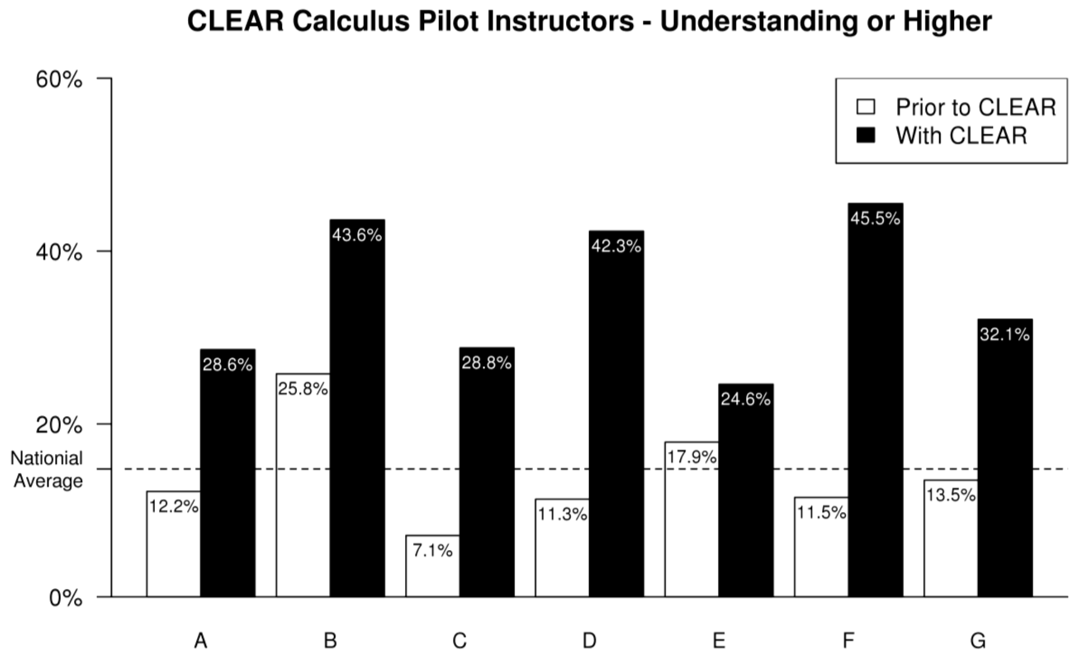

Figure 5. Shits in items requiring understanding or higher level reasoning.

The questions in Figure 3 are standard procedural questions, which demand cognitive behavior at the recall and apply procedure level. However, to perform the task in Figure 4, a student would have to solve a procedural task equivalent to the task in Figure 3 and then apply understanding of the tangent line.

The conceptual emphasis of the labs was a common theme attributed to the shift to more conceptual exam problems in the instructor interviews, highlighted by the following quotation from one pilot instructor.

> The labs had an effect on my learning goals for the class as well as my assessment of them. Because of the deeper nature of lab problems, I was able to focus more on the problem solving process as opposed to answers. When many textbook problems have only one step, it is often difficult to distinguish between these.

Additionally, the following quotation demonstrates one instructor's desire to test more conceptually demanding problems on an exam, despite using conceptually demanding coursework.

> I don't look at the labs as being an assessment. I would categorize them more as an activity. The main value for the students is doing it, and I want them to learn something by doing it, and I'm not so focused on using it as a measure of what they know. I think that in addition to being helpful ways of understanding the calculus

concepts, the notion of approximations and knowing how good they are worthwhile things for students to know themselves, even if they're not kind of inherently part of Calculus. So for that reason, they showed up a lot in class and they showed up on the exam.

Items Involving Representations Other Than Symbolic

In the national study, only 34.6% of the items involved representations other than symbolic. Thus for almost two thirds of the items from the national sample both the question statement and the solution elicited from the students were represented symbolically. Four of the seven pilot instructors in our study were below the national average prior to using CLEAR Calculus. However, while using the labs, six out of seven instructors were significantly above the nation average.

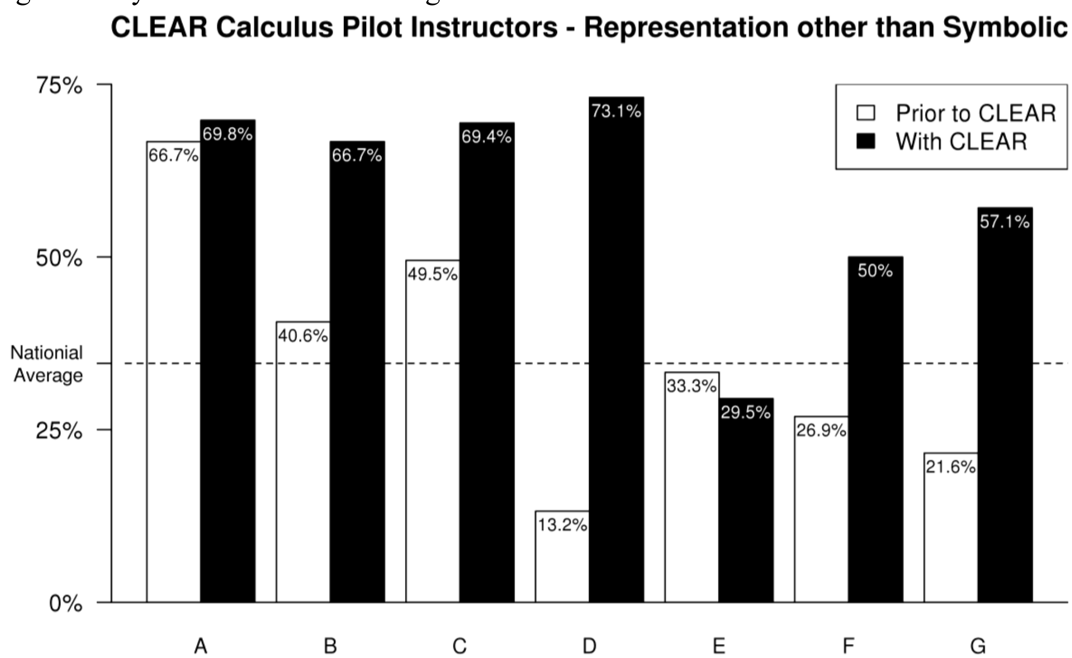

Figure 6. Shifts in items involving representations other than symbolic.

An example demonstrating the shift toward representation other than symbolic is given in Figures 7 and 8.

Determine the critical points of the function $f(x) = ax^2 + \frac{b}{x}$.

Figure 7. Question from a pilot instructor's exam prior to CLEAR Calculus.

Artisanal rocking chair construction has been going particularly well, and the work-space needs to be expanded. The original building has a square footprint of 75 ft by 75 ft. You buy 100 feet of drywall to construct the walls of the new extension. You are going to build a rectangular extension (see figure) to the building using one wall of the existing building and the other three walls from the new drywall. What dimensions should the new extension be to maximize the floor area of the new room?

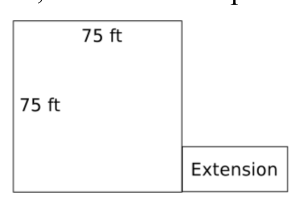

Figure 8. Question from the same pilot instructor's exam with CLEAR Calculus.

In Figure 7, both the presented task and the required solution are represented symbolically. However, Figure 8 presents and applied task, in which students will need to write a symbolic formula similar to the one given in Figure 7 in the process of solving the problem.

In the instructor interviews, the shift to representations other than symbolic was attributed to increased treatment of real-world problems through the labs. Tallman et al. found in the national sample problems were rarely stated in real-world contexts (13.2% of the tasks and 7% of the solutions). In our study, the percentage of applied/modeling items in either the statement or the solution increased from 17.1% to 32.7%. One pilot instructor explained,

> I think that they get at a little more numerical understanding of these ideas that is often not really part of the traditional calculus class. The traditional calculus class, you're world is elementary functions. If you're given an elementary function for something, then you have all these computational tools to deal with it. But in traditional calculus classes, if you have a function that's not an elementary function, then you are stuck. But that's not a good reflection of reality, and in real life you don't get elementary functions handed to you for any particular data that you're trying to understand, even if calculus tools might be useful for that. I think it's even more true in this day and age when anything dealing with elementary functions is very easy for a computer to do. So I think that this was sort of a way to help them have tools that apply more broadly, and if they understand at a conceptual level what a derivative is, and these more numerically based ideas about how to work with them in more than an algebraic context, then that will be more valuable to them.

Items Requiring Explanation

The numbers of items on the majority of the pilot instructors' exams prior to CLEAR Calculus was above the above the national average of 2.4%. While using the labs, all the pilot instructors were significantly above the national average.

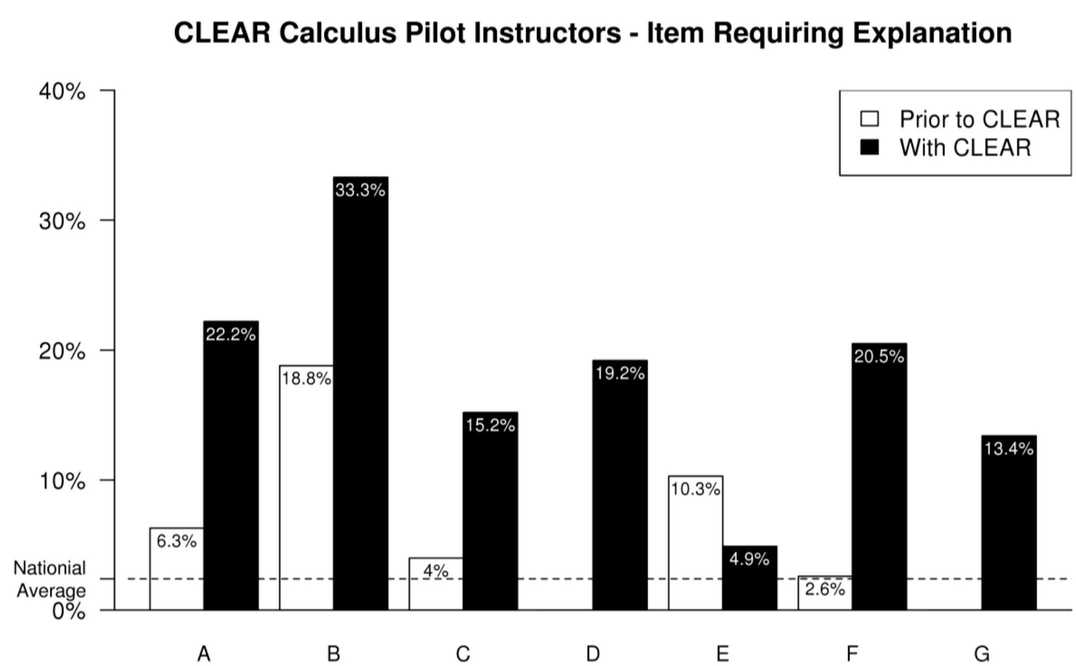

Figure 9 *Shifts in items requiring explanation*

The following Figure is an example from a pilot instructor's exam with CLEAR Calculus.

The following table gives the number of cars, $C = f(t)$, in millions, in the US in the year t.

t	1940	1950	1960	1970	1980	1990	2000
C	27.5	40.3	61.7	89.2	121.6	133.7	133.6

a) Is $f'(t)$ positive or negative during the period from 1940 to 1980? What does this mean about car sales during this period?
b) Is $f''(t)$ positive or negative during the period from 1940 to 1980? What does this mean about car sales during this period?
c) Estimate $f'(1975)$, and include the units for this number. Interpret this answer in terms of passenger cars.

Figure 10. Question from a pilot instructor's exam with CLEAR Calculus.

All three items in Figure 10 require an explanation. This examples also demenstrate a broader shift in assessement practices, which were not neccessarly related to the approximation framework.

One of the goals of the CLEAR Calculus project was mathematical rigor. The following quotation from one pilot instructor highlights how the approximation framework together with explanations is analogous to the rigours $\varepsilon - \delta$ and $\varepsilon - N$ arguemnts in analysis.

> I wanted them to show an understanding of that process, the understanding that this process does guarantee a sufficient accuracy. And what I was hoping to lead them away from was, "Oh I'll just choose a difference quotient between 1 and 1.000001," where they choose an arbitrary number of zeros, "and I'm sure that will probably be good enough." The point here is that this method gives you a guaranteed error bound, right? You know for sure that you are within this interval of the correct answer. And I was hoping for them to be able to articulate that.

Broad Open-Ended Items

Due to the nature of broad open-ended items we would not expect a typical calculus I exam to contain a large number of broad open-ended items. Tallman et al. found that less than 1% of the items in there study were broad open-ended. Three of the pilot instructors increased their inclusion of broad open-ended items on their exams.

The following example taken from a pilot instructor's exam with CLEAR Calculus demonstrates a broad open-ended task.

If you are trying to approximate $g'(2)$, is it possible that $\frac{g(2.1)-g(2)}{.1}$ and $\frac{g(2)-g(1.9)}{.1}$ are **both** underestimates? If so, give an example of such a function g and explain why this is the case. If not, explain why it is impossible.

Figure 11 *Question from a pilot instructor's exam with CLEAR Calculus*

In the task presented, students first have to decide if the situation presented is possible or not.

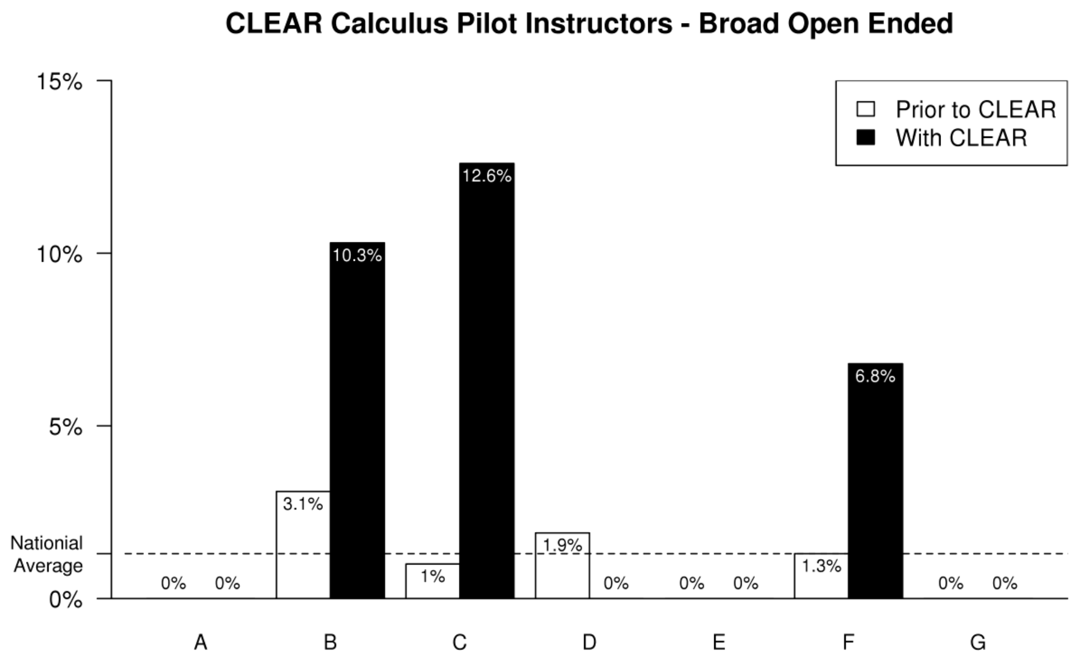

Figure 12 *Shifts in broad-open ended items*

A common theme in the instructor interviews was the goal of conceptual understanding. The following instructor attributed the shift to more broad open-ended items to this goal of conceptual understanding.

> I want to know what they're doing. If they say "overestimate" and they get it right, I don't know if that's because they actually know something about derivatives. This is based on the Approximation Framework... So what I was hoping to find out, do they understand and are they able to connect it with the concavity. It seemed like the most natural way to do that was to do it more open-ended, rather than to try to come up with a question that is designed in such a way that if they don't understand that, they can't get the right answer. It seemed just a little more natural if I'm looking for them to understand a specific thing is to ask them to tell me about that specific thing.

Discussion

All but one of the seven pilot instructors participating in this study demonstrated notable shifts in their assessment practices. Prior to implementing CLEAR Calculus labs in their classes, their exams resembled the national averages in requiring conceptual understanding, using multiple representations, and requiring explanations. While piloting the CLEAR Calculus materials, the seven instructors averaged a 270% increase in the proportion of exam questions requiring conceptual understanding, 162% increase in use of representations other than symbolic, and 346% increase in items requiring explanations. Three of these instructors also asked more questions involving open-ended responses. Due to starting near the low national averages, large shifts are certainly possible with even moderate changes in practices. Nevertheless these shifts were large enough that many of the pilot instructor's exams while using the labs would have constituted outliers in each category among the random national sample analyzed by Tallman et al. (2016).

Pilot instructors viewed their shifts in assessment practices as positive and attributed them to multiple aspects of the CLEAR Calculus labs aligned with the design goals as well as to other broader factors. The important quantities and their interrelationships emphasized in the Approximation Framework guiding the labs are salient, useable, and consistent across all of the primary mathematical representations used in calculus (Figure 1, Design Criteria 4). Instructors cited this coherent use of multiple representations throughout the lab materials for establishing meaningful ways to assess their students using representations other than only symbolic. The labs also engage students in conceptually accessible approximation concepts in a consistent way across all of the calculus concepts defined in terms of limits (Figure 1, Design Criteria 1 & 3). Instructors cited these features for providing important global ideas and a foundation of common reasoning to assess (for example, choosing appropriate tools to find an underestimate or overestimate as required). While remaining conceptually accessible, the labs are also designed to engage students in activities that reflect the structure of standard ε-δ and ε-N definitions and proofs (Figure 1, Design Criteria 2). The pilot instructors cited the connection to rigorous mathematical argumentation as providing an opportunity to require additional explanation or justification from students (for example, justifying that their approximation is sufficiently accurate).

Our continued analysis of this data will explore these patterns in greater depth and provide a foundation for further interviews with the pilot instructors. For example, the most experienced of the pilot instructors was the sole exception to the shifts displayed by the others. Thus, we plan to explore the role of background and experience with each of the instructors to identify their potential connections to changes in assessment practices. Similarly, we seek to better understand the rationale behind shifts in use of questions that are not directly derived from the Approximation Framework questions (Figure 2). Finally, by pairing items on exams and our common Calculus Concepts Assessment administered to most students across the pilot sites, we will identify and characterize any correlation of assessment focus and differences in student learning.

Covariational and parametric reasoning

Teo Paoletti
Montclair State University

Kevin C. Moore
University of Georgia

Researchers have argued that students can develop foundational meanings for a variety of mathematics topics via quantitative and covariational reasoning. We extend this research by examining two students' reasoning that created an intellectual need for parametric functions. We first describe our theoretical background including different conceptions of covariation researchers have found useful when analyzing students' activities constructing and representing relationships between covarying quantities. We then present two students' activities during a teaching experiment in which they constructed and reasoned about covarying quantities. We highlight aspects of the students' reasoning that we conjecture created an intellectual need for parametric functions, a need we capitalized on in a later session. We conclude with implications the students' reasoning has for future research and curriculum design.

Key words: Covariational reasoning; Quantitative reasoning; Parametric Functions; Cognition

An increasing number of researchers have made contributions to the literature base on students' quantitative and covariational reasoning (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Carlson, Larsen, & Jacobs, 2001; Castillo-Garsow, 2012; Confrey & Smith, 1995; Ellis, 2007; Ellis, Ozgur, Kulow, Williams, & Amidon, 2015; Johnson, 2012a; Thompson, 1994a, 1994b). These contributions have been with respect to students' understandings of various content areas (e.g., function classes, rate of change, and the fundamental theorem of calculus) and to their enactment of important mental processes (e.g., generalizing, modeling, and problem solving). Although maintaining the common intention of understanding students' covariational reasoning, researchers' treatments of covariation are varied. For instance, Confrey and Smith (1994, 1995) approached covariation in terms of reasoning about discrete *numerical values*, finding patterns in these values, and interpolating patterns between them. In contrast, Thompson and Saldanha (Saldanha & Thompson, 1998; Thompson, 2011) approached covariation in terms of coordinating changes in two continuous *magnitudes*, thus not constraining covariation to the availability of specified numerical values.

In this work, we illustrate students conceiving of and representing covarying quantities in ways compatible with Thompson's and Saldanha's descriptions of covariation. We identified this reasoning while exploring the research question, "What ways of reasoning do students engage in during activities intended to emphasize reasoning about relationships quantitatively and covariationally?" Before characterizing students' reasoning during a study framed around this research question, we provide our theoretical background including the perspectives on covariation that informed our work. We also describe the methods—teaching experiments and clinical interviews—we used to investigate students' covariational reasoning. We then focus on the students' actions during the closing sessions of the teaching experiment to discuss how the students used graphs in the Cartesian coordinate system to represent relationships they perceived to constitute some situation or phenomena. We highlight the parametric nature of the students' reasoning that we recognized during on-going analysis and describe our efforts at affording the students opportunities to become explicitly aware of the parametric nature of their reasoning. We then provide a discussion of our findings and relate our results to research examining students' understandings of parameters and parametric functions. We conclude by describing research and curricula implications of this study.

Theoretical Background

Researchers have drawn from interpretations of Piagetian and radical constructivist theories of knowing and learning to develop definitions and frameworks that describe the mental processes and conceptual structures entailed in reasoning about relationships between quantities (Carlson et al., 2002; Johnson, 2012a, 2012b; Moore & Thompson, 2015, in preparation; Steffe, 1991; Thompson, 1994a, 2011). Of importance to this report, Carlson et al. (2002) presented a framework that allows for a fine-grained analysis of students' covariational reasoning. The authors identified mental actions students engage in when coordinating covarying quantities including coordinating *direction of change* (quantity A *increases* as quantity B *increases*; MA2), *amounts of change* (the *change* in quantity A *decreases* as quantity B *increases in equal successive amounts*; MA3), and *rates of change* (quantity A *increases at a decreasing rate* with respect to quantity B; MA4-5) (Figure 1a).

Carlson et al. (2002) described the aforementioned mental actions in relation to the Bottle Problem (Figure 1b). As they described, when coordinating the relationship between volume of water and height of water in the bottle as water is poured into the bottle, a student first conceives that the two quantities are changing (MA1). The student can then coordinate that as volume of water increases, height also increases (MA2). Next, the student can coordinate that for equal changes in volume, represented by each colored cross sectional area in Figure 1c, successive increases in height decrease until the widest part of the bottle, at which point increases in height increase until the neck of the bottle (MA3). As the student re-constructs this relationship, she may coordinate the average (MA4) and instantaneous (MA5) rate of change of liquid volume with respect to liquid height as water is poured into the bottle. In this report, we focus on students' enactment of MA1-3 as part of their conceiving and representing relationships between covarying quantities.

Mental Actions of the Covariation Framework

Mental action	Description of mental action
Mental Action 1 (MA1)	Coordinating the value of one variable with changes in the other
Mental Action 2 (MA2)	Coordinating the direction of change of one variable with changes in the other variable
Mental Action 3 (MA3)	Coordinating the amount of change of one variable with changes in the other variable
Mental Action 4 (MA4)	Coordinating the average rate-of-change of the function with uniform increments of change in the input variable.
Mental Action 5 (MA5)	Coordinating the instantaneous rate of change of the function with continuous changes in the independent variable for the entire domain of the function

Figure 1: Carlson et al.'s (2002) framework and the Bottle Problem.

We also leverage the work of Thompson and Saldanha to characterize student thinking in this study. Saldanha and Thompson (1998) stated, "Our notion of covariation is of someone holding in mind a sustained image of two quantities' values (magnitudes) simultaneously" (p. 298). The researchers argued students' images of covariation are developmental and described an operative image of covariation in which a student is capable of imagining two quantities being tracked for some amount of time with the correspondence of the two quantities an emergent property of this image. Such an understanding entails a student coupling the two quantities to form a multiplicative object. Saldanha and Thompson (1998) described, "As a multiplicative object, one tracks either quantity's value with the immediate, explicit, and persistent realization that, at every moment, the other quantity also has a value" (p. 298).

Extending this description, Thompson (2011) provided a first-order model of such an understanding in which an individual conceives of a quantity's value, x, varying over (conceptual) time, t. The individual could then conceive of covering the domain of t-values using intervals of size ε, and consider the variation of x within these intervals (i.e. considering x_ε as the set of x-values $(x(t), x(t+\varepsilon)) = x(t_\varepsilon)$). Thompson (2011) concluded his description, "I can now represent a conception of two quantities' values covarying as $(x_\varepsilon, y_\varepsilon) = (x(t_\varepsilon), y(t_\varepsilon))$. I intend the pair $(x_\varepsilon, y_\varepsilon)$ to represent conceiving of a multiplicative object—an object that is produced by uniting in mind two or more quantities simultaneously" (p. 47). Apparent in this description of covariational reasoning is the parametric nature of covariational reasoning; a student imagines two quantities varying with respect to (conceptual or experienced) time, eventually coordinating these two quantities in a way that variation in either quantity necessarily entails variation in the other quantity to form a multiplicative object.

Drawing on the aforementioned perspectives of covariation, Moore and Thompson (2015, in preparation) defined *emergent shape thinking* as a student conceiving graphs in terms of an emergent, progressive trace constituted by covarying magnitudes. We use Figure 2 to represent instantiations of an emergent image of a trace representing liquid height and liquid volume in a bottle covarying as liquid is poured into the bottle. Adopting Thompson's (2011) notation, the student understands $h_\varepsilon = h(t_\varepsilon)$ and $v_\varepsilon = v(t_\varepsilon)$ both increase as time, t_ε, increases. A student with such an image of a graph understands that the magnitude of the blue segment represents the height of liquid in the bottle and the magnitude of the red segment represents the volume of liquid in the bottle at a certain moment of (experiential or conceptual) time, and that the resulting trace is a product of tracking how these two quantities covary with respect to (experiential or conceptual) time. That is, the student understands the graph as being formed by a trace of the multiplicative object $(h_\varepsilon, v_\varepsilon) = (h(t_\varepsilon), v(t_\varepsilon))$ for all values t_ε.

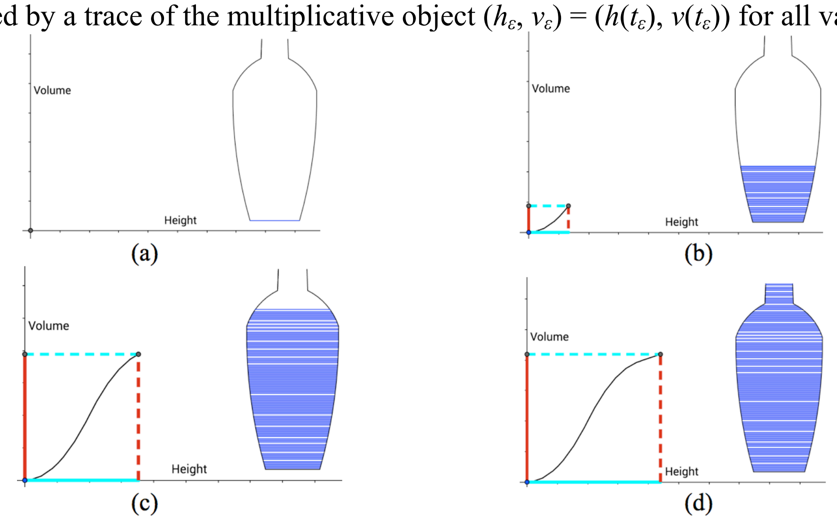

Figure 2: Four instantiations of an emergent conception of height and volume of liquid in a bottle covarying as liquid is poured into a bottle.

Subjects, Methodology, and Methods

We conducted a semester long teaching experiment with two undergraduate students, Arya and Katlyn (pseudonyms). The students were enrolled in a secondary education mathematics program at a large state institution in the southern U.S. Both students were juniors (in credit hours taken) who had successfully completed a calculus sequence and at least two additional courses beyond calculus. The teaching experiment consisted of three individual semi-structured task-based clinical interviews (per student) (Clement, 2000) and 15 paired teaching episodes (Steffe & Thompson, 2000). Each clinical interview and teaching episode lasted approximately 1.25 hours. We video and audio recorded the sessions and we captured and digitized records of the students' written work at the end of each episode.

We used semi-structured task-based clinical interviews (Clement, 2000) as individual pre- and post-interviews to determine the meanings and reasoning the students brought to the teaching experiment and to examine if any shifts had occurred throughout the teaching experiment. Clinical interviews provided us insight into students' meanings without intending to create shifts in their meanings. We used minimal heuristics to probe student thinking as we did not intend to promote shifts in student thinking (Hunting, 1997); we note that although we did not intend to promote shifts, such shifts might have occurred as addressing tasks or questions caused the students to reflect on their activity in such a way that raised perturbations for the students.

We used the teaching experiment as an exploratory tool, giving us firsthand experiences with the students' mathematics and allowing us to explore the mathematical progress the students made over the semester (Steffe & Thompson, 2000). Consistent with the teaching experiment methodology, we began the teaching experiment with a hypothesis we intended to examine, but we also created and tested many hypotheses during the teaching experiment. This sometimes led to our abandoning our initial research question to explore new conjectures created in the moment of interacting with the students (Steffe & Thompson, 2000). Specific to this report, we describe students' activities resulting from one such instance in which we made a conjecture regarding the students' understandings during our on-going analysis that we explored in a later session.

When analyzing the data we conducted a conceptual analysis—"building models of what students actually know at some specific time and what they comprehend in specific situations" (Thompson, 2008, p. 60)—to develop and refine models of the students' mathematics. By *students' mathematics*, we mean the students' body of understandings that are fundamentally unknowable to us as researchers (Steffe & Thompson, 2000). With the goal of building viable models of the students' mathematics in mind, we analyzed the records from the teaching episodes using open (generative) and axial (convergent) approaches (Clement, 2000; Strauss & Corbin, 1998). Initially, we identified instances of Arya's and Katlyn's behaviors and actions that provided insights into each student's mathematics. We used these instances to generate tentative models of the students' mathematics that we tested by searching for supporting or contradicting instances in their other activities. When evidence contradicted our constructed models, we made new hypotheses to explain the students' ways of operating and returned to prior data with these new hypotheses in mind for the purpose of modifying previous hypotheses or characterizing shifts in students' ways of operating.

Task Design

Throughout the teaching experiment, we provided Arya and Katlyn tasks prompting them to represent relationships between covarying quantities. We followed certain principles when designing these tasks. (a) We designed tasks to include situations that would be familiar and accessible to the students, with most tasks including videos, applets, or images of phenomena (e.g., circular motion). (b) We avoided providing specific values for quantities as we were interested in the students' capacity and propensity to engage in reasoning that was magnitude based (i.e., emergent shape thinking). (c) We often asked students to construct multiple graphs related to a situation to explore if, and if so how, the students leveraged their images of the quantities and covariation between quantities when creating multiple graphs that may or may not differ in appearance. This principle was based on our findings (Moore, Silverman, Paoletti, & LaForest, 2014; Moore, Stevens, Paoletti, & Hobson, 2016) that students' meanings for functions and graphs can become problematic when attempting to differentiate and represent numerous relationships (possibly under numerous axes orientations).

To illustrate these design principles, we used a variation of the aforementioned *Bottle Problem*, which was designed by the Shell Centre (Swan & Shell Centre Team, 1985) that several researchers have used productively to investigate students' covariational reasoning (e.g., Carlson et al. (2002), Carlson et al. (2001), Johnson (2012, 2015), Stalvey & Vidakovic (2015)). Reflecting (a) and (b), we provided the students with a pictured bottle that provided no numerical information and asked them to imagine the experience of filling the bottle with liquid. We then asked them to graph the relationship between volume and height of liquid in the bottle as it filled with liquid. Reflecting (c), and after they constructed a graph for a given bottle and a bottle for a given graph, we altered the prompt to ask the students to imagine liquid evaporating from the bottle. We then asked the students to represent the relationship between liquid height and liquid volume in the bottle for this new scenario.

Results

We first summarize the students' activities when creating graphs to represent how the liquid height and liquid volume covaried as a bottle filled. We then present their activities addressing liquid evaporating from the bottle in order to illustrate the students representing an additional aspect of the situation in their graph: the direction in which they imagined the graph tracing. We conclude by highlighting the students' activities on a task that we implemented during a later clinical interview in which we asked the students questions that we conjectured would explicitly raise the notion of a parametrically defined function.

Overview of students' activities addressing the (filling) Bottle Problem

As the teaching experiment progressed, the students exhibited activities indicative of reasoning about graphs as emergent traces representing two covarying quantities they conceived as constituting some situation. For instance, during the first part of the Bottle Problem each student conceived that the two quantities increase in tandem and then determined how the volume of liquid changes for equal successive increases in liquid height; each student coordinated how the volume and height of liquid in a bottle covaried in terms of direction of change (MA2) and amounts of change (MA3). Each student then created a graph while maintaining an explicit focus on how all drawn points and traces represented the relationship she conceived between the height and volume of liquid.

As an example, consider Katlyn's activity as she created her graph (see Figure 3c). Katlyn had already marked equal changes of height in her bottle (Figure 3a) and shaded the first three areas representing the volume in these height intervals (Figure 3b) (Excerpt 1).

Excerpt 1. Katlyn coordinates the relationship between liquid volume and liquid height using the bottle.

Katlyn: This volume [*the volume in* (A)] is obviously smaller then this one [*the volume in* (B)]. But they're, like when you add them together like that's the height, or that's the volume at that height. And then when we move from here to here [*pointing to* (B) *and* (C)] um this volume [*the volume in* (C)] is also bigger then the one before it [*the volume in* (B)] so when we add it on again it's like continuing to grow… the volume is increasing [*pause*] more with equal changes in height

Katlyn's image of the situation entailed MA1-3 relative to the relationship between liquid height and liquid volume as the bottle filled. Katlyn then drew coordinate axes, marked equal changes along the horizontal height axis, and constructed her graph (Excerpt 2),

Excerpt 2. Katlyn represents the relationship between volume and height in a graph.

Katlyn: This first equal change in height [*pointing to* (A) *in* Figure 3*a*] gives you like this much volume every single time [*draws segments representing the volume in* (A) *at* *each height increment, recreated as solid blue segments in* Figure 3*c*]. So you're always going to have that 'cause we're adding them up. Um and then the next one is going, like when we move up in height again [*motioning from* (A) *to* (B) *in* Figure 3*a*] the next volume that you're going to add on is bigger. But since we're adding them we can add that one to the rest of them [*draws segments extending from the original segment at the second and successive equal changes of height representing the volume in* (B) *recreated as solid red segments in* Figure 3*c*].

Katlyn continued in this way as she constructed her graph representing the relationship she inferred from the situation. She reasoned about the magnitudes of the color-coordinated segments she drew as representing amounts of volume within specific height intervals, understanding that each added segment corresponded to an amount of volume added to the total volume. Katlyn's careful attention to the quantities and use of magnitudes indicates Katlyn maintained an understanding of the trace of her curve as representing two magnitudes as represented in Figure 2. Using Thompson's (2011) notation, she conceived her graph as composed of coordinate points $(h_\varepsilon, v_\varepsilon) = (h(t_\varepsilon), v(t_\varepsilon))$ with $h(t_\varepsilon)$ and $v(t_\varepsilon)$ representing height and volume as conceptual time, t_ε. elapses.

Addressing water evaporating from the bottle

After the students had constructed and discussed graphs for multiple bottles, we asked them to graph the relationship between height and volume of liquid in the bottle in Figure 3a as the liquid evaporated. We requested they complete this graph on the same board as a graph representing the relationship between height and volume of liquid in the bottle as the bottle filled. Indicating they did not anticipate that their previous graph could represent the posed relationship, the pair first drew a new set of axes then spent two minutes considering this new relationship and deciding how to label their axes. After they decided to label the horizontal axis height, as in Katlyn's original graph (Figure 3d), Arya noted they should start at "full volume, full height." Katlyn then pointed to her original graph (Excerpt 3).

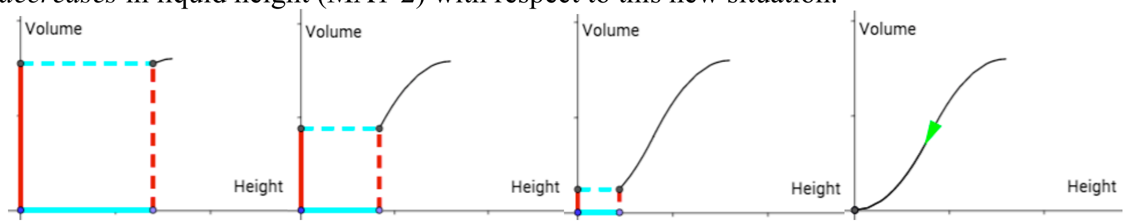
Excerpt 3. Katlyn describes how to represent the relationship between height and volume as water evaporates from the bottle.

Katlyn: It's going to look backwards… We can literally just travel this way instead [*motioning over the completed prior graph from the top-right most point back to the origin*]. [*To the researchers*] We're done, we're just going to travel this way [*again motioning over the original curve from the top-right most*].

[*Shortly after this, Katlyn elaborated as to how she conceived the graph as representing water evaporating from the bottle*]

Katlyn: If we're looking at it like equal changes of height… if we start at this, this height [*pointing to the maximum height value on the horizontal axis*] and this volume [*points to the maximum volume value on the vertical axis then to the top-left most point on the graph*], and then, oh some water evaporated, now we're at this new height [*pointing to tick 4 in* Figure 3b], now we're going to be at this volume [*placing her marker on her curve corresponding to the height and volume at tick 4*]. Okay more water evaporated [*pointing to tick 3 in* Figure 3*b*] now were at this height this volume [*placing her marker on her curve corresponding to the height and volume at tick 3*]… We don't need a new graph, it's the same."

As when addressing water entering the bottle, Katlyn's careful attention to the magnitudes of quantities represented on the axes are indicative of emergent shape thinking. Katlyn now conceived the graph as $(h_{2\varepsilon}, v_{2\varepsilon}) = (h(t_{2\varepsilon}), v(t_{2\varepsilon}))$ with $h(t_{2\varepsilon})$ and $v(t_{2\varepsilon})$ decreasing as conceptual time in this second situation, $t_{2\varepsilon}$, elapses (recreated in Figure 4a-c). Katlyn described this relationship by identifying how liquid volume in the bottle *decreased* for equal *decreases* in liquid height (MA1-2) with respect to this new situation.



(a) (b) (c) (d)

Figure 4: (a)-(c) A recreation of the students' graph as an emergent trace and (d) a recreation of their graph with the added arrow representing the direction of the trace.

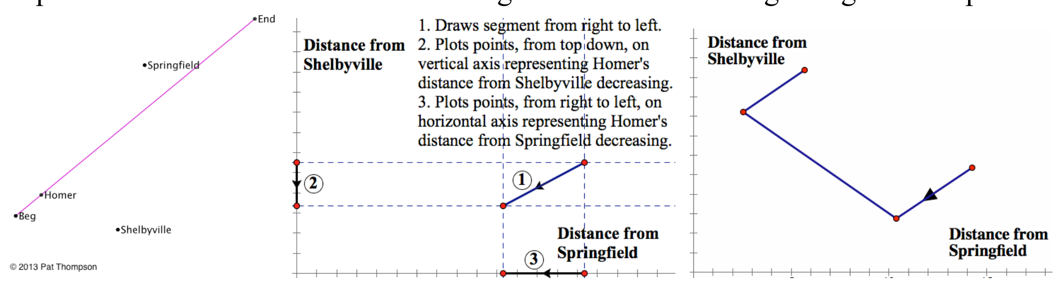
To investigate if using the same curve for a new context created a perturbation for the students, a researcher asked, "Is the situation the same? You're ending up with the same graph." Katlyn responded, "No, I just want to draw little arrows... we're going this way now [*draws an arrow on the curve pointing towards the origin, recreated in* Figure 4d]." As she addressed the displayed graph representing two different situations, Katlyn represented this difference by adding an arrow to indicate the direction in which the graph is traced out with respect to the second situation; Katlyn parameterized her graph (from our perspective) with respect to conceptual time to differentiate how the displayed graph is traced out depending on the situation. Adopting Thompson's (2011) notation, Katlyn understood the displayed graph as composed of points (h, v) representing the appropriate magnitudes of height and volume of liquid in the bottle, regardless if liquid is entering or leaving the bottle. In the first scenario, she understood $(h, v) = (h_{1\varepsilon}, v_{1\varepsilon}) = (h(t_{1\varepsilon}), v(t_{1\varepsilon}))$ with $t_{1\varepsilon}$ representing conceptual time as liquid enters the bottle. In the second scenario she understood $(h, v) = (h_{2\varepsilon}, v_{2\varepsilon}) = (h(t_{2\varepsilon}), v(t_{2\varepsilon}))$ with $t_{2\varepsilon}$ representing conceptual time as liquid evaporates from the bottle.

Addressing the Car Problem

During our on-going analysis, we conjectured that the students' activities addressing how the same graph could represent the relationship between volume and height of liquid either as it enters or evaporates from a bottle may have led to their experiencing an intellectual need (Harel, 2007) for parametrically defined functions. Harel (2007) described, "The term *intellectual need* refers to a behavior that manifests itself internally with learners when they encounter an intrinsic problem—a problem they understand and appreciate" (emphasis in original, p. 13). Specifically, we conjectured the students experienced an intrinsic problem as they attempted to represent a new situation in a graph created to represent a different situation but, ultimately, appearing the same as another completed graph. The students resolved this by adding an arrow to their graph to indicate the direction of the trace producing the graph. Further, we hypothesized that this reasoning had the potential to support them in becoming explicitly aware of the parametric nature of their reasoning as well as possibly bringing to the surface parametric functions.

We intended to explore the extent that we could support the students in bringing the parametric nature of their reasoning to the forefront as they addressed the *Car Problem* that Saldanha and Thompson (1998) designed and used to investigate students' covariational reasoning. We asked the students to represent the relationship between an individual's (Homer) distances from two cities (Shelbyville and Springfield) as he travels back-and-forth on a road (Figure 5a). Because the relationship is such that neither distance is a function of the other distance, we conjectured raising the idea of function after each student constructed a graph might support her in reasoning about an explicitly defined parametric function.

Both students initially described the directional variation (MA2) of each distance (e.g., as Homer moves from the beginning of his trip, the distance from each city decreases). As Arya attempted to represent this relationship in her graph, she drew a segment from right to left getting closer to the horizontal and vertical axis (indicated by (1) in Figure 5b). After Arya re-described the directional relationship she conceived (MA1-2), she moved to her graph and marked points on each axis to confirm her graphed segment represented that Homer's distance from each city was decreasing (MA2) (indicated by (2) and (3) in Figure 5b). Arya continued this process to draw her completed graph (Figure 5c). As in previous situations, Arya conceived her graph as an emergent trace representing two projected covarying magnitudes, indicated by her explicit attention to the magnitudes of the quantities represented on the axes when drawing each segment. Further, and similar to the students' activities addressing the Bottle Problem, Arya added an arrow to her completed graph (Figure 5c) to represent an additional aspect of the situation: the direction the graph was traced in correspondence to how Homer traveled along the road from the beginning of his trip.



(a) (b) (c)

Figure 5: (a) The Car Problem applet, (b) a recreation of Arya's work, and (c) a recreation of Arya's final graph.

Arya subsequently described that her graph did not represent either distance as a function of the other. Hoping to raise the idea of a parametrically defined function, a researcher asked, "What if your input was total distance traveled and your output was two-dimensional?" He then described the output as being composed of both distance from Springfield and distance from Shelbyville. Arya stated that this relationship represented a function as each total distance input corresponded to exactly one pair of distances.

Similarly, addressing whether the relationship with the same two-dimensional output but with 'distance on the path' as the input represented a function, Katlyn identified, "Well that's what [my graph] shows, right?" Katlyn described that for any of Homer's distances on the path there was only one corresponding coordinate point on her graph, concluding that this relationship represented a function. Katlyn added, "I understand, like, what I've been drawing this whole time is like, how I'm traveling on like this purple path. But I don't, I never thought of that as my input, but it really is." Both students were able to assimilate a question concerning a one-dimensional input and two-dimensional output to consider a parametrically defined function after they had engaged in constructing the relationship and the graph as an emergent trace representing their conceived relationship.

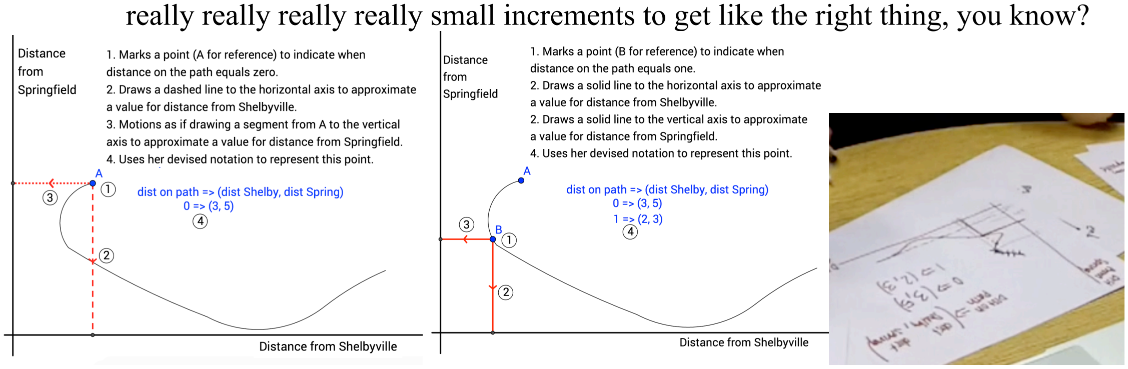
Katlyn spontaneously continued to consider the parametrically defined function. Katlyn wrote "Dist. on Path => (dist. Shelby, dist. Spring)" as a notational system she used to consider specific instances of Homer's distance on the path and the corresponding instances of the two-dimensional output. After labeling the point representing Homer's position on the path at Beg (labeled A for reference in Figure 6a), Katlyn continued (Excerpt 4).

Excerpts 4. Katlyn re-constructs her graph as defined by a parametric function.

Katlyn: So my distance zero on my path [*writes 0 =>, see* Figure 6*a*], and my output, distance from Shelbyville is [*marking a dashed line from A to the horizontal axis, indicated by (2)*] like, um, three. [*laughing*] Whatever, it doesn't matter, and then the distance from Springfield [*motions as if drawing a line from A to the vertical axis, indicated by (3)*], five [*finishes writing 0 => (3, 5)*]. So now I'd say I would start [*pointing to A*] at three five. Then I would do like one [*writes 1 => as seen in* Figure 6*b*]. Pretend that this is one [*tracing along her graph from A to B*].

KM: So by, what do you mean by pretending this is one?

Katlyn: [*pointing to B in* Figure 6*b*] I guess like what, this is like [*pause, points to a position on the road on the computer screen*] one. I don't know, the first portion that I've decided to call one on this purple curve [*using her fingers to indicate an interval starting at Beg along the road in* Figure 5*a*]. This is [*pointing to B in* Figure 6*b*] distance on my path, I've traveled a distance of one on my path then I'm this far away from Shelbyville [*drawing a solid segment from B to the horizontal axis, indicated by (2) in* Figure 6*b*] which is probably like two and then I'm [*drawing solid line from B to the vertical axis, indicated by (3) in* Figure 6*b*] this far away from Springfield which is like [*finishes writing 1 => (2, 3), indicated by (4)*]. And so it makes sense but I'm just like, you'd have to go at like really really really really small increments to get like the right thing, you know?



(a) (b) (c)

Figure 6: (a) and (b) recreations of Katlyn's work and (c) an image of her final work.

As Katlyn conceived of and represented the relationship with a one-dimensional input and two-dimensional output, she created her own notational system for such a relationship. Further, she considered that creating an accurate graph using this definition would require "really really really really small" incremental changes in her input. We note that although she choose specific values for each quantity (e.g., 0 => (3, 5)), to Katlyn the actual values were not critical to her thinking (e.g., "distance from Shelbyville is like, um, three. [*laughing*] Whatever, it doesn't matter"); her reasoning was focused on comparing the magnitudes of the distances from each city with respect to changes in distance on the path and she used fictitious numbers to support her in doing this. Throughout, Katlyn's understanding of the graph as an emergent trace of points representing a coordination of the distance from each city (i.e. a multiplicative object) supported her reasoning parametrically and becoming conscious of this reasoning.

Discussion

In this section we highlight important findings relative to the students' covariational and parametric reasoning. We also relate our findings to existing research on students developing understandings of parameters and parametric functions.

Students' emergent shape thinking

The students developed and maintained images of covariation we interpreted to be compatible with the descriptions of Thompson, Saldanha, and Moore (Moore & Thompson, 2015, in preparation; Saldanha & Thompson, 1998; Thompson, 2011). Specifically, the students' words and actions (e.g., Katlyn saying "we're going this way now" as she traced along her curve recreated in Figure 4), along with their careful attention to the quantities' magnitudes represented along the axes, indicate they imagined their constructed graphs as traces of a point, with the point representing a multiplicative object and the trace involving coordinating two covarying magnitudes.

We highlight the interplay between the mental actions described by Carlson et al. (2002) and the students thinking of graphs emergently. Specifically, the students first constituted the situations in terms of covarying quantities (i.e., at MA1-3 in the Bottle Problem and at MA1-2 in the Car Problem). After conceiving of covarying quantities in the situation, the students represented this relationship using a graph by carefully attending to the quantity on each axis and representing the directions (MA2) and/or amounts of change (MA3) they inferred from their activity constructing the situation. Throughout this process, the students' mental actions (MA1-3) provided a root for the students accurately representing the relationships they conceived. That is, while the students anticipated that their graphs represented emergent traces coordinating two covarying quantities as described by Moore & Thompson (2015), in order to construct an accurate graphical representation they enacted MA1-3 as they constructed relationships with respect to the situation and then enacted MA1-3 in a graphical context in order to construct a graph representing an equivalent relationship.

An intellectual need and explicitly coordinating three quantities

Recall Harel (2007) described, "*intellectual need* refers to a behavior that manifests itself internally with learners when they encounter an intrinsic problem—a problem they understand and appreciate" (emphasis in original, p. 13). We conjecture the students' activities addressing the Bottle Problem raised an intellectual need for parametric functions, a need that we capitalized on with the Car Problem. When addressing water evaporating in the Bottle Problem, the students' activities resulted in their encountering an intrinsic problem: the students came to understand one curve as corresponding to two different experiential situations. This resulted in them seeking to determine how to differentiate between the two situations while using the same completed curve. We conjecture that this intellectual need, which was supported by their emergent shape thinking, was critical to the students considering the parametric nature of the relationships they represented. By understanding one curve as representing two different emergent traces, the students became explicitly aware of their thinking about the curve in terms of two related quantities *and* conceptual time.

When addressing the Car Problem, we interpreted each student's initial activities to indicate her reasoning parametrically about the relationship between Homer's distance from the two cities covarying as Homer's total distance or 'distance on the path' varied. However, the students did not explicitly conceive their graph parametrically until we described a relationship or function with a one-dimensional input and two-dimensional output.

Addressing this question, the students brought to the surface a particular conception of the graph, a graph as an emergent trace, in relation to "function" (i.e. a uniqueness mapping). Both students described such a parametrically defined relationship as representing a function with Katlyn explicitly addressing the novelty of this reasoning (e.g., "I never thought of that as my input, but it really is").

In one study examining students' understandings of parametric functions and parameters, Keene defined dynamic reasoning as "developing and using conceptualizations about time as a dynamic parameter that implicitly or explicitly coordinates with other quantities to understand and solve problems" (2007, p. 231). Arya and Katlyn's reasoning was compatible with Keene's (2007) definition of dynamic reasoning with their initial activities in each problem being compatible with Keene's description of *implicitly* coordinating time with other quantities. Although the students engaged in reasoning that was parametric or dynamic in nature when responding to both tasks, the students did not exhibit activities to indicate they were *explicitly* aware of the parametric nature of their reasoning until they addressed later questions that we designed to focus in this area.

Developing parametric function understandings and the "same graph"

Our data provides evidence that conceiving of and representing relationships between covarying quantities can lead to more formal parametric function understandings. For example, Katlyn's activity addressing the Car Problem indicate how a student who engages in emergent shape thinking and then considers the parametric nature of this reasoning can spontaneously conceive of and use a notation for parametric functions and consider the importance of using small incremental changes of the input to draw an accurate representation of a parametrically defined relationship. Katlyn's activity is compatible with other researchers' findings that indicate students can leverage their quantitative and covariational reasoning to develop foundations for more formal mathematical ideas (Ellis et al., 2015; Johnson, 2012a; Thompson & Carlson, in press).

Related to these findings, Stalvey and Vidakovic (2015) investigated how students conceive an invariant relationship between two simultaneously varying quantities with respect to a third quantity and how this reasoning relates to parametric functions. They were interested in how students might conceive of the rate of change of two quantities as independent from the third quantity (i.e., the parameter). Similar to our prompt involving water evaporating from a bottle, the researchers asked the students to consider water emptying from two identical coolers at different rates to investigate how students might conceive that the rate of change of height with respect to volume is the same regardless of the rate at which water emptied from the cooler.

Stalvey and Vidakovic (2015) presented a genetic decomposition for parametric functions (a model for how an individual might construct an understanding of a specific mathematical concept), which included some features we observed in Arya and Katlyn's reasoning. For instance, Stalvey and Vidakovic described a student imagining a point tracing out a curve in the coordinate system. Further, the researchers' main focus (i.e., the last step of their genetic decomposition) involved students conceiving "a relationship between x and y as invariant" (ibid, p. 193) across two different experiential situations, which is compatible with Arya's and Katlyn's understanding of the graph in Figure 4d as $(h, v) = (h(t_{1\varepsilon}), v(t_{1\varepsilon}))$ and $(h, v) = (h(t_{2\varepsilon}), v(t_{2\varepsilon}))$.

Although our students' activities are compatible with some of Stalvey and Vidakovic's genetic decomposition, our main interest was not on students conceiving of an invariant relationship between the rate of change of height and volume. Instead, our interest was students understanding one graph as being able to represent more than one possible trace. As such, our results provide a contrast to Stalvey and Vidakovic's (2015) genetic decomposition in regards to students' developing parametric function understandings. Specifically, by engaging in emergent shape thinking the students in our study were attentive to the direction they conceived the graph being traced out; these students did not conceive of their graph for water entering and evaporating from the bottle as being "the same" or invariant in that the students understood that these situations resulted in different *emergent*, *progressive* traces.

We note Stalvey & Vidakovic's (2015) interest was in students developing an understanding that the rate of change of two parametrically defined quantities *with respect to each other* does not depend on the parameter and our focus was on students coordinating two covarying quantities without an explicit focus on the rate of change of the two quantities. We conjecture these two foci complement each other. If students first construct and represent different relationships via emergent shape thinking they likely would be better suited to coordinate relative changes of one graphed quantity with respect to the other graphed quantity with the explicit understanding that the rate of change of the two quantities *with respect to each other* does not depend on the parameter. For example, consider two parametric functions, $t \to (x,y)$ and $t \to (u,v)$, $0 \le t \le 2\pi$, such that $(x, y) = (t, \sin(t))$ and $(u, v) = (2\pi - t, \sin(2\pi - t))$. A student who engages in reasoning compatible with Thompson's and Salandha's descriptions of covariation (Moore & Thompson, 2015, in preparation; Saldanha & Thompson, 1998; Thompson, 2011) imagines (x, y) and (u, v) as producing different emergent traces (Figure 7a-c) that result in the same completed graph (Figure 7d). Compatible with Stalvey and Vidakovic's (2015) focus, as the student re-constructs her images of the phenomena and relationships between the quantities, she can choose to consider the relationships between the paired quantities without the parameter t, possibly leading to the student identifying invariances between the relationships defined by $y = f(x)$ and $v = g(u)$ including their respective rates of change. Further, the interplay of these two approaches may lead to students engaging in even more sophisticated and nuanced covariational reasoning (e.g., conceiving in this case as x *increases* from 0 to $\pi/2$, y increases at a decreasing rate and as u *decreases* from $\pi/2$ to 0, v decreases at an increasing rate and produces the same completed graph).

Implications and Future Research

Unlike other researchers who have set out to examine students' understandings of parameters and parametric function in differential equations or calculus settings (Keene, 2007; Stalvey & Vidakovic, 2015; Trigueros, 2004), we intended to examine students' understandings of pre-calculus concepts through their quantitative and covariational reasoning; although this reasoning is parametric in nature (see Thompson, 2011), we did not expect to examine the students developing explicit *parametric* understandings. The fact that the students spontaneously engaged in reasoning that we interpreted as creating an intellectual need for parametric functions has both curricular and research implications.

First, these findings support researchers' conjectures (Carlson et al., 2002; Kline, 1970, 1974; Oehrtman, Carlson, & Thompson, 2008; Smith III & Thompson, 2008; Thompson, 2011; Thompson & Carlson, in press) that curricular approaches providing students opportunities to reason about relationships between quantities can be productive for students' function understandings. Although this report highlighted the students' construction of parametric functions, Arya and Katlyn's activities considering a one-dimensional input and two-dimensional output gives more general insights into the students' function understandings. Each student understood a question about the 'function-ness' of a relationship required explicitly defining input and output quantities then considering if there was a unique output value for each input value. Hence, researchers and curriculum designers might examine how providing students opportunities to construct and represent relationships between covarying quantities can support their developing formal function understandings.

Second, future researchers and curriculum designers might examine how providing students with experiences in constructing graphs as emergent traces can provide foundations for more explicit and formal introductions to parametric functions. For instance, and stemming from the current study ending before we could more extensively pursue the students' reasoning about parametric functions, researchers and educators should further explore how using different situations that result in students constructing and reasoning about the same completed graph via different emergent traces has the potential to create an intellectual need for parametric functions.

Concluding Remarks

Before the onset of the teaching experiment we conjectured that students reasoning about relationships quantitatively and covariationally could be productive for their mathematical learning and set out to further explore students' reasoning in situations we intended to provide them to opportunities to engage in such reasoning. Although we *did not* set out to explore students developing understandings of a particular mathematical concept, the students engaging in reasoning about relationships quantitatively and covariationally led to their constructing, re-constructing, or creating intellectual needs for several content areas typically presented in K-16 school mathematics (e.g., parametric functions, inverse functions, and function more generally).

We find this notable for several reasons. First, this leads us to reiterate researchers' calls (Carlson et al., 2002; Oehrtman et al., 2008; Smith III & Thompson, 2008; Thompson & Carlson, in press) for increased attention to students' quantitative and covariational reasoning in K-16 school mathematics. Second, we highlight that if mathematics education researchers are too strictly focused on students constructing specific content in K-16 school mathematics (e.g., certain function classes), then we as researchers limit our scope to these specific ideas. In such cases, as with Stalvey & Vidakovic (2015), we can construct descriptions that viably explain how someone with a sophisticated understanding of a concept may have developed such an understanding but overlook how students who are novices with these concepts can develop foundational understandings that later support them in developing these more sophisticated understandings (Thompson, 2002). For instance, by focusing on different ways students might conceptualize graphs as emergent traces and the products of such reasoning, we identified students engaging in reasoning that supported them in developing function and parametric function understandings. We conjecture engaging in quantitative and covariational reasoning can support students in developing foundational ideas for other content areas in K-16 mathematics (e.g., coordinate systems, constant and varying rates of change, differentiation) in ways that can be overlooked if we only focus on specific content topics.

Re-claiming: One way in which conceptual understanding informs proving activity

David Plaxco
University of Oklahoma

Abstract: In this research, I set out to elucidate the construct of Re-Claiming - a way in which students' conceptual understanding informs their proof activity. This construct emerged during a broader research project in which I analyzed data from individual interviews with three students from a junior-level Modern Algebra course in order to model the students' understanding of inverse and identity, model their proof activity, and explore connections between the two models. Each stage of analysis consisted of iterative coding, drawing on grounded theory methodology (Charmaz, 2006; Glaser & Strauss, 1967). In order to model conceptual understanding, I draw on the form/function framework (Saxe, et al., 1998). I analyze proof activity using Aberdein's (2006a, 2006b) extension of Toulmin's (1969) model of argumentation. Reflection across these two analyses contributed to the development of the construct of Re-Claiming, which I describe and explore in this article.

Key words: Mathematical Proof, Conceptual Understanding, Abstract Algebra

Mathematical proof is an important area of mathematics education research that has gained emphasis over recent decades. Inherent in the process of proving is the notion that one must validate (or refute) some mathematical relationship that one might not necessarily know before he or she engages in the activity of proving. Each proof involves the statement of a mathematical relationship, which is either intuitively driven or presented to the individual, and the validity of which is either in question or taken as unknown. The individual then sets out to draw on his or her specific notions about the concepts involved in the relationship in order to show that the relationship is valid relative to his or her own mathematical reality, logic, reasoning, and perception of expectations within a mathematical community in which he or she might intend to communicate such proof activity. Once the relationship is validated (or refuted), there is new potential for the prover to begin to incorporate this new relationship into his or her understanding of the concepts involved (perhaps slowly and over time, perhaps quickly and with immediate consequences). In this brief description of the proving process, one might identify two general interactions: the ways in which a prover's current conceptual understanding informs proving activity in the moment and the potential the individual has to alter his or her understanding of the very concepts about which he or she is proving.

The majority of empirical research in proof focuses on individuals' proof production (e.g., Alcock & Inglis, 2008), individuals' understanding of or beliefs about proof (e.g., Harel & Sowder, 1998), and how students develop notions of proof as they progress through higher-level mathematics courses (e.g., Tall & Mejia-Ramos, 2012). Researchers have also generated philosophical discussions that explore the purposes of proof (e.g., Bell 1976; de Villiers, 1990). Much of this latter discussion centers on the explanatory power of proof (e.g., Weber, 2010), with the primary focus being on the techniques and methods involved in a given proof (e.g., Thurston, 1996), rather than the development of concepts or definitions (Lakatos, 1976). Few studies, however, use grounded empirical data to explicitly discuss the relationships between an individual's conceptual understanding and his or her engagement in proof (e.g., Weber, 2005). Rather, research tends to isolate proof as a discipline in-and-of itself – relatively decontextualized from the specific mathematical conceptions the prover brings to bear in a given situation. In this research, I focus on individual students' engagement in Abstract Algebra proofs that involve inverse and identity. Specifically, I seek to investigate the question: "*How might students' conceptual understanding of identity and* *inverse relate to their proof activity?*" In this article, I introduce a construct, re-claiming, that addresses one way in which conceptual understanding informs proving activity. I then provide examples from one participant's interview responses that illustrate the underlying interactions between conceptual understanding and proof activity involved in re-claiming.

Theoretical Frameworks

In this research I operationalize participants' conceptual understanding using Saxe et al.'s constructs of form and function (Saxe, Dawson, Fall, & Howard, 1996; Saxe & Esmonde 2005; Saxe et al, 2009). Throughout the literature, forms are defined as cultural representations, gestures, and symbols that are adopted by an individual in order to serve a specific function in goal-directed activity (Saxe & Esmonde, 2005). Three facets constitute a form: a representational vehicle, a representational object, and a correspondence between the representational vehicle and representational object (Saxe & Esmonde, 2005). Saxe focuses on the use of forms to serve specific functions in goal-directed activity as well as shifts in form/function relations and their dynamic connections to goal formation. Through this framework, learning is associated with individuals' adoption of new forms to serve functions in goal-directed activity as well as the development of new goals in social interaction. Saxe, Dawson, Fall, and Howard (1996) describe how one might think of learning using *form/function* relations, saying, "Mathematical development in the form/function framework can be understood as a process of appropriating forms that have been specialized to serve developmentally prior cognitive functions and respecializing them such that they take on new properties" (p. 126). Accordingly, the *form/function* framework provides an appropriate theoretical framing for investigating the ways that individuals' understanding of identity and inverse relates to their engagement in the goal-directed activity of proving.

Saxe (1999) discusses how a *form* can be schematized as a vehicle for mathematical meaning. This schematization involves a representational vehicle, a representational object, and a semantic mapping (correspondence) between vehicle and object (p. 23). Saxe (1999) goes on to state that, "inherent in the microgenetic act is a schematization of a correspondence between the latent qualities of the vehicle and object such that one can come to stand for the other" (p. 24). He continues, "individuals structure cultural forms … into means for accomplishing representational and strategic goals. This dynamic process allows for the flexibility of forms to serve different functions in activity, in that the same forms may be structured into means for accomplishing different ends" (Saxe, 1999, p. 26). These quotes draw focus toward the ways in which *forms* are able to shift during goal-oriented activity. This aspect of the *form/function* framework informs the focus of the current study by drawing attention to the ways in which participants structure the *forms* and *functions* upon which they draw during proof activity, specifically with regards to the ways in which specific forms might support varied reasoning within different proving contexts.

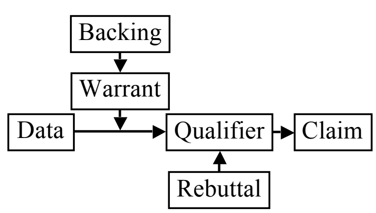

Figure 1. Visual representation of Toulmin models

In order to model participants' proof activity, I use Aberdein's (2006a) adaptation of Toulmin's (1969) model of argumentation. Several researchers have adopted Toulmin's model of argumentation to document proof (e.g., Fukawa-Connelly, 2013). This analytical tool organizes arguments based on the general structure of claim, warrant, and backing. In this structure, the claim is the general statement about which the individual argues. Data are general information, facts, rules or principles that support the claim and a warrant justifies the use of the data to support the claim. More complicated arguments may use backings, which support the warrant; rebuttals, which account for exceptions to the claim; and qualifiers, which state the resulting force of the argument (Aberdein, 2006a). This structure is typically organized into a diagram, with each part of the argument constituting a node and directed edges emanating from the node to the part of the argument that it supports (Figure 1).

Aberdein (2006a) provides a thorough discussion of how Toulmin models might be extended to organize mathematical proofs, including several examples relating the logical structure of an argument to a Toulmin model organizing it. Using "layout" to refer to the graphic organization of a Toulmin model, Aberdein includes a set of rules he to coordinate more complicated mathematical arguments in a process he calls combining layouts: "(1) treat data and claim as the nodes in a graph or network, (2) allow nodes to contain multiple propositions, (3) any node may function as the data or claim of a new layout, (4) the whole network may be treated as data in a new layout" (p. 213). The first two rules are relatively straightforward – the first focuses on the treatment of the graphical layout, as for the second, one can imagine including multiple data sources in the same data node. The third and fourth rules provide a structure for combining different layouts and rely on organizational principles that Aberdein uses. He provides examples of combined layouts (Figure 2).

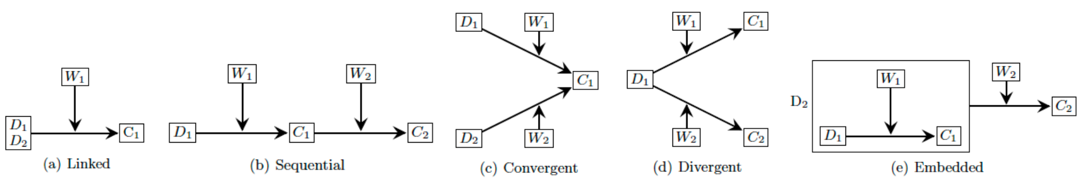

Figure 2. Five Ways of Combining Layouts (Aberdein, 2006a, p.214)

Together, these two theoretical frameworks support the development deeper models of the participants' conceptual understanding and proof activity. Further, juxtaposition of these models, affords more holistic insight into the motivations of participants' proof activity, specifically contextualizing the argumentation that a participant develops in the moment relative to documented consistencies in his or her ways of thinking as well as affording insight into subtle, in-the-moment shifts in the ways that participants draw on and use the very concepts about which they are proving. This directly addresses a student's proof activity as situated relative to his or her conceptual understanding, each of which is treated as an emergent, dynamic facet of the student's mathematical reality. In short, the combined use of these frameworks allows researchers hold both concept and activity as integral and integrated, each continually informing the other throughout the student's proving process.

Methods

Data were collected with nine students in a Junior-level introductory Abstract Algebra course, entitled *Modern Algebra.* The course met twice a week, for seventy-five minutes per meeting, over fifteen weeks. The curriculum used in the course was *Teaching Abstract Algebra for Understanding* (TAAFU; Larsen, 2013), an inquiry-oriented, RME-based curriculum that relies on Local Instructional Theories that anticipate students' development of conceptual understanding of ideas in group theory. Three individual interviews (forty-five to ninety minutes each) took place at the beginning, middle, and end of the semester, respectively. These interviews were semi-structured (Bernard, 1988) and used a common interview protocol so that each participant was asked the same questions as the others. Unplanned follow-up questions were asked during the interview to probe students' descriptions and assertions. The goal for each interview was to evoke the participants' discussion of inverse and identity and engage them in proof activity that involved inverse and identity. I developed initial protocols for these interviews, which were then discussed and refined with fellow mathematics education researchers.

Each interview began by prompting the student to both generally describe what "inverse" and "identity" meant to them and also to formally define the two mathematical concepts. Additional follow-up questions elicited specific details about what the participant meant by his/her given statements, figures, etc. The interview protocol then engaged each participant in specific mathematical tasks aimed to elicit engagement in proof or proof related activity. Each participant was asked to prove given statements, conjecture about mathematical relationships, and describe how he or she might prove a given statement. As with the questions about defining, each of these tasks had planned and unplanned follow-up questions so that all participants were asked at least the same base questions, but their reasoning was thoroughly explored. Throughout the interviews I kept field notes documenting participants' responses to each interview task. I also audio and video recorded each of the interviews, and all participant work and the field notes were retained and scanned into a PDF format. As I shifted to analysis of the data, I narrowed my focus to three of the participants (John, Tucker, and Violet) and transcribed each interview, including thick descriptions of participants' gestures and the timing of pauses in participants' speech.

The retrospective analysis of the three participants' interview responses consisted of three stages, which I ordered so that each stage built upon the previous stages toward a resolution of the general research question. This consisted of an iterative coding process to generate thorough models of the participants' conceptual understanding and engagement in proof and proof-related activity. I analyzed each participant's data separately, coordinating each analysis chronologically so that the model of each participant's conceptual understanding corresponded with his or her proof activity over the semester. I then investigated relationships between each participant's conceptual understanding and proof activity, exploring instances in which meaningful interactions between understanding and activity occurred.

Modeling individual students' conceptual understanding

The form/function analysis for participants' understanding consisted of iterative analysis similar to Grounded Theory methodology (Charmaz, 2006; Glaser & Strauss, 1967). This analysis is differentiated from Grounded Theory most basically by the fact that the purpose of this specific analysis was not to develop a causal mechanism for changes in the students' conceptual understanding, but rather that it was used to develop a detailed model of students' conceptual understanding at given moments in time. For each interview transcript, I carried out an iteration of open coding targeted towards incidents in which the concepts of inverse and identity were mentioned or used. In this iteration, I focused on the representational vehicles used for the representational objects of identity and inverse and pulled excerpts that afforded insight into the correspondence that the participant was drawing between the representational vehicle and object in the moment. Along with the open codes, I developed rich descriptions of the participants' responses that served as running analytical memos. After the open coding, I carried out a second iteration of axial coding using the constant comparative method, in which open codes were compared with each other and generalized into broader descriptive categories. These categories emerged from the constant comparison of the open codes and were used to organize subsequent focused codes until saturation was reached. Throughout this process, I wrote analytical memos documenting the decisions that I made in forming the focused codes and, in turn, providing an audit trail for the decisions made in the development of the emerging categories. This supports the methodology's reliability (Charmaz, 2006).

Modeling proof activity

In the second stage of analysis, I first separated statements that conveyed a complete thought, initially focusing on complete sentences and clauses. I then reflected on the intention of each statement, focusing on prepositions and conjunctions that might serve to distinguish the intentions of utterances that comprise the sentence or clause. Following this, I compared these utterances to the model's constructs, focusing on which node an utterance might comprise. I constantly and iteratively compared each utterance relative to the overarching argument in order to parse out how the utterance served the argument in relation to other statements within the proof. For each proof, I then generated a working graphic organizer (i.e., a figure with the various nodes and how they are connected), including corresponding transcription highlighting the structure of the participant's argument. I then iteratively refined the graphical scheme to more closely reflect the structure of the argument as the participant communicated it. After this process, I completed a final iteration in which I compared the scheme to the participant's communication of the proof in its entirety to ensure that the model most accurately reflected the participant's communication of the proof. An expert in the field then compared and checked the developed Toulmin schemes against transcript of the interview in order to challenge my reasoning for the construction of the scheme, supporting the reliability of the constructions of the Toulmin schemes.

Relating conceptual understanding and proof

During the third and final stage of analysis, I focused on the participants' use of forms and functions within nodes of the Toulmin scheme, comparing the roles that specific forms and functions served in various nodes within the argument. I also focused on the shifts in which the participants' generated new, related arguments, specifically attending to concurrent shifts in forms and functions. I compared across arguments, looking for similarities and differences between the forms upon which the participant drew and the functions that the forms serve within the respective arguments. As in the previous stages, the analysis across conceptual understanding and proof centered on an iterative comparison of the patterns emerging across the analyses of the three participants' argumentation. In this comparison, I noted differences and similarities in the overall structures of Toulmin models for arguments. Further, I attended to the aspects of form/function relations that served consistent roles across similar types of extended Toulmin models. I continuously built and refined hypothesized emerging relationships through constant comparative analysis and memos. Through this process, I characterized constructs that unify the patterns found between the roles forms and functions of identity and inverse served across Toulmin schemes for the three participants.

Results

In this section, I discuss data from Tucker's second (midsemester) interview in order to demonstrate the construct of re-claiming that emerged during the third stage of analysis. I first discuss specific aspects of the form/function model of Tucker's understanding of inverse and identity. These codes of Tucker's conceptual understanding are relevant for discussing selected parts of his response to Question 7 of the protocol, which asked the participants to prove or disprove whether a defined subset H of a group G was subgroup of G (Figure 3). The reader might recognize the set H in question as the normalizer of the element h. This is can equally be thought of as the subgroup of elements that commute with h or the set of elements that fix h under conjugation, as the definition in the problem statement is structured.

Importantly, at the time of the interview, the notions of conjugation and normalizer had not been address in class. The students were familiar with proving whether subsets were subgroups, although, to this point in the semester, this often occurred with specific instantiations of subsets that the students could enumerate, rather than set notational definitions, although the participants were familiar with notation used to define subsets.

"Prove or disprove the following: for a group G under operation * and a fixed element $h \in G$, the set $H = \{g \in G : g*h*g^{-1} = h\}$ is a subgroup of G."

Figure 3. Asking participants to prove about the normalizer of *h*

For the sake of space, I have chosen to share three sub-arguments of Tucker's proof in response to question 7, specifically because they help demonstrate the construct of re-claiming without shifting between different participants' conceptual understanding and proof activity or shifting the focus of mathematical content too drastically. Further, I focus on Tucker's understanding of inverse so that the reader might gain a better sense of how Tucker drew on forms of inverse to serve specific functions in his goal-oriented activity. Tucker's response to Question 7 lasted about 40 minutes and involved several shifts between the three subgroup rules. Because of this, Tucker's proving activity in response to the prompt was modeled with Toulmin schemes for 11 sub-arguments, three of which are discussed in this article. These three sub-arguments provide a glimpse into Tucker's proving process in his effort to show that *H* satisfies the inverse and closure subgroup rules (that *H* contains each of its element's inverse and that the product under the group operation, *, of any two elements in *H* is also an element of *H*).

Form/function codes for Tucker's understanding of inverse

Tucker's discussion throughout the interviews supported the development of several codes for functions of inverse, three of which he used during the parts of his proof activity discussed herein: an "end-operating" function of inverse in which Tucker operates on the same end of both sides of an equation with a form of inverse, a "vanishing" function of inverse in which an element and its inverse are described as being operated together and are removed from an algebraic statement, an "inverse-inverse " function of inverse characterized by an element serving a function of inverse in relation to its inverse, and an "inverse of a product" *function* of inverse in which the inverse of a concatenation (or product) of elements is the reverse order of the inverses of those elements (e.g., $(g*h)^{-1} = h^{-1}*g^{-1}$) . Throughout his proof activity in these excerpts, Tucker draws on the "letter" form of inverse to serve these functions. Although these functions of inverse are consistent with ways inverses are typically used in formal mathematics, Tucker drew on these functions with varying fidelity to their formal treatment depending on the problem contexts in which he was engaged. Tucker continually demonstrated that he was able to use the "letter" form of inverse to serve these functions of inverse in order to appropriately manipulate equations and maintain logically consistent equations. When considering these functions of inverse relative to the Toulmin models of Tucker's proof activity, the functions tended to serve as warrants within Sequential layouts, connecting equations (serving as data) to logically equivalent equations (serving initially as a claim, then as data for the next claim in the sequence). This is evident in two of the three sub-arguments discussed in this article.

Proving that *H* satisfies the inverse subgroup rule

As mentioned, I will discuss three sub-arguments of Tucker's proof that help to explicate the construct of re-claiming. During his response to Question 7, Tucker read over his work saying, "I- you know what I might do actually?" (line 1078). He then explained

So, right now, we have *g* star *h* star *g* inverse is equal to *h*. We want to get to somewhere that looks like- … Want to show. *g* inverse star *h* star *g* is equal to *h*. In order for the inverse of *g* to satisfy this (points to definition of *H*) right here. Cause that's what you do when you put in the *g* inverse. (lines 1084-1086).

With this excerpt, Tucker began a subargument (Figure 4) of his broader, overarching proof for Question 7 in which he attempted to show that the set *H* contains the inverse of each of its elements. He began with the equation used to define *H*, saying, "right now, we have *g* star *h* star *g* inverse is equal to *h*" (line 1085), which serves as initial data (Data1.1) for the argument. He then described wanting to show that $g^{-1}*h*g = h$, which serves as the claim in the subargument (Claim1). He supported this claim by explaining that this goal means that g^{-1} satisfies the given equation, saying, "Cause that's what you do when you put in the *g* inverse" (line 1087). This warrants the claim by reflecting Tucker's previous activity in which he replaced *g* in the equation used to define *H* with its inverse and drew on the "inverse-inverse" function of inverse to rewrite the equation ($g^{-1}*h*g = h$). Although he had discussed the need to show that the set *H* satisfies the inverse subgroup rule earlier in his response, this the first time during his response that Tucker outlined a plan for demonstrating that the set contained inverses. This constitutes a shift in Tucker's description of what it would mean for the set *H* to contain inverse elements. Specifically, he anticipates manipulating the definition of *H* to result in the same equation he had obtained by substituting g^{-1} into the definition of *H*.

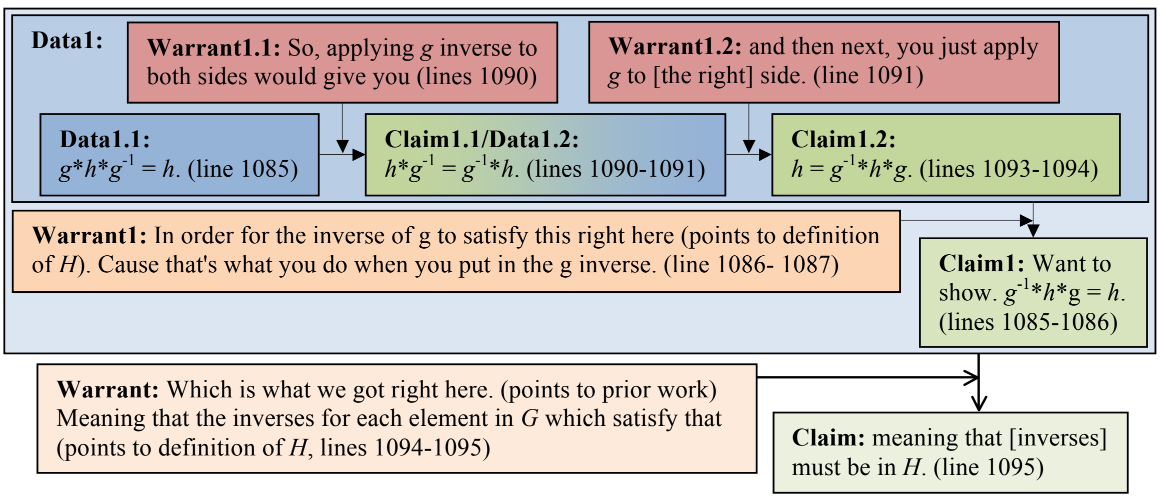

Figure 4. Tucker's inverse subproof in response to Interview 2, Q7

Tucker then continued, explaining how he might manipulate the first equation so that it looks like the second equation. Tucker began by left-operating with g^{-1}, saying, "let's apply the *g* inverse to that. So, applying g inverse to both sides would give you *h* star *g* inverse is equal to *g* inverse star *h*" (Warrant1.1, lines 1089-1091). This process comprises a warrant that draws on the "end-operating" and the "vanishing" functions of inverse to support the claim that a new equation (Claim1.1/Data1.2) can be produced. This equation then serves as data as Tucker describes right-operating with *g* to produce the equation $h = g^{-1}*h*g$ (Claim1.2). Similar to the left-operation with g^{-1}, this draws on the "end-operating" and "vanishing" functions of inverse to warrant the new claim. However, this action also subtly draws on the "inverse-inverse" function of inverse in that Tucker is using the element g as the inverse of its own inverse in order to cancel the g^{-1} on the right end of the left-hand side of the equation. Tucker then interpreted the result of this activity, saying, "Which is what we got right here. Meaning that the inverses for each element in *G* which satisfy that (points to definition of H), mean that must be in H" (lines 1093-1095), which comprises a warrant and claim for the overarching argument that H contains the inverses of its elements.

Tucker's work in this instance exemplifies the construct of re-claiming (Figure 5), which I define as the process of reframing an existing claim in a way that affords an individual the ability to draw on a specific form and the functions that it serves in meaningful (to the student) ways to support the new claim, which the student is then able to connect back to the original claim. In this study, it was often the case that re-claiming occurred when a participant was asked to prove or disprove a general statement and, in response, interpreted the general statement using a specific form to produce a new claim in terms of this form. For instance, in this example, Tucker substituted the "letter" form of inverse into the definition of H to produce the equation $g^{-1}*h*g = h$. An important part of successfully re-claiming is the consistency between the original claim and new claim. In this case, Tucker's new claim successfully reflects the assumption that g^{-1} satisfies the definition of the set H. The individual must also be able to interpret any possible hypotheses or assumptions of the original claim with respect to the new form upon which he or she draws. Again, Tucker successfully uses the assumption that g satisfies the definition of H and uses this as initial data in his construction of an argument. Once the individual generates appropriate initial data from the given hypotheses and assumptions, he or she is then able to draw on the new form to serve specific functions, which affords the development of meaningful argumentation toward the new claim. The various functions of inverse that Tucker was able to draw on to manipulate the equation in the initial data allowed Tucker to produce meaningful connections between the initial data he generated and his re-claimed claim. Finally, after supporting the new claim, the individual should be able to provide a warrant for how or why this claim supports the original claim.

Proving that *H* satisfies the closure subgroup rule

Among the other sub-arguments that Tucker generated during his response to Question 7, he produced two sub-arguments to show that H satisfies the closure subgroup rule which also help demonstrate re-claiming. Tucker describes this subgroup rule, saying, "[we] have to prove that all of those star themselves will yield you back another one" (line 762), which constitutes Claim of this sub-argument (Figure 5). He follows this by describing his approach, saying,

> *a* be an element of *H* and *b* be an element of *H*, then by definition of the set, *a* star *h* star *a* inverse is equal to *h* and *b* star *h* star *b* inverse is equal to *h*. And it looks like we can just, like, set these equal to each other. So, *a* star *h* star *a* inverse is equal to *b* star *h* star *b* inverse. See, what we're trying to do here is prove that *a* star *b* is also in *H* to prove that there's closure. That's what you've got to do to prove closure. So- In order to prove- I'm just gonna write this out. Trying to show that *a* star *b* is an element *H*, which means *a* star *b* (mumbles, writing) - I'm just gonna need to write star between that - star *h* star *a* star *b* inverse is equal to *h*. So that's what we gotta, um, we need to prove. Um- Okay. I think it would be easiest to rearrange (points to $a*h*a^{-1} = b*h*b^{-1}$) this so that we get that (points to $(a*b)*h*(a*b)^{-1}$ = h). Hm. That's a good question. I don't know how we're supposed to do that, though. (lines 764-775)

This excerpt provides transcript of the entirety of this sub-argument, except for Tucker's initial claim. Notice that Tucker begins by fixing two elements of H, a and b. These serve as initial data (Data1) in a sequence in which Tucker draws on the definition of the set to warrant (Warrant1) the generation of two equations: $a*h*a^{-1} = h$ and $b*h*b^{-1} = h$

(Claim1/Data2). These equations then serve as data in order for Tucker to generate a third equation ($a*h*a^{-1} = b*h*b^{-1}$) comprised of the left-hand sides of the first two equations set equal to each other, serving as a second claim that is warranted by the phrase “it looks like we can just set these two equal to each other” (lines 766-767). Together, these data, warrants, and claims follow the structure of a sequential argument that serves as data that Tucker indicates should eventually support the claim that the element $a*b$ must satisfy the equation used to define H.

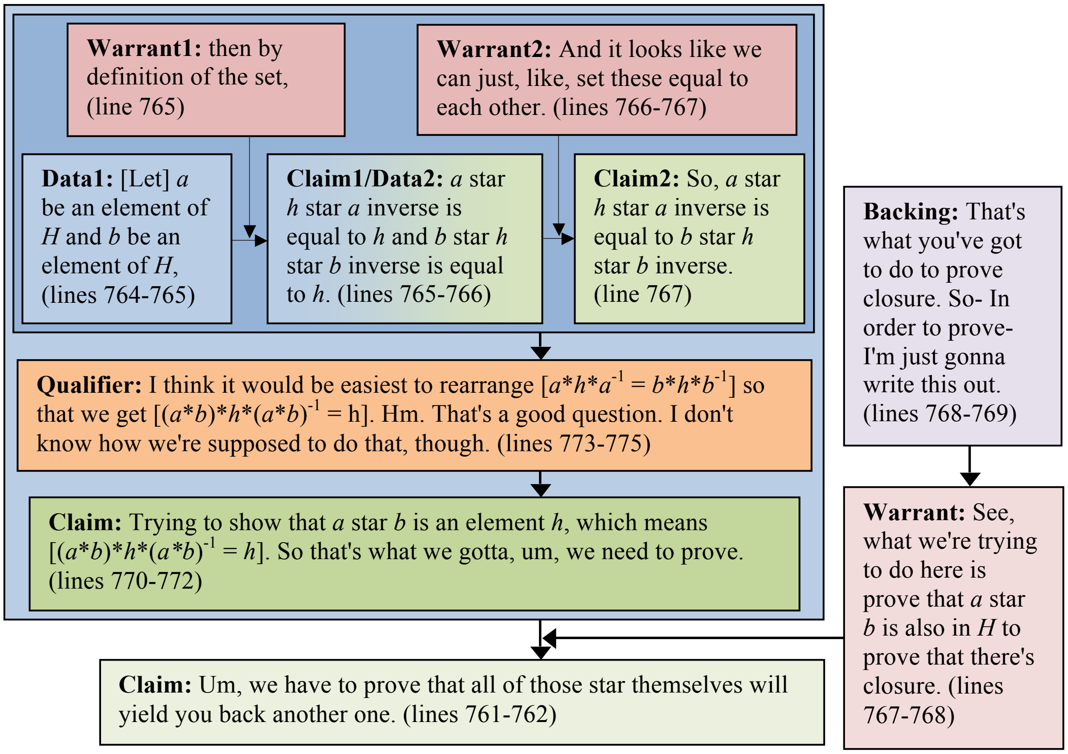

Figure 5. Tucker’s first closure sub-argument in response to Interview 2, Q7

Tucker follows this initial sequential argument by rephrasing the original claim to reflect the definition of the set H. Specifically, similarly to Claim1/Data2, Tucker replaces g and g^{-1} with the algebraic statement “($a*b$),” yielding the equation “$(a*b)*h*(a*b)^{-1} = h$.” This shifts the goal of the proof from a more general description of closure to an algebraic framing that reflects the data that Tucker has produced. He then provides a series of statements that qualify, warrant, and back the embedded argument to support this new claim. First, he alludes to rearranging the equation “$a*h*a^{-1} = b*h*b^{-1}$” to “get that” while pointing to the written “$(a*b)*h*(a*b)^{-1} = h$,” but admits that he is unsure how he might do this, which qualifies his argument. Tucker then provides a warrant for how his data might serve the claim that elements in H satisfy closure, saying, “See, what we're trying to do here is prove that a star b is also in H to prove that there's closure” (lines 767-768). He adds, “That's what you've got to do to prove closure. So- In order to prove- I'm just gonna write this out” (lines 768-769), which serves as backing for this warrant. Tucker’s argument then stalls as he again expresses his uncertainty in the qualifier, saying, “This is a little trickier. I'm open to suggestions here” (line 784). At this point, Tucker has reframed the original claim that he has set out to prove and generated an equation that might serve as initial data in this argument, but reaches an impasse as he is unsure how he might be able to connect the two equations.

Later in his response to Question 7, Tucker returned to the closure subgroup rule, making a new sub-argument (Figure 6) to show that H satisfies the closure rule. Tucker initially indicated that he is still unsure of how to prove that the set satisfies closure. When asked what tools he could use, Tucker replies, "existence of inverses and identity. I don't know" (line 1148). The interviewer reminds Tucker that associativity holds and suggests, "Or you could just un-group stuff" (line 1154). This likely provided Tucker with some insight into a possible approach to the proof, as he said, "And, like, kinda like modify this right side as well, or- (4 seconds) Okay, so, if we bring that over-" and began writing. He then began this sub-argument by saying, "So, we know that a works and b works" (line 1163), which serves as the first data (Data1) in support of the claim, "We wanna show that $a*b$ works" (line 1164, Claim). It is likely that Tucker is using the word "works" here to indicate that they satisfy the definition of H. This sense is supported by Tucker generating the equations $a*h*a^{-1} = h$ and $b*h*b^{-1} = h$. Tucker then provides an argument that reflects his anticipated goal in the qualifier of the prior sub-argument, which he had described, saying, "I think it would be easiest to rearrange [$a*h*a^{-1} = b*h*b^{-1}$] so that we get [$(a*b)*h*(a*b)^{-1} = h$]" (lines 773-774).

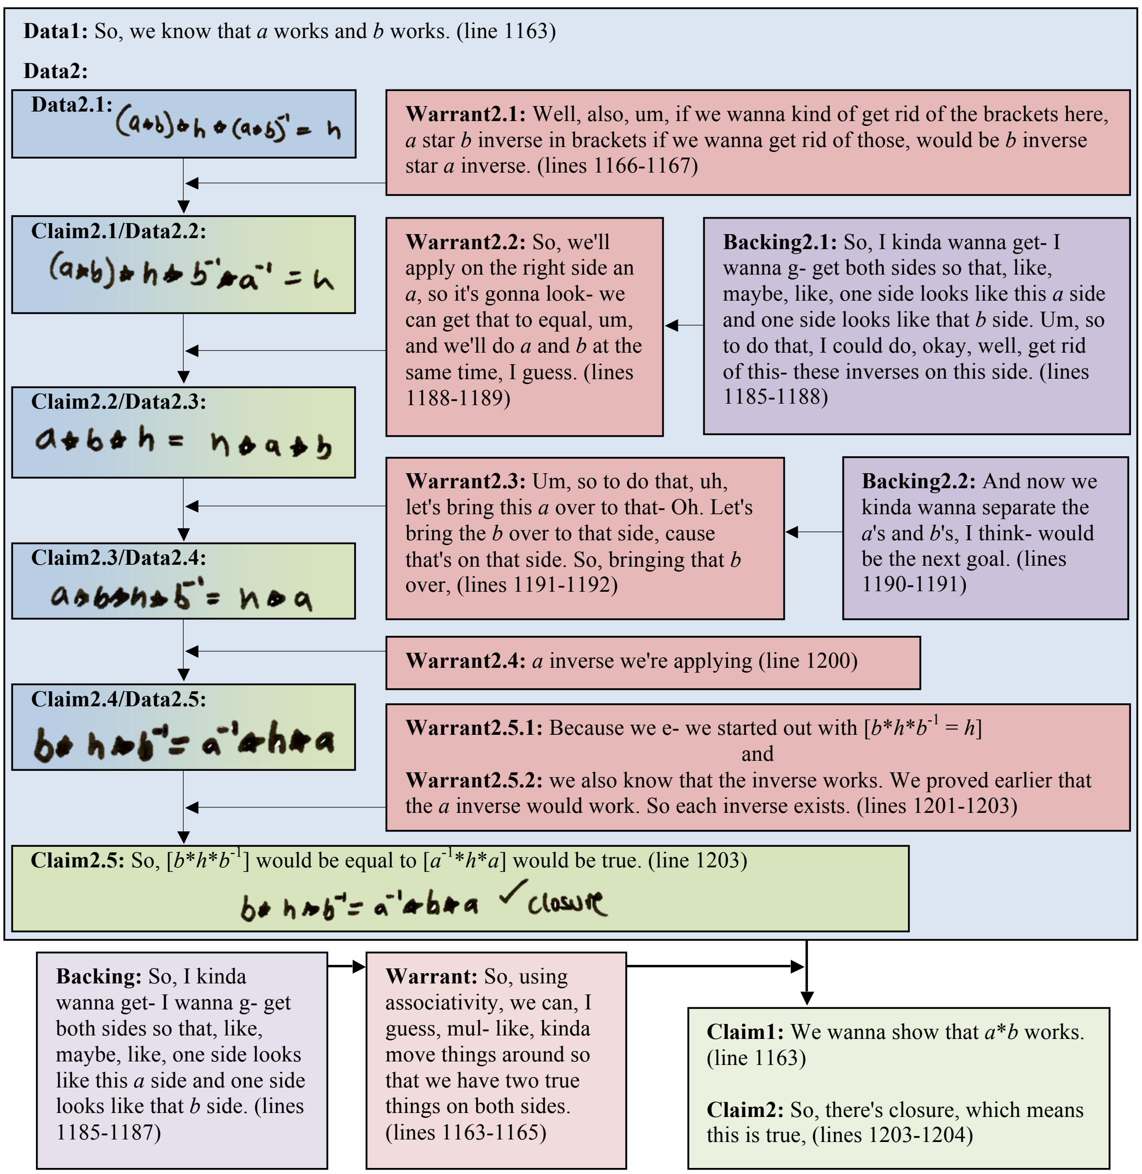

Figure 6. Tucker's second closure sub-argument in response to Interview 2, Q7

Tucker describes how he expects to approach the proof, saying, “So, using associativity, we can, I guess, mul- like, kinda move things around so that we have two true things on both sides” (lines 1163-1165), which serves to warrant Tucker’s re-claiming. He then draws on the “inverse of a product” function of inverse (Warrant2.2) to support rewriting the equation $(a*b)*h*(a*b)^{-1} = h$ (Data2.1) as $(a*b)*h *b^{-1}*a^{-1} = h$ (Claim2.1/Data2.2). Tucker draws on this new equation to serve as data for developing yet another equation, first backing his activity by describing his reasoning for changing the equation, saying,

> So, I kinda wanna get- I wanna g- get both sides so that, like, maybe, like, one side looks like this *a* side and one side looks like that *b* side. Um, so to do that, I could do, okay, well, get rid of this- these inverses on this side. (lines 1185-1188)

This supports a strategy that it seems Tucker anticipates helping to eventually generate the desired equation. Tucker generates the new equation by drawing on the “end-operating” and “vanishing” *functions* of inverse to simultaneously remove the a^{-1} and b^{-1} from the right end of the left-hand side of the equation and concatenate a and b on the right end of the right-hand side of the equation, resulting in the new equation $a*b*h = h*a*b$ (Claim2.2/Data2.3). In doing so, he warrants his activity by saying, “So, we'll apply on the right side an a, so it's gonna look- we can get that to equal, um, and we'll do a and b at the same time, I guess” (lines 1188-1189).

Tucker continues by drawing on the same *functions* of inverse to remove the b that he had just concatenated on the right-hand side of the equation and concatenate b^{-1} on the left-hand side of the equation, essentially undoing part of his activity in which he generated the equation in (Claim2.2/Data2.3). He explains,

> And now we kinda wanna separate the *a*'s and *b*'s, I think- would be the next goal. Um, so to do that, uh, let's bring this *a* over to that- Oh. Let's bring the *b* over to that side, cause that's on that side. So, bringing that *b* over… (lines 1191-1192)

This serves as warrant and backing for Tucker to generate the equation $a*b*h*b^{-1} = h*a$ (Claim2.3/Data2.4). Tucker immediately follows Claim2.3 by saying, “a inverse we’re applying” (line 1200), which warrants the equation $b*h*b^{-1} = a^{-1}*h*a$. Throughout this entire data-warrant-claim sequence, new equations are generated by Tucker’s manipulation of the previous equation, drawing primarily on the “end-operating” and “vanishing” *functions* of inverse, the “inverse of a product” *function* of inverse, and also, implicitly, the “inverse-inverse” *function* of inverse. Having generated the equation $b*h*b^{-1} = a^{-1}*h*a$, Tucker interprets his work, saying, “…we started out with this and we also know that the inverse works. We proved earlier that the a inverse would work. So each inverse exists. So, that would be equal to that would be true. So, there's closure, which means this is true” (lines 1201-1204). In the first part of this excerpt, Tucker provides two warrants (Warrant2.5.1, Warrant2.5.2) that support the claim that the equation $b*h*b^{-1} = a^{-1}*h*a$ is true, seemingly drawing on the equation $b*h*b^{-1} = h$ in Data1 and his prior sub-argument showing that H satisfies the inverse rule for subgroups, which supports the equation $h = a^{-1}*h*a$. However, Tucker does not explicitly draw on these two equations or any sense of transitivity, instead saying “we started out with this” (lines 1201-1202) while pointing to the statement $b*h*b^{-1}$ and “a inverse would work. So each inverse exists” (lines 1202-1203), while pointing to the statement $a^{-1}*h*a$. Tucker finally concludes, “So, there’s closure, which means this is true” (lines 1203-1204, Claim2).

In this sub-argument, Tucker’s re-claiming activity is slightly different from the prior sub-argument. As before, Tucker begins by drawing on a specific form of inverse to reframe the original claim that H is closed under the operation (*). He also generated initial data from the hidden hypotheses of the original claim (considering two elements that are elements of H; Data1). However, the data that Tucker chooses to manipulate in order to reach some conclusion in the Embedded, Sequential Toulmin scheme is the assumption that $a*b$ satisfies the definition of H. He then develops a chain of reasoning that leads back to an equation that Tucker recognizes as verifiably valid based on his assumption in Claim1 that a and b each satisfy the definition of H. This reflects a not-uncommon proof approach in which the prover assumes the result that he or she intends to show and deductively shows that the result is equivalent to the assumption(s) he or she is able to make about the conjecture. Still, Tucker's activity reflects a type of re-claiming in which he was able to draw on a specific form to generate a new claim and initial data. From this claim and data, Tucker leveraged specific functions of inverse to demonstrate that the initial data and new claim were logically equivalent. Tucker's work is warranted by his initial claim that he would try and generate and equation that was true from his assumption that $a*b$ satisfied the definition of H.

Conclusions

This discussion of Tucker's proof activity should afford a sense of the various facets involved in re-claiming. Specifically, in re-claiming, it is not sufficient, to only reframe a claim. Rather, one must likely also reframe its related (often hidden) hypotheses. These aspects of reclaiming reflect the frequently taught proof mantras of "what do I know?" and "what do I want to show?" In this case, Tucker describes needing to show that $g^{-1}*h*g = h$ and begins with the equation $g*h*g^{-1} = h$, which reflects the assumption that g satisfies the definition of H. In the context of the form/function framework, these restated hypotheses serve as initial data (drawing on a specific form of identity or inverse) in a new argument in which the participant is able to draw on the form of identity or inverse with which the data is reframed to serve appropriate functions of identity and inverse in support of the new claim. The individual should then be able to reason that this new argument supports the original claim. In this sense, Re-Claiming provides a type of proof activity in which an individual's conceptual understanding (forms upon which an individual draws and the functions that these forms are able to serve) informs his or her proof approach. Specifically, the access to a form that is able to serve specific functions affords the individual an opportunity to generate a meaningful argument that he or she would likely not have been able to produce without Re-Claiming the initial statement. This activity is not necessarily an inherent necessity of a given conjecture, but rather depends on the individual's understanding in the moment.

The current research was constrained by several factors. First, my focus on three students' responses to individual interview protocols limits analysis of the relationships between conceptual understanding and proof activity, warranting further analysis of different participants' conceptual understanding and proof activity. Also, although this analysis was informed by the broader contexts of the classroom environment, the focus on the individual interview setting affords insight into a specific community of proof in which argumentation develops differently than in other communities. For instance, the structure of the interview setting necessitated that participants developed their arguments solely relying on their own understanding in the moment and for the audience of a single interviewer. My early observations of and reflections on the development of argumentation in the classroom and homework groups included the mutual development of argumentation in which participants' argumentation was informed by their interactions. Accordingly, analysis of the other collected data is warranted.

This research contributes to the field by drawing on the form/function framework to characterize students' conceptual understanding of inverse and identity in Abstract Algebra.

This affords insight into the forms upon which students participating in the TAAFU curriculum might draw as well as the various functions that these forms are able serve. The broader research also contributes to the field by providing several examples of how Aberdein's (2006a) extension of Toulmin's (1969) model of argumentation might be used to analyze proofs in an Abstract Algebra context. Further, this research draws attention to an aspect of the relationships between individuals' conceptual understanding and proof activity. These results situate well among the work of contemporary mathematics education researchers. For instance, Zazkis, Weber, and Mejia-Ramos (2014) have developed three constructs that also draw on Toulmin schemes to model students proofs in which the researchers focus on students development of formal arguments from informal arguments. These constructs provide interesting parallels with the three aspects of relationships between conceptual understanding and proof activity developed in the current research. Zazkis, Weber, and Mejia-Ramos (2014) describe the process of rewarranting, in which an individual relies on the warrant of an informal argument to generate a warrant in a more formal argument. However, the current research focuses more on the aspects of conceptual understanding that might inform such activity.

Moving forward from this research, I intend to analyze the data from other participants' individual interviews in order to develop more form and function codes for identity and inverse, affording deeper insight into the various form/function relations students in this class developed. Such analysis should also explore the proof activity of the other participants in the study, which would provide a larger sample of proof activity, in turn affording new and different insights into the relationships between mathematical proof and conceptual understanding. I also intend to analyze the sociomathematical norms and classroom math practices within the classroom. This will afford insight into the sociogenesis and ontogenesis of forms and functions at the classroom and small group levels in order to support and extend the individual analyses – which are focused on microgenesis – in the current research.

Physics students' construction and use of differential elements in an unconventional spherical coordinate system

Benjamin Schermerhorn
University of Maine

John Thompson
University of Maine

As part of an effort to examine students' understanding of non-Cartesian coordinate systems when using vector calculus in the physics topics of electricity and magnetism, we interviewed four pairs of students. In one task, developed to compel students to be explicit about the components of specific coordinate systems, students constructed differential length and volume elements for an unconventional spherical coordinate system. While all pairs eventually arrived at the correct elements, some unsuccessfully attempted to reason through spherical or Cartesian coordinates, but recognized the error when checking their work. Analysis of student work identified actions and aspects of students' concept images when constructing differential vector elements. Findings suggest that attention to multiple components and dimensionality were useful aspects of students' concept image, while students had difficulty appropriately applying the idea of projection.

Key words: Coordinate Systems, Differential Elements, Physics, Vector Calculus

It may seem obvious that the farther a physics student progresses within their degree program the more difficult the mathematical computation becomes, but physics does not employ mathematics as merely a calculational tool. It is equally important for students in upper-division physics courses to reason using mathematics in the development of their physical models when problem solving. Many problems in upper-division courses require students to walk a fine line between physical context and mathematical understanding, only to turn around and carry this mathematical reasoning back across the metaphorical high-wire to make sense of the physical context in which they started. For students in junior-level electricity and magnetism (E&M), this is no easy task. In fact, students in upper-division E&M courses have difficulty setting up appropriate calculations, interpreting mathematical results physically, accounting for underlying spatial situations, and accessing appropriate equations or methods of solutions (Pepper et al. 2012). Thus we see that not only is mathematical understanding important, it is an area of difficulty for many students.

E&M courses expect students to employ knowledge of single-variable calculus, multivariable calculus, and vector calculus. Notably, physics students' exposure to vector calculus and non-Cartesian coordinate systems often occurs in physics courses before these topics are taught in a mathematics course sequence. Physics students typically learn relevant concepts and theorems of vector calculus in their E&M course.[1] The reason for the emphasis on vector calculus instruction is largely due to the need for physics students to use vector calculus as a conceptual reasoning tool, as well as the particular application of vector calculus in non-Cartesian coordinate systems. While infinite sheets or plates of charge can easily be solved with use of a

[1] A greater asynchrony occurs in some introductory mechanics courses, in which mechanical work is defined as a line integral. Many departments have a "mathematical methods for physics" course that surveys a wide range of mathematical concepts and techniques. Still, in many cases vector calculus is taught far later in the course than is needed in a parallel E&M course.

Cartesian coordinate system, symmetries exist in common physical systems that favor other coordinates: point charges, spherical volumes, and spherical shells are more easily thought about in spherical coordinates, just as line charges and problems involving straight wires can be made quick work of with cylindrical coordinates. The choice of a coordinate system is one of the many tasks left to the student when problem solving.

Hand in hand with the choice of a coordinate system, students are expected to use differential line, area, and volume elements, as well as position vectors that describe the locations of charges distributed over volumes, surfaces, and lines, in order to set up appropriate integrals. As many E&M equations involve vector calculus (line and area integrals), differential line and area elements are used as vector quantities and thus have a specific direction, while the volume elements are scalar. The ubiquitous nature of the differential element, coupled with coordinate system confusion, present an area of student difficulty at the boundary of mathematics and physics that is ripe for study.

Related Literature

Various physics education researchers have explored student difficulties with the mathematics applied in Electricity and Magnetism (E&M). Early work addressed student use and understanding of integration (Doughty *et al.,* 2014; Meredith & Marrongelle, 2008; Nguyen & Rebello, 2011). As a part of this work, student understanding of the differential element began to come into focus. Nguyen and Rebello identified student difficulty determining the appropriate differential element when setting up integration, as well as particular difficulty with discerning the meaning of a differential area element (Nguyen & Rebello, 2011). Expanding upon this, later work identified what the differential represented in students' conceptual understanding of integration (Hu and Rebello, 2013). In many cases, students interpreted the differential as an identification of the variable of integration; in these cases the differential possessed no further physical meaning. This work highlights the fact that many students often disregard the true meaning of differential when performing calculations and is a common finding in the literature (Artigue *et al.,* 1990; Jones, 2013; Nguyen & Rebello 2011; Sealey & Thompson, 2016).

Little other work has looked at student understanding of differentials in a multivariable or vector calculus setting, where differentials have particular meaning in regards to a specific path of motion or area over which a flux is taken. As part of a larger paper detailing the many student difficulties in E&M, Pepper and colleagues found that students had difficulty articulating complex symmetry arguments and noted student mistakes with differential elements during a homework help session (Pepper *et al*., 2012). One group incorrectly wrote a spherical differential area as $da = d\theta d\phi$, without the necessary $r^2 \sin\theta$ scaling factor needed to make it an appropriate area. Another group used $dxdydz$ as a length element when calculating a line integral and became confused when they recognized that this possessed features of a volume. These types of errors are consistent with both a limited understanding of the differential and difficulties reasoning mathematically when accounting for the underlying spatial situations./

Physics education researchers have identified difficulties in student understanding when applying Gauss's and Ampère's Laws, two key equations of E&M courses that involve a surface integral and line integral, respectively (Guisasola et al., 2008; Manogue et al., 2006; Pepper et al., 2012; Wallace & Chasteen, 2010). Much of this work has looked at how students recognize and apply specific symmetries, due to the constraint of these problems requiring highly symmetric cases. The need for symmetry comes from the "inverse nature" of both laws (Manogue *et al*., 2006); rather than attempting to solve the line or area integral to obtain a result, students must make arguments about the direction and magnitude of the electric and magnetic fields, in order to extricate the field terms from the dot product and integral. Other work in vector calculus has looked at how students have addressed calculation, understanding, and application of gradient, divergence, and curl in both mathematics and physics settings (Astolfi and Baily 2014; Bollen *et al*., 2015). In particular it was found that while students were adept at mathematical calculation, they had little ability to reason physically about gradient, divergence, and curl when applied to vector fields.

When it comes to the teaching and mathematical application of vector calculus, Dray and Manogue highlight numerous disciplinary conventions that can hinder students understanding (Dray and Manogue 1999; 2003; 2004). In particular, the lack of standardization of cylindrical, and spherical coordinates is of significant concern (2003). In mathematics courses, beginning with the introduction of two-dimensional polar coordinates, θ is typically used as the azimuthal angle (rotating about the z-axis). When moving to a three-dimensional coordinate system, it is common practice for mathematicians to use ϕ as the polar angle (measured from the z-axis). In physics the roles of the angles are swapped, with θ as the polar angle and ϕ the azimuthal angle. While the authors do not highlight any student work in particular, results from work published in 2010 looking at students abilities to write $\vec{r}$ in spherical coordinates for six points, each located on a Cartesian axis, touched upon this as a student difficulty (Hinrichs, 2010). Of 28 volunteers, no student was able to correctly answer the original question by writing $\vec{r} = r\hat{r}$, and only slightly fewer than half of the students were able to write the correct r, θ, and ϕ for each point. The most common mistakes were with the writing of the angles, with 20% of the total switching the values for θ and ϕ. While disciplinary conventions can be an obstruction to student understanding early in the course, even when these are addressed, students can still have difficulty constructing these differential elements.

Research Design and Methodology

The overarching goal of this study is to address student understanding and use of vector calculus in upper-division physics. By the end of the first semester of a year-long, junior-level E&M sequence, students are expected to have a working knowledge of spherical coordinates. As part of instruction in the course, students are taught how to build each term of a differential length element, a procedure replicated in the course textbook (Griffiths, 2013). The majority of the following semester is then spent using this coordinate system (as well as cylindrical and Cartesian coordinate systems) in particular problems. This involves making determinations of differential elements to use in integration and construction of position vectors.

Given the importance of these differential elements and different coordinate systems to the calculations, the current focus of the research seeks to address the following questions:

- How do students make sense of and work with coordinate systems, specifically cylindrical and spherical coordinates?
- How do students construct differential vector elements in a given coordinate system?

In order to address these questions further clinical think-aloud interviews were conducted with pairs of students (N=8) at the end of the first semester of a year-long, junior-level E&M sequence. Pair interviews allowed for a more authentic interaction and sharing of ideas between students with minimal influence from the interviewer. This report focuses on a task based on an unconventional spherical coordinate system (see Figure 1). Students were asked to conclude whether the system was feasible, and to build and verify the differential line and volume elements. As students work through these tasks, we are able to see how they reason about the differential elements in a specific coordinate system, thus giving insight into the choice and use of these elements in their problem solving.

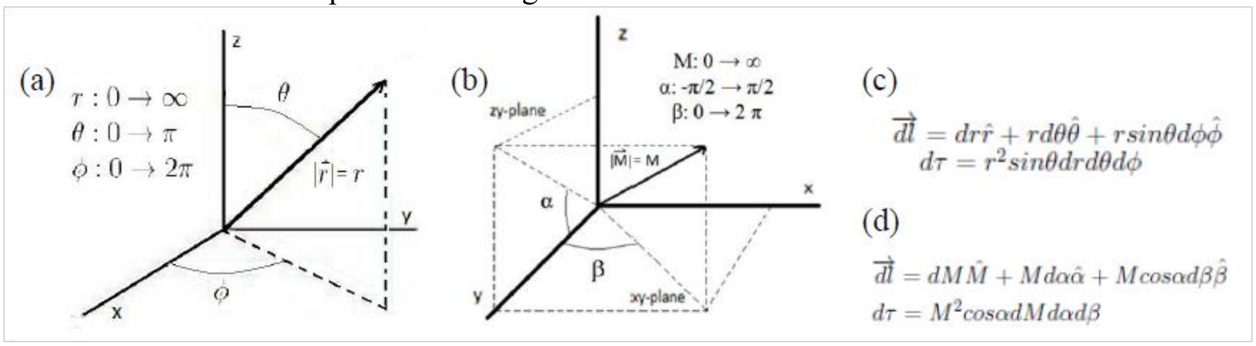

Figure 1. (a) Conventional (physics) spherical coordinates; (b) an unconventional spherical coordinate system given to students, for which they were to construct differential length and volume elements. The correct elements for each system are in (c) and (d), respectively.

The unconventional system, schmerical coordinates, is left-handed and depicts both angles as measured from the y-axis. The left-handed nature allows us to determine if any Cartesian elements presented by students are the result of recall or accurate (but unnecessary) projections. This also means β is placed differently than the analogous φ in spherical coordinates while not changing the length element. Likewise, the placement of α is different than θ. It should be noted that by symmetry and arguments based on the range of the angles, α can also be placed between the vector **M** and the xy-plane. The variation in the placement of the angles from spherical coordinates requires students to recall and use various techniques of building differential elements.

The theoretical framework we adopted for this preliminary stage of the study is that of *concept image* and *concept definition* (Tall and Vinner 1981). A student's concept image represents that student's entire cognitive structure about a particular idea, including any properties, processes, and mental pictures a student may recall. Unlike the actual concept definition, the concept image is a dynamic construct dependent upon specific contexts and may contain elements that are contradictory or false. The idea of concept image has recently been adopted by physics education researchers studying student use of mathematics, particularly in the context of vector differential operators and integration in electromagnetism courses (Bollen et al., 2015; Doughty et al., 2014).

A relevant framework from the physics education research literature is that of *resources* (Hammer, 2000), which is an extension of diSessa's knowledge-in-pieces framework (diSessa, 1993). These frameworks consider the elements of knowledge used in student problem solving in physics. More recent work has extended these to include reasoning elements and epistemological perspectives in the context of using mathematics in introductory physics (Tuminaro & Redish, 2007) as well as mathematical procedures in more advanced physics (Wittmann & Black, 2015).

We are limiting our analytical framework here to that of concept image; it is the more prevalent in the mathematics domain, which is where this work is situated. Future efforts will reconcile this framework with the resources model and possibly align the two frameworks for interdisciplinary work.

With the concept image framework in mind, each interview was videotaped and transcribed for analysis using modified grounded theory (Strauss & Corbin, 1998; Bryant & Charmaz, 2007). The tasks administered here provided us with views of students' concept images of the differential length and volume elements. We also used the activity of element construction to observe the aspects of the concept images presented in student discussion. Analysis of student responses to the unconventional coordinate system allows us to develop a clearer picture of student understanding, as well as specific student difficulties (Heron, 2003) and successes when working with coordinate systems that they apply to particular problems throughout the semester.

Results

In addressing the feasibility of the unconventional coordinate system, all students correctly determined that schmerical coordinates would allow one to map any point in space. Students also made the determination that the unconventional system would be useful for solving the same types of problems as spherical coordinates. The similarity to spherical coordinates was challenging for some students, but upon recognizing that α and θ covered the same range of π radians, students recognized the similarity of the systems.

Following a decision on the feasibility of the system, students were asked to construct a differential length element for the system. Analysis of students' concept images has allowed us to identify four particular aspects that students associate with and use when constructing a differential element as part of our interviews. Table 1 defines each aspect and provides an example of how students attended to and drew upon these aspects during construction.

Aspects	Explanation	Example 1	Example 2
Component & Direction	Writing sum of terms Each component displaced independently	(67) F: Yeah, so like there, dl, there are **three different dl's**. There is dl with respect to M, dl with respect to a, α, and dl with respect to β…	(67) F: …you can change M and you can change α and you can change β, but **if you change α the effects are different from if you change β or you change M.**
Dimensionality	Units of length in each term	(28-30) A:… This **doesn't have any units of length**…so, it needs to have **some M term**.	(89) C:…but **sine** of something **isn't a length,** so we're going to have to also have **something else in there.**
Differential	Small changes (of displacements)	(74) C: Right. So you have **a change in your $\hat{M}$** is going to be your **dM, it's your change in your M**.	(147) E: …ok, **dl_α, so that means we're moving a little bit in α** so we need the r, that's that, there and then times a little α, $d\alpha$.
Projection	Use of cosine/sine explicitly (not rote recall)	(90-92) D: I mean, it's like $M\cos\alpha$ **would put us where we're… down** in the B hat range.	(273) E: …but if we're pointed way up here, then **we need to take the cosine** so that we're, we have the **component of r that is actually in the β plane**, and then we can move a $d\beta$ length amount...

Table 1. Examples of the four aspects identified from student work when building differential length elements in the interviews.

The *component and direction* aspect involved students' attention to the summation of three different components as well as the idea that each component of the vector equation is displaced independently. Many of the students placed emphasis on the aspect of *dimensionality,* specifically attending to the need of each component to have units of length. Students used the aspect of *differential* to talk about needing small displacements or changes in specific directions. Due to the nature of the coordinate system, the aspect of *projection* (obtaining a component of a vector in a particular plane) is relevant to appropriately explain the need for a $\cos\alpha$ in the β-component. However many students did not apply this last aspect to their construction.

In addition to identifying necessary concepts for building there were several actions that students took during the interviews: *rote recall* of length elements from other systems*; mapping* of the variables to spherical or Cartesian; and *grouping* of elements, typically based on variable. *Grouping* as we identify it here is distinguishable from the grouping resource identified by Wittmann and Black (2015), where terms in a differential equation are combined into a single new term. We highlight instances where students engaged in these actions in Table 2.

Actions	Explanation	Example
Grouping	Combining elements by like variables or terms	(47) H: You've got $rdr\,\hat{r}$ plus, **is it sin $\boldsymbol{\theta\ d\theta}$ or is there an $\boldsymbol{r}$ in there?**
Mapping	Direct matching of variables from existing coordinate system	(35-37) B:...so now we have just to compare so we have $\boldsymbol{r}$ **it is $\boldsymbol{M}$, $\boldsymbol{\theta}$ is $\boldsymbol{\alpha}$=...=$\boldsymbol{\varphi}$ is $\boldsymbol{\beta}$.**
Rote Recall	Writing elements from Cartesian or spherical	(112-116) G: **dτ in spherical** is r^2 $sin\theta$=... =$d\theta$ dr=...=$d\varphi$

Table 2. Examples of identified actions taken by students when constructing differential length elements in the interviews.

Students application of recall and mapping versus building of length terms

Each group of students appeared to approach the problem in different ways. Some attempted to reason about the length elements through direct mapping from spherical or Cartesian coordinates. Whether a student chose to build the differential length element from the necessary concepts and ideas or recalled ideas from memory provided insight into how students approach multivariable differential elements in integration in E&M.

When asked to construct a differential length element, the graduate students (A and B) each initially took a different approach.

> A: Alright, let's try, dl, well let's do the easy one first, dM, and I know you don't like this but=
> B: Yes, [laughs]
> A: =it's easy for me, um [draws $\widehat{M}$] So these angles are a bit more difficult, say you do this $d\alpha$. This doesn't have any units of length=
> B: [independently writes differential length element from spherical coordinates]
> A: =so, it needs to have some M term. I think it is just like that, isn't it [writes $Md\alpha$]. For α? [sweeps arm down as if covering the space of the angle] Yeah.
> B: You can, you can check from this, um…
> A: For α it doesn't have any dependence on this other angle over here, but when you're talking about β, um [looking at the spherical $\overrightarrow{dl}$ that B wrote]
> B: So this is dl [gestures to spherical differential he wrote], okay? dr r [hat], $rd\theta$ θ [hat],=
> A: No, I have this backwards (erases α terms)
> B:= $r\sin\theta\ d\varphi\ \varphi$ [hat], so now we have just to compare so we have r it is M, θ is α=
> A: (writes β's in place of α terms)
> B: =φ is β.

We see from this exchange that student A is attempting to reason using the aspects of *component and direction* and *dimensionality*, while student B is attempting to make use of the existing spherical coordinates using *recall* and *mapping*. Once student B makes the direct mapping, the two students work together and finish the construction of the differential element so that it mirrors the spherical length element and includes $\sin \alpha$.

It is notable to mention that the actions made by student A in the last few lines of the transcript were later illuminated as due to a use of the mathematical convention for spherical coordinates. This would be acceptable as long the angles were also changed in a student's description of the differential element, which was not the case for student A. Using limits for the angles from the mathematical convention coupled with a physics interpretation of the differential volume element results in a value of zero for integration (of $\sin \alpha \, d\alpha$ from $-\pi/2$ to $\pi/2$) along with potential for several conceptual inconsistencies, as seen here. The two students drew a spherical coordinate system and student B instituted the physics convention, allowing A to fix his mistake.

The second pair of students, C and D, progressed in a similar fashion but spent more time discussing the choices and reasons for their actions. The pair began building using all four aspects but did not attend appropriately to the differential when constructing the β length component, as depicted in the following exchange.

> D: I mean, it's like $M \cos \alpha$ would put us where we're =
> C: I like, no
> D: = down in the b[β]-hat range. And so judging by what you're saying is we just need that there [writes a "d" in front of $M \cos \alpha$ to make a dM],

After further difficulties in building, C and D recall the differential volume element from spherical coordinates to reason about the components of the differential length element for schmerical coordinates. While they had previously recognized the appropriate term for projection, the direct mapping resulted in the incorrect use of $\sin \alpha$ in the β length component, as it had for the graduate students.

The third pair of students, E and F, provided a contrast to the previous two groups. The two students resolved to build the integral from scratch and made a deliberate choice to not "fog their minds with preconceived notions of how things should work." As a result they spent the interview weaving together aspects of *component and direction, differential,* and *dimensionality,* building each component of the length vector independently; later they added each component together to represent the entire differential length element. The aspect of *projection* was entirely absent from their reasoning. At one point they made a comparison to spherical but agreed that they should not include a $\sin \alpha$ term, given that they could not justify the need. As a result, their differential element lacked any trigonometric function.

The final pair, G and H, focused entirely on *rote recall* and *mapping*. Neither student, however, could appropriately construct a spherical differential length element, due to lack of consideration of *dimensionality* coupled with difficulty with *grouping* terms by variable (as is done in integration) rather than by appropriate length component. This difficulty pushed them toward building an element in Cartesian coordinates using the form $xdx\hat{x} + ydy\hat{y} + zdz\hat{z}$. They then decomposed $\vec{M}$ into x, y, and z components for a right-handed system, rather than the given left-handed coordinates. Recognizing the determined differential element was in Cartesian coordinates and not in schmerical coordinates, the students returned to the idea of building the differential length element later in the interview by recalling the method of construction they had learned in class at the beginning of the semester.

Themes in students building of differential elements

Identification of these four building aspects and three actions afforded us the ability to determine the order and grouping of these aspects as students progressed through the interviews. We were then able to generalize across the interviews and observe recurring patterns in students' construction. We were able to identify which aspects or combination of aspects were productive and when the absence, or misapplication, of an idea in student thinking hampered further construction. Analysis across all of the interviews identified specific difficulties faced by individual groups or that were commonly held by several students, which we were able to connect to the scope and sequence of aspects that emerged in the interviews.

Productive combination and sequence: Component and direction *and* dimensionality

Analysis across groups identified that the use of *component and direction* coupled with *dimensionality* was very productive for students in the first three pairs when considering the differential length element as a whole. For the third pair of students, the combination of these two aspects was additionally beneficial when constructing each individual components of the differential.

F: So then if you have β—
E: $d\beta$.
F: Oh, yeah.
E: So you're going to have a length component in the β-hat direction.

For each term, the pair would isolate a specific direction of movement and then discuss what a length element in that direction was comprised of.

The role of dimensionality

In general, d*imensionality* alone was a strong factor for the students that used the aspect. Students C and D were particularly adamant about accounting for units of length.

C: ...it's going to be like, so if it's going to be some trig thing but sine of something isn't a length so we're going to have to also have something else in there.

C and D used the aspect of *dimension* to reason about the variables of each term, to an extent that later in the interview they could not recall whether or not differential angles or unit vectors gave units of length to their vector components. While the pair made a comparison to the spherical volume element, the concern persisted as they continued to construct terms. Other students often did not provide additional reasoning for including an M in their construction, as was seen in early transcripts.

A: … This doesn't have any units of length…so, it needs to have some M term.

However, student E specifically addressed the idea of arc length, combining aspects of *direction, dimension,* and *differential,* which made using the radius of length M apparent.

E: =so it's M times some Δ, I think it's M times $\Delta\beta$, a small β, because it's like if you take r times its small θ then that is the arc length=
F: Yeah.
E: =around a circle.
F: Yeah, okay.
E: Right, so like $rd\theta$ would be like the length component around a circle, so this would be $Md\beta$.

The final pair of students did not attend to dimensionality and subsequently had difficulty with early recall from spherical and Cartesian coordinate systems.

The role of the differential

Particular concept images of differentials were important to students' reasoning abilities. The treatment of differentials in terms of small amounts of motion (Artigue et al., 1990; Roundy et al., 2015; Von Korff & Rebello, 2012) was helpful to the building of terms. This idea is trivial for students here, but other views may be coming into play. C and D had particular trouble constructing the α and β components due to difficulties with reasoning about the differential, thinking only in terms of changes rather than small motions applied to the $\vec{M}$, and more specifically not attending to the need to have a $d\beta$ with the β-hat term.

Grouping terms within components

Groups CD and GH assembled the differential length component by sorting terms in the recalled spherical differential volume element. Both pairs grouped angular terms based on variables, rather than length components (Figure 2). Some attention to dimensionality was present in both cases, however. Initially both pairs of students wrote the $\sin\theta$ term with $d\theta$ in a similar fashion to how it would appear when looking at the integration of each term for a differential volume element. In typical E&M problem solving, the writing of differential volume elements (e.g. $r^2\ sin\theta dr d\theta d\varphi$ for spherical coordinates) involves a grouping of terms in a way that dissociates the variables from their particular length component. This was something student C paid attention to when writing her differential volume element.

> C: ... I was trying to figure out which I guess um I don't know vector direction each come from, um, because I feel like, right? This is right, right? We just write it r^2 for convenience right? It comes from separated out [terms].

C and D were later able correct the incorrect grouping of terms when reasoning through how the differential element was constructed in spherical coordinates. For student H, this dissociation of variable from the length components went further:

> H: You've got $r\ dr\ \hat{r}$ plus, is it $\sin\theta\ d\theta$ or is there an r in there?
> G: I think there is an r there, it's an r because you want, you want at that radius uh, plus a small angle.

Student H seems to have a concept image where the grouping of terms based on like variable is dominating the correct ideas for each length component. If this were the case, all the r terms in the differential length component would have been grouped with $\hat{r}$. This goes further to show how a lack of reasoning about *dimensionality* can hamper problem solving in E&M.

$$d\tau = \underbrace{r\sin\theta d\theta}, \underbrace{r d\phi}, \underbrace{dr}$$

$$r^2 \sin\theta\ d\theta\, d\phi\ dr$$
$$r dr\ \hat{r} + r\sin\theta\ d\theta\ \hat{\theta} +$$

Figure 2. (left) Incorrectly recalled differential spherical volume element written by student C and (right) unsuccessful attempt to reconstruct differential spherical length element by students G and H.

Construction and checking of differential volume elements

When asked to construct a volume element for schmerical coordinates, pairs AB and CD immediately knew to multiply the length components together. While this may seem trivial for the pair CD, having constructed the length elements through recall of the spherical differential volume, the pair acknowledged that they understood the volume element originated from the multiplication of length components. Both pairs of students also knew they could check their volume element by integrating to a constant radius to attain the equation for the volume of a sphere, but due to their incorrect trigonometric function, both checks of the differential volume resulted in an integration to zero over the domain of α. At this point, students recognized an error in their differential length element. Student A immediately recognized the mistaken projection due to the direct mapping and articulated that the change in placement of the angle makes $\cos\alpha$ the appropriate projection. Both students C and D were stricken by the result of the integration and only postulated that the error may have been with the $\sin\alpha$, recognizing this caused the integration to zero. Shortly following this exchange, they were also able to recognize the mistake in the projection.

When asked to check their volume element, F attempted to reason dimensionally, saying the integration of the M terms would given units of length cubed, so it didn't matter what the remaining integrals yielded. Unconvinced, E suggested the integration of the full differential volume element. The resulting π^2 in their answer convinced them that a sine or cosine was needed, but the justification around the aspect of *projection* was not immediately seen. Eventually E and F arrived at the correct differential length element.

When it came to the differential volume element, G and H mapped from the spherical differential, as they were both comfortable with that element. Early on in the construction they accounted for the different placement of α but the decided a direct mapping would be okay and included a $\sin\alpha$ term. After reconstructing a differential length element and obtaining correct terms, G and H were asked if they still satisfied with their differential volume element, which included a different trigonometric function from their length element.

H: I still like our volume element=
G: Yeah, I think so.
H: = I don't know about you, this one over here, I still think that
G: They're the same, yeah.
Interviewer: Okay, and can you check that that volume element is correct?
G: Isn't that kind of the same question?
H: Oh, you want us to actually do this integral out.
G: Oh. No, but see in down here we've gone with the $\cos\alpha$.
H: Oh, we've gone cosine, oh yeah.
G: And so we might want cosine. Yeah, I think we do, oh wait, let's see, oh not that's, alright, yeah we do want these, we want these to agree so they need to be, this needs to be a cosine [in the volume element].
...[After the exchange the pair start working out the integration]
G: Why did we change it to cosine?
H: I'm sorry?
G: Actually wait no, because the negative sign, the negative $\sin\frac{\pi}{2}$ is one=

As G and H are checking their differential volume element, they were hesitant to change their volume element and even after deciding that the length and volume element should agree, student G questioned the switch in trigonometric functions as the pair began to check their volume element, but was then comfortable with the choice, seeing that the mathematics arrived at the expected answer. The overreliance on spherical coordinates as well as the overly direct mapping from one coordinate system to another by the first two pairs of students is reminiscent of *x,y syndrome* (White & Mitchelmore, 1996), where a particular process in remembered in terms of symbols rather than how it comes about. Likewise, the symbols of the differential are remembered in the form that they are first taught and lose any particular meaning.

Conclusion

Our results suggest students do not have a robust understanding of how to build differential elements, but are able to check the validity of these elements and adjust terms appropriately. When working in an unconventional spherical coordinate system, students used a mixture of approaches to construct differential length and volume elements. Some attempted to reason about the length elements through direct mapping from spherical or Cartesian coordinates. We found students could implement successful strategies using necessary concepts. Particular attention to *component and direction* as well as *dimensionality,* both a coupling of the aspects and as individual aspects, allowed students to think productively about terms. Using the aspect of *differential* to think in terms of small changes was also useful to students. Interviews also highlighted a number of difficulties students face when working with differential length elements. An overreliance on rote recall and mapping led to difficulties for a number of students. It was also noted that students had particular difficulty grouping terms within recalled spherical length and volume elements. Students' inattention to *dimensionality* and *projection* hampered construction of terms. The successes and difficulties surrounding dimensionality speak to the importance of reasoning about units and dimensions when it comes to work in physics.

However, the determination and subsequent checking of the volume element seemed to help elicit ideas or connections between aspects that were not used when working on the length components. This suggests that while some students have an incomplete understanding of the coordinate systems due to misapplication of particular aspects, for others the requisite aspects are present but not accessed.

Student interviews have been particularly useful in exploring student understanding in this area, since for written problems seen earlier in the course sequence, rote memorization may have taken the place of conceptual understanding without hampering students' ability to arrive at the correct answer. We see similar results in the findings of Bollen and colleagues (2015) where students are able to correctly perform the calculations for differential vector operators but are unable to explain what the results mean. These cases are reminiscent of Tall and Vinner (1981), who stated that a restricted concept image can develop when students work for long periods with the same application of a given formula, even if the student is first presented with the formal definition. Then when students are met with a broader context, the student may be unable to cope. This implies that in order to improve student instruction in differential vector elements in E&M, more focus should be given to how length, area, and volume elements are constructed and determined when problem solving. Results of this study will be used to develop instructional resources to be used in E&M or the methods of theoretical physics course.

Further work seeks to explore how students reason about differential area elements, given the prevalence of these in flux integrals in E&M. We also seek to explore the role differential vector elements play in students' understanding when these elements represent abstract quantities such as electric fields in physics problems, as well as make comparison about students' thinking and use of differential vector elements between the contexts of math and physics. Additionally, we are analyzing student responses in terms of symbolic forms (Sherin, 2001), identifying a range of forms that students invoke when constructing and interpreting vector expressions as well as building from partially remembered equations.

Students' interpretation and justification of "backward" definite integrals

Vicki Sealey
West Virginia University

John Thompson
University of Maine

The definite integral is an important concept in calculus, with applications throughout mathematics and science. Studies of student understanding of definite integrals reveal several student difficulties, some related to determining the sign of an integral. Clinical interviews of five students gleaned their understanding of "backward" definite integrals, i.e., integrals for which the lower limit is greater than the upper limit and the differential is negative. Students initially invoked the Fundamental Theorem of Calculus to justify the negative sign of the integral. Some students eventually accessed the Riemann sum appropriately but could not determine how to obtain a negative quantity this way. In our research, we analyze various concept images for the differential, and see the primary obstacle here as interpreting the differential as a width, and thus an unsigned quantity, rather than a difference between two values.

Key words: Definite integrals, Calculus, Differential

In this preliminary report, we examine the role of the differential in the "backward" definite integral, $\int_b^a f(x)dx$ where $a < b$. The definite integral is a fundamental concept in calculus, with applications throughout mathematics and science. Studies of student understanding of definite integrals reveal several difficulties (Bajracharya, Wemyss, & Thompson, 2012; Bezuidenhout & Oliver, 2000; Jones, 2013; Lobato, 2006; Orton, 1983; Sealey, 2006, 2014; Sealey & Oehrtman, 2005). The existing literature on definite integrals tends to support a specific approach to developing an understanding of the definite integral, specifically by recognizing it as the sum of infinitely small products, which are formed via Riemann sums (Jones, 2013; Meredith & Marrongelle, 2008; Sealey, 2014). Additionally, Sealey (2006) and Jones (2013) point out that recognizing the Riemann sum as a sum of products of the function value $f(x)$ and the increment on the *x*-axis (Δx) is necessary for students to understand the meaning of the *area under the curve,* which is, arguably, the most prominent metaphor/interpretation of the definite integral. On the other hand, reasoning about a definite integral as area under the curve may limit students' ability to apply the integral concept (Norman & Prichard, 1994; Sealey, 2006; Thompson & Silverman, 2008).

Another aspect of the definite integral that leads to student difficulties is the meaning of the differential itself. Students treat the differential as an indicator of the variable of integration rather than a fundamental element of the product in integration of both single- and multivariable functions (Artigue et al., 1990; Hu & Rebello, 2013; Jones, 2013; Nguyen & Rebello, 2011). This could stem from, or lead to, a failure to understand the product layer of the integral (Sealey, 2014; Von Korff & Rebello, 2012). In other recent work, students treat *dx* as a graphical width (Bajracharya et al., 2012; Wemyss, Bajracharya, Thompson, & Wagner, 2011) or a small amount or quantity of whatever the *x*-axis represents (Artigue et al., 1990; Hu & Rebello, 2013; Roundy et al., 2015), rather than an infinitesimal difference or change in *x* (Von Korff & Rebello, 2012), both for positive and negative integrals.

Interpreting the sign of the integral has been shown to be difficult for students. Definite integrals that have a negative result are of particular difficulty geometrically. Students often do not treat the area as a negative quantity, effectively associating it with spatial area rather than the quantity represented by the product of $f(x)\,dx$. This is true for integrals for which $f(x)$ is negative, i.e., below the x-axis (Bezuidenhout & Oliver, 2000; Lobato, 2006; Orton, 1983; Rasslan & Tall, 2002), as well as those for which dx is negative, i.e., the direction of integration is in the negative direction (Bajracharya et al., 2012). The former type of negative integral is more common, but the latter also has relevance to applications in physical situations (e.g., finding thermodynamic work during the compression of a gas).

The notion of dx as a signed quantity is somewhat controversial, depending on the way one defines the differential. The perspective here, which is consistent with applications in physics and other fields, is that dx is defined as an infinitesimal *change* in the quantity *x,* akin to the limit of the change in x for the products in a Riemann sum: $\Delta x = \frac{b-a}{n}$; $dx = \lim_{n\to\infty} \frac{b-a}{n}$. This is consistent with Von Korff & Rebello (2012), who argue that infinitesimal quantities and infinitesimal products are important for an understanding of the meaning of definite integrals. Generally the sign of these quantities is not of interest, since $b>a$ in most cases. However, if $b<a$, then Δx, and thus dx, are negative. In Stewart's (2016) most recent text, he explains that the backward integral is negative because Δx is negative, but does not explicitly refer to dx as a signed quantity.

Theoretical Perspective

Given the prior work in this area, we wanted to explore the facets of students' concept image (Tall & Vinner, 1981) of the definite integral that apply to the sign of the integral. As described earlier, it was noted in the literature that the differential can be viewed as a variable of integration, as a width of a rectangle, as a small amount of a given quantity, or as a difference or change in a quantity. In particular, the role of the differential in a backward integral, $\int_b^a f(x)dx$, is crucial in interpreting the sign of the integral. We suspected that students would not recognize the fact that the differential would be negative for backward integrals, and we were interested in exploring whether certain concept images for the differential were more productive for viewing the differential as a negative quantity. Thus the backward integral had the potential to illuminate students' understanding of the meaning of differentials, definite integrals, and to some extent, the Riemann sum, beyond what has been seen in the literature to date.

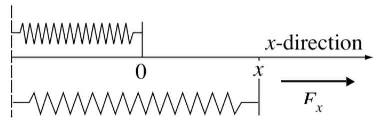
Methods

During clinical interviews, students were asked a series of questions about the relationship between forward and backward integrals. As this was a pilot study, we chose to interview five students at various levels: two second-semester freshmen (both double majors in math and physics and concurrently enrolled in a second-semester calculus course), one junior math major, one senior math major, and one first-semester Ph.D. level graduate student in math/math education. The interview subjects were volunteers who were either former students or teaching assistants of one of the authors. Interviewees received a $10 gift card at the conclusion of the interview.

Prior to the interviews, we developed an interview protocol and agreed upon the order in which the questions would be asked of the students, starting with the open ended general expressions shown below and concluding with a physical example.

1. General expressions: $\int_a^b f(x)dx$ and $\int_b^a f(x)dx$

2. Specific expressions: $\int_1^3 2x\,dx$ and $\int_3^1 2x\,dx$
3. Physical scenario: Work required to stretch a spring, $\int_{x_1}^{x_2} F\,dx$, where $F = kx$ (see Fig. 1)



Force needed to hold spring (with "stiffness" k) in place at position x away from equilibrium

$$F = kx$$

Work – Energy transferred into spring – to move end of spring from x_1 to x_2

$$W = \int_{x_1}^{x_2} F\,dx$$

Figure 1. Information given to interview subjects for spring question.

In each case we gave the forward integral first, then asked about the backward integral of the same expression. Interviews were semi-structured, following the same order of topics for each of the five interviews, but allowing for off-script questions in order to clarify our understanding of the students' responses. For example, with the general expressions, we first gave the students a paper containing the integral expression $\int_a^b f(x)dx$ and asked the students how they would read that expression. Next, we asked them to, "Explain what you know and understand about that expression." In the third section of the interview, students were asked about the work done on a spring. Bajracharya et al. (2008) found that students could justify the sign of a negative integral represented graphically by imagining a physical context that could be represented by the given graph. This led us to include a physical scenario involving a backward integral in order to explore its effect on evoked student concept images. Our initial task provided the integral expression as well as the expression for the force on a spring and a figure to demonstrate the scenario. Students were asked to interpret this integral for an extension of the spring (i.e., where $x_1 < x_2$), and then to interpret the integral with the limits reversed, rather than explicitly asking about a compression of the spring. During the students' explanations, we asked clarifying questions in order to refine our understanding of the students' responses and their meanings. Since this was a pilot study, we also allowed for time at the end of each interview to go off script and ask additional questions.

Interviews were videotaped and transcribed for analysis. During the first round of data analysis, both authors viewed the videos multiple times and made notes of the ways in which the students explained the sign of the integral in both the forward and backward integral. In subsequent analysis of the videos and the transcripts, we paid particular attention to how (or if) the students could describe the definite integral as a sum of products, and how (or if) they described the definite integral as area under a curve. Finally, we noted which of the concept images of the differential each student held, which were evoked during each interview question, and also attempted to identify other concept images that emerged from the data.

Data and Results

All five students were able to describe the definite integral in terms of area under a curve, and most students sufficiently described it as the sum of very small rectangles, whose heights were values of $f(x)$. Some students described the width of the rectangles as dx and some as Δx, and often used the two quantities interchangeably. Overall, we were satisfied with the students' ability to describe a definite integral as the sum of products.

All students initially used the Fundamental Theorem of Calculus (FTC) to justify why $\int_a^b f(x)dx = -\int_b^a f(x)dx$. Specifically, they were able to state that $\int_a^b f(x)dx = F(b) - F(a)$, where $F(x)$ is the antiderivative of $f(x)$, and then that $\int_b^a f(x)dx = F(a) - F(b)$, which would have the opposite sign. Graphically, the students had much more difficulty explaining why one of the quantities should be negative. In the following analysis, we discuss students' use of area under a curve and its connection to the FTC, their concept images of the differential, and the role of the application problem in their understanding of the backward integral.

Using area under the curve and the Fundamental Theorem of Calculus

All of the students seemed comfortable discussing the integral as the area under the curve. While they were able to consider the total area as the sum of small rectangles (or trapezoids), all students had difficulty explaining why the backward integral was negative in terms of area under a curve, and thus this ended up being an interesting part of our analysis.

Sara, a sophomore mathematics and physics double major, evaluated $\int_1^3 2x\,dx$ by finding the area of the large triangle (Fig. 1a) and subtracting the area of the small triangle (Fig. 1b) to obtain the desired area (Fig. 1c). She noticed that these calculations corresponded to the values she obtained when applying the FTC to the same problem: the area of the large triangle corresponded to $F(3)$, and the area of the small triangle to $F(1)$. Then, when computing $\int_3^1 2x\,dx$, she reversed the order of her subtraction, subtracting the area of the large triangle (Fig. 1a) from the area of the small triangle (Fig. 1b), and said, "But I'm not sure why that order is. I mean I know why for the integral [symbolically] because it's written that way, but if you were to solve this geometrically, I don't know why you would change the order of the subtraction."

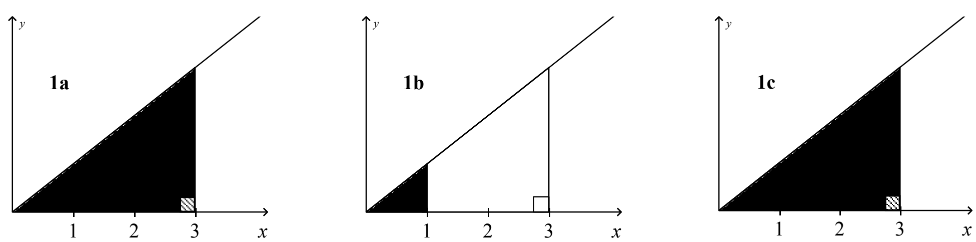


Figure 2: Sara's method of computing the area

Matt, a junior math major, also was able to justify the relationship between the forward and backward integral symbolically using the FTC, but also struggled to justify the result graphically. When computing the area under the function $2x$ between $x = 1$ and $x = 3$, he recognized it as a trapezoid. Instead of using Sara's method of subtracting the smaller triangle from the larger triangle (Fig. 1), Matt added the area of the lower rectangle (Fig. 2a) to the area of the upper triangle (Fig. 2b) to obtain the total area (Fig. 2c).

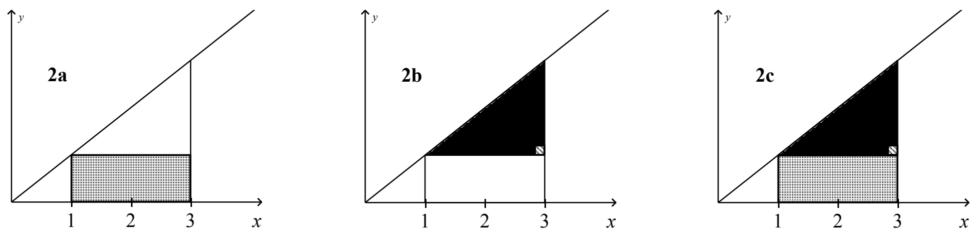

Figure 3: Matt's method of computing the area

Matt's solution is perfectly valid, but did not mimic the calculations from the FTC, as did Sara's method. Matt tried several different ways to graphically justify the negation of the backward integral but was never completely content with his justification. He noted that the backward integral represented the same area as the forward integral, but the backward integral would have to be negative since the limits were reversed "because I already know that, like as a fact, that it's a negative if you want to flip the bounds." He did state that he believed there *should* be a graphical justification, but he did not know what one would be. We do not mean to imply that Sara's solution was in some way better than Matt's, but simply note the connection to the FTC in Sara's solution. In fact, both Sara and Matt used solutions that sidestep the need for thinking about the Riemann sum and the *dx* specifically.

Student thinking about the differential

Most of the students were able to think about *dx* in at least two ways. Many of the students mentioned that the *dx* refers to the variable of integration, and most also were able to describe Δx, but not *dx* as the width of individual rectangles under a curve. Subsequent data analysis will note which concept images for *dx* and Δx were evoked in different circumstances, which concept image was evoked first, and if/when the students changed the way in which they thought about the quantities Δx and *dx*. Of particular interest to us is whether or not the students can conceive of *dx* as a signed quantity, as either a negative width, or as a negative value obtained from $x_2 - x_1$. According to our preliminary analysis, none of the students thought about *dx* as a signed quantity on their own accord, but with prompting from the interviewers, some were able to do so.

Near the end of Sara's interview, we pushed her to consider each rectangle under the curve, which she had described at the beginning of her interview. Sara was comfortable with $f(x)$ being negative or positive, depending on if it was above or below the *x*-axis, but when she was directly asked if *dx* could have a sign, said, "Well no, I don't think *dx* would ever be negative because it's just a distance, it's not like an actual value."

Matt eventually was able to think about Δx as a negative quantity and described *dx* as the limit as Δx approached zero. After many attempts from Matt, the interviewer asked him if *dx* could be negative. His response indicated that he was not confident in his answer, saying,

> "That's probably the hidden spot that I couldn't figure out before. Yeah I would say that this *dx* would be negative [from *a* to *b*] and this one would be positive [from *b* to *a*] because it's approaching 0 so this [from *a* to *b*] would still stay positive […] and this one [from *b* to *a*] would stay under, yeah I'm going to say this *dx* here [from *b* to *a*] is negative and this *dx* is a positive *dx* [from *a* to *b*], and I guess that's where it's hidden and that's what their difference is? I don't know."

Anna, a senior math major, spoke often of Δx, but rarely of *dx*. She had no trouble thinking about Δx as a negative width, but did not seem comfortable thinking about *dx* as being positive or negative. Her explanation of why the backward integral was negative was because the width was negative, and she used an explanation referring to the sum of the areas of a finite number of rectangles to explain, "You're going to have that negative width times a positive value, which is going to give you a negative number, so you're going to get the addition of a bunch of negative numbers." Much later in the interview, one of the interviewers asked Anna if it was possible for dx to be positive or negative, and Anna responded, "I've actually never thought of that. So I'm not sure. I mean I guess it could, but I just always viewed the dx as the indication of what term to integrate to. So I'm not actually sure, I guess."

Nick, a mathematics graduate student, focused his explanation as to why the backward integral was negative on direction. He said that the dx represents a change, and that change implies motion. He seemed to be thinking about the variable x representing time, and mentioned more than once that the backward integral would be like playing a movie in reverse. On another note, Nick spent a great deal of time during the interview talking about the two terms that made up the product in the definite integral, namely the $2x$ and the dx in $\int_3^1 2x\,dx$. He knew that when multiplying two quantities to obtain a negative result, exactly one of the terms multiplied must be negative. He debated if the x turned negative or the dx turned negative. He "voted" for the dx to be negative, again tying this to the direction. But this answer did not sit well with him: "I've just, in my head for so long, always assumed dx to be a positive, you know, change in x and for so long never thought this deep into the pieces." He said to be sure, he would have to go back to the definition of Δx in the textbook to see if he was right.

The role of the physics context in student thinking

Our data suggest that the spring task seems to evoke the concept images of dx as a small but finite amount, change, or difference in the position of the end of the spring in students who already were engaging with the idea of the differential.

Matt had indicated a concept image of dx as a variable indicator, but during the spring extension discussion, he said that it would be "the change in the distance from each, like, individual from like your x_1 to x_2 and it's going to be every, like, small small distance." Upon prompting from an interviewer about the change in his view of dx, Matt responded, "when you think about just, like, the pure math problems, that's all you really think about — just the fact that dx is just telling you […] what variable to use […] But […] here, it represents, it represents something…" Given physical meaning, Matt was able to interpret dx as a small displacement of the spring.

Similarly, Anna pointed out that before the interview, she thought of dx as "the term you're supposed to integrate to." She had a clear sense of the product layer and of the adding up pieces conceptualization of the definite integral, multiplying $f(x)$ by Δx "to get the area limits" for a Riemann rectangle. She immediately realized that Δx is negative for the backward integral in the first task, and how that leads to the negative sign on the result: "you're going to have that negative width times a positive value, which is going to give you a negative number, so you're going to get the addition of a bunch of negative numbers." During the discussion of the spring compression integral, she stated that dx is "kind of representative of that infinitely small piece which would still be able to have a negative change as we are heading smaller, because it's directional so because it's getting smaller it's negative."

However, we also saw a case where this context did not promote this particular concept image of dx as an infinitesimal signed quantity. In the math contexts, Alex displayed reasonable area under the curve and antiderivative images of the definite integral, although he did show some confusion graphically with the integrand representing the area. He never mentioned dx in his discussion (except when reading the definite integrals aloud); instead focusing on more macroscopic differences, either Δx or the whole interval $(b - a)$. His image of Δx was primarily as a width (he says "length") on the x-axis; this could be a signed quantity, since reversing the limits of the integral "would make your width negative." But Alex had a strong aversion to the idea of negative area; for him the negative sign was added when limits were reversed "to negate the negative distance" because otherwise you would have an negative area, "which isn't really a thing." Similarly, he did not connect the sign of the backward integral (for a positive function) to the sign of Δx.

With the spring task, Alex considered that the forward work integral represented the energy put into the spring and that the backward integral was energy lost. He discussed the meaning of this: "It is totally okay for there to be negative work, but that's usually, that's defined upon reference frames. Whether work was done on a system or by a system." As Alex continued, his discomfort with a negative integral emerged:

> "Whether you start at x_1 or you start at x_2, it's still the same amount of force over the same amount of distance so there's no reason why the flipped bound, this second, x_2 to x_1, there's no reason why that shouldn't be able to have a positive answer because it is still the same amount of force over the same amount of distance."

It seems as if Alex used the idea of reference frame to justify the arbitrary positive sign of the integral and avoided the need to consider the sign of the differential quantity. Our interpretation of Alex's response is that his concept image was limited by his failure to acknowledge dx in the discussion and thus he failed to recognize the role of dx in determining the sign of the integral.

The inclusion of the physical context of the spring, as well as Nick's evoking of motion or time contexts for the integrals, seemed to help subjects make sense of the differential itself and also of the sign thereof. This supports our reasoning for including the spring task in the interviews, and is consistent with earlier reports of students invoking physical contexts on their own in order to interpret a negative integral, either a backward integral of a positive function or a forward integral of a negative function (Bajracharya et al., 2012; Wemyss et al., 2011). On the other hand, it is possible that any reasoning on the spring task about the differential in backward integrals may have arisen due to priming of this issue in the previous two tasks of the interview. While Alex could be considered a counterexample of this, to be certain, additional data would need to be collected with a rearranged or otherwise varied protocol.

Discussion and Conclusion

Students recognized the negative value of the backward integral based on the FTC/antiderivative difference formula, but when asked for a geometric interpretation, most said they hadn't thought about it before and had difficulty making a reasonable interpretation on their own. Most students' graphical explanations of why the backward integral yields a negative result seemed to invoke the direction of the integration, treating the area as a macroscopic negative quantity, but failed to recognize the role of the differential in generating that sign. We know from the literature and our own prior research (Bajracharya et al., 2012; Sealey, 2006; Thompson & Silverman, 2008) that students often lack an understanding of *why* or *how* area under a curve is a representation of a definite integral. Our subjects, who we acknowledge may be more advanced than the average calculus student, did not seem to have this difficulty: they were able to describe the definite integral as the sum of the areas of very small rectangles, and adequately described the product layer that makes up these small rectangles. They could all explain that $f(x)$ represented the height of the rectangles and that Δx (and sometimes dx) represented the width of the rectangle.

However, thinking about the backward integral adds another level of difficulty to describing the definite integral in terms of area. The students did not always recognize that Δx and dx could be negative values. Instead of thinking about Δx as a difference, (e.g., as $(x_{i+1} - x_i)$ or as $\frac{b-a}{n}$), they initially thought of Δx as the width of a rectangle, and usually assumed it was always a positive value, leading to the assumption of a positive backward integral. Alex's use of this reasoning above in the spring task is consistent with previous work in this area (Bajracharya et al., 2012; Wemyss et al., 2011), and suggests the consequence of a limited concept image of the differential.

We certainly do not mean to imply that Δx and dx should never be thought of as a width. In fact, research by Hu and Rebello (2007) suggested that dx-as-width is an important perspective for problem solving in physics. Instead, we emphasize the necessity for being able to think about dx as positive or negative widths *and* the change between two quantities. With moderate prompting, most of our research subjects were able to do this; future research will examine what type of instruction or intervention enables students to make this connection.

Supporting preservice teachers' use of connections and technology in algebra teaching and learning

Eryn Stehr
Michigan State University

Hyunyi Jung
Purdue University

The Conference Board of the Mathematical Sciences recently advocated for making connections and incorporating technology in secondary mathematics teacher education programs, but programs across the United States incorporate such experiences to varying degrees. This study explores opportunities provided by secondary mathematics teacher preparation programs for preservice teachers (PSTs) to (1) expand their knowledge of algebra by making connections and using technology and to (2) learn how to incorporate their own use of connections and technology in algebra teaching. We explore the research question: What opportunities do secondary mathematics teacher preparation programs provide for PSTs to learn about connections and encounter technologies in learning algebra and learning to teach algebra? We examine data collected from five teacher education programs chosen from across the U.S. Our data suggest not all secondary mathematics teacher preparation programs integrate experiences with making connections of different types and using technology to enhance learning across mathematics and mathematics education courses. We present overall findings with examples.

Key words: Algebra, Technology, Connections, Secondary Teacher Training

Algebra plays a prominent role in mathematics education reform efforts because it is valued both as a foundational subject in mathematics and as a gatekeeper for college entrance and careers (Kilpatrick & Izsák, 2008). Particularly in the United States, preparing future secondary mathematics teachers to teach algebra has gained importance because of changing populations and changing perspectives on effective algebra teaching. First, in response to algebra-for-all initiatives, more states include algebra as a high school graduation requirement (Teuscher, Dingman, Nevels, & Reys, 2008). Due to these new requirements, not only are more secondary mathematics teachers teaching algebra in their first professional position, but these new teachers are also expected to teach algebra to a more diverse population of students than ever before (Stein, Kaufman, Sherman, & Hillen, 2011). Hence it is critical to study how teaching programs prepare preservice teachers (PSTs) for teaching algebra. Second, reform initiatives (e.g., NCTM, 1989, 2000; CCSSO, 2010) have changed expectations of teachers. In *The Mathematical Education of Teachers II (METII)*, the Conference Board of the Mathematical Sciences argued that "a careful look at the mathematics [e.g., algebra] that is taught in high school reveals that it is often developed as a collection of unrelated facts that are not always justified or precisely formulated" (p. 56, CBMS, 2012). CBMS recommended increased attention to how future mathematics teachers are supported in developing a deep understanding of mathematics, with algebra as one large area of focus. Although may experiences may occur in mathematics education courses, CBMS recommended that experiences supporting the development of connected, coherent understanding of mathematics should also occur in mathematics courses.

The current study is situated within a larger project that explored opportunities that teacher preparation programs provide PSTs to learn algebra and learn to teach algebra. In this smaller study, we have chosen to focus particularly on two approaches to learning algebra and learning to teach algebra: making algebraic connections and using technologies strategically.

Standards for both secondary mathematics content and teacher preparation have emphasized the importance of developing PSTs' abilities to make connections and to use appropriate educational technologies in their own mathematical learning and in their future mathematics teaching. Particularly with respect to PSTs' mathematics courses, *Mathematics Education of Teachers II (METII)* recommended that instructors of mathematics courses support PSTs in "forming connections" (p. 56) and that experience with technology "should be integrated across the entire spectrum of undergraduate mathematics" (CBMS, 2012, pp. 56-57).

Standards developed for teacher preparation program accreditation agencies have emphasized the importance of developing PSTs' abilities to see mathematics as a complex, connected system woven through other non-mathematical disciplines as well as a way to make sense of the real world (Council of Chief State School Officers [CCSSO], 1995; National Council of Teachers of Mathematics [NCTM], 2012). Although different research and policy documents may use the term *making mathematical connections* in slightly different ways, here we mean, broadly, identifying relationships between mathematical ideas, objects, structures, etc. For example, identifying the many ways functions may be represented or used within a particular domain, across multiple mathematical domains, in real-world relationships, or in the mathematics of other disciplines.

PSTs must think about mathematics as a "whole fabric" as they make connections among mathematical topics and in relation to others (NBPTS, 2010). To support this view of mathematics, PSTs need to make connections within algebra, and between algebra and other mathematical fields, while linking algebra with real-world situations. PSTs should prepare to teach using "rich mathematical learning experiences" and provide their future students with opportunities to "make connections among mathematics, other content areas, everyday life, and the workplace (NCTM, 2012). Further, PSTs should also be able to prepare to support their future learners in reflecting "on prior content knowledge, link[ing] new concepts to familiar concepts, and mak[ing] connections to learners' experiences" (CCSSO, 1995).

Teacher preparation standards have emphasized the importance of PSTs' encountering technologies in mathematics and mathematics education courses (CBMS, 2001, 2012; CCSSO, 1995; NCTM, 2012). In this study, we define technology broadly as electronic software, such as calculators, mathematical software, and online applets. *METII* recommended that PSTs have experiences with technology "integrated across the entire spectrum of undergraduate mathematics" (p. 56). *METII* warned that technology should not be used "in a superficial way, without connection to mathematical reasoning" (p. 57) but that PSTs should have opportunities to encounter a variety of technologies and to learn to use technology in a variety of ways; for example, to offload routine computations, operations, representations; to apply previous knowledge to more complex problems; and to explore and experiment to understand subtle mathematical concepts. Teachers also need support in critically evaluating and strategically using technology in mathematics teaching and learning (CBMS, 2012; CCSSO, 1995; NCTM, 2012). That is, PSTs should have opportunities in mathematics and mathematics education courses to learn to use a variety of technologies in support of three big ideas: using technology as practical expedient, using technology to enhance learning, and thinking critically about the choice and use of technologies in mathematics teaching and learning.

This study explores opportunities provided by secondary mathematics teacher preparation programs for PSTs to (1) expand their knowledge of algebra by making connections and using technology and to (2) learn how to incorporate their own use of connections and technology in algebra teaching. We explore the following research question: "What opportunities do secondary mathematics teacher preparation programs provide for PSTs to learn about connections and encounter technologies in learning algebra and learning to teach algebra?" Making connections in the service of algebra teaching and learning might include making connections within algebra, between algebra and other mathematical fields, between algebra and non-mathematical fields, and between ideas in advanced algebra and school algebra. Encounters with technology in the service of algebra teaching and learning might include using or learning about a variety of algebra-appropriate technologies, as well as thinking critically about technology use.

Method

This study is part of *Preparing to Teach Algebra (PTA),* a mixed-methods study that explores opportunities provided by secondary mathematics teacher preparation programs to learn algebra and to learn to teach algebra. The *PTA* project consists of a national survey of secondary mathematics teacher preparation programs and case studies of five universities. The current study is a qualitative analysis of the case studies focusing on the opportunities provided to PSTs to encounter technology and to make connections in learning algebra and learning to teach algebra.

The *PTA* project purposefully chose to explore secondary mathematics teacher preparation programs at five universities. We refer to these universities as Great Lakes University (GLU), Midwestern Research, Midwestern Urban, Southeastern Research, and West Coast Urban Universities. We chose the first three before beginning the project, and the latter two after analyzing results of a national survey. We initially chose to focus on three universities (Great Lakes, Midwestern Research, Midwestern Urban) to deliberately vary the type of institution, location, demographics, and type of program. Some details are shown in Table 1 below. Great Lakes, Midwestern Research, and Midwestern Urban Universities varied in their context, Carnegie Classification, and the average number of graduates. For example, Midwestern Research University was a doctorate-granting institution with very high research activity, while Great Lakes and Midwestern Urban Universities were large master's-level universities. In addition, Great Lakes University was unique in that the mathematics educators and mathematicians both were in the Department of Mathematics (mathematics educators at Midwestern Research and Midwestern Urban Universities were in the College of Education). Midwestern Urban University was unique in its ethnic diversity: only 40% of its students were Caucasian with 32% Hispanic and 10% African American. Great Lakes and Midwestern Research Universities had populations of 91% and 83% Caucasian, respectively.

We chose two additional sites (Southeastern Research and West Coast Urban) based on responses from a national survey that we developed and administered early on in the project. While Great Lakes, Midwestern Research, and Midwestern Urban Universities are all located in the Great Lakes region of the United States, Southeastern Research is in the Southeast and West Coast Urban is in the Far West. West Coast Urban University was chosen because its program is post-baccalaureate, so students do not take any mathematics course requirements in the program, but only mathematics education and general education courses.

Table 1.
Demographic Characteristics of the PTA Case Study Programs and Universities.

	Great Lakes	Midwestern Research	Midwestern Urban	Southeastern Research	West Coast Urban
Context	Small City	Mid-size City	Large City	Mid-size City	Large City
Carnegie Classification[1]	Master's L[2]	Doctorate RU/VH[3]	Master's L[2]	Doctorate RU/VH[3]	Master's L[2]
Degree-Seeking Undergraduate Race/Ethnicity Enrollment Percentages[4]	2% Asian 5% Black 4% Latin@ 84% White 3% Multiracial	4% Asian 4% Black 5% Latin@ 71% White 4% Multiracial	9% Asian 10% Black 35% Latin@ 37% White 2% Multiracial	9% Asian 7% Black 5% Latin@ 73% White 3% Multiracial	16% Asian 5% Black 59% Latin@ 8% White 2% Multiracial

[1] The Carnegie Foundation for the Advancement of Teaching (2010).
[2] Master's L: Master's Colleges and Universities (larger programs)
[3] RU/VH: Research Universities (very high research activity)
[4] Race-Ethnicity enrollment statistics were collected from the Common Data Set for each university (2013-14). Only categories with at least 2% in at least one of the universities were included in the table. Nonresident aliens and race/ethnicity unknown categories were not included.
[5] Average annual number of graduates across three academic years (2009-10, 2010-11, 2011-12).

We compiled data by conducting two focus groups of 3-4 PSTs and 10-13 instructor interviews at each site and collected corresponding instructional materials from each instructor we interviewed. In the instructor interviews at each site, we included required mathematics, mathematics for teachers, mathematics education, and general education courses selected for potential algebra content. West Coast Urban University, as a post-baccalaureate program, required no mathematics courses and so we conducted only 3 interviews with instructors of mathematics education and general education courses.

Among other interview questions, we asked instructors which types of technologies they used in a particular course and how they supported PSTs in making connections in algebra. Similarly, we asked PSTs in focus groups to identify required courses that incorporated opportunities to make connections or to use technology in learning algebra or learning to teach algebra. We asked PSTs explicitly about their required or shared experiences with connections and with technology.

Prior to considering the data for mentions of connections or technology, the *PTA* project team had coded data for algebraic content. In analyzing data, four researchers worked in pairs, reading the interview and focus group transcripts and discussing potential opportunities reported by instructors or PSTs. For this study, we focus more narrowly on Abstract Algebra, Linear Algebra, and Secondary Mathematics Methods courses at the five universities. Different universities required different sequences of Secondary Mathematics Methods: Great Lakes required two courses, Midwestern Research required two, Southeastern Research required three, and Midwestern Urban and West Coast Urban required one each. Also, we asked mathematics instructors approximately how many PSTs were in each course. Table 2 shows the percentages of PSTs in the Abstract Algebra and Linear Algebra courses at each university. Note that West Coast Urban University did not require these courses, so they are not listed. The Midwestern Research Abstract Algebra course was a mathematics for teachers course, so it only included PSTs.

Table 2.
Number of Students and Proportion of Preservice Teachers in Linear Algebra and Abstract Algebra courses at Great Lakes, Midwestern Research, Midwestern Urban, and Southeastern Research Universities.

University	Linear Algebra	Abstract Algebra
Great Lakes	21 (50%)	20 (70%)
Midwestern Research	50 (unknown)	*Algebra for Teachers:* 19 (100%)
Midwestern Urban	25 (50%)	15 (about 50%)
Southeastern Research	33 (33%)	24 (60%)

For connections, the two researchers individually coded data sources based on the major four types of connections (e.g., connections within algebra, connections between algebra and mathematics) and met to make consensus on the coding. We then developed summary documents of each university, including tables of the number of opportunities and quotations in each course. We will analyze the quotations to document different types of opportunities that were reported (e.g., algebraic topics that PSTs were exposed, specific activities that PSTs engaged with, or/and opportunities to help PSTs learn to teach connections).

For technology, the two researchers have considered instructors' interviews and instructional materials. We captured types of technologies mentioned by course instructors, as well as details of the experiences the rationale (if any) given by the instructor detailing why (or why not) technology were used (e.g., "dulls the mind" or "representations help students understand quantitative situations"). Based on previous research, we will analyze instructors' reports of technology use to understand why opportunities are or are not provided in particular mathematics or mathematics education courses, and to understand the types of experiences provided, whether the experiences are as a "practical expedient," or to "advance learning," or to provide opportunities for PSTs to think critically about choice and use of technology by engaging with potential affordances and limitations (CBMS, 2001).

Results

For the purposes of this paper, we focus on finding exemplars of *types* of experiences provided to PSTs across the four different programs and focus on experiences in Abstract Algebra, Linear Algebra, and Secondary Mathematics Methods courses. That is, we are not evaluating the programs; rather, exploring strengths and challenges of each program to understand what rich experiences across a program's offerings could look like, and to understand the challenges that arise. First, we consider *connections*; we describe the types of experiences making algebraic connections that instructors told us they provided PSTs. Then, we consider *technologies* and the types of encounters with technologies and algebra that instructors reported providing.

Connections

In terms of connections, we describe the types of connections that the instructors reported PSTs had opportunities to learn and learn to teach about, the purposes of making these connections, and the ways of providing such connections to PSTs in Linear Algebra, Abstract Algebra, and Secondary mathematics methods courses.

Types of connections. We focused on four types of connections provided in these courses: connections (a) within algebra, (b) between algebra and other mathematics, (c) between algebra and non-mathematics, and (d) between school and college algebra. We provide examples of each type of connections in this section.

Of the connections within algebra, instructors of Linear Algebra and Abstract Algebra discussed connections around common structures or big ideas. For example, an Abstract Algebra instructor at Great Lakes said, "We certainly emphasize connections within algebra. In looking at common structures, and themes behind different number systems and the way algebra works in those number systems." Similarly, a Linear Algebra instructor at Midwestern Urban remarked, "Once they have studied how to solve systems of equations, they see that everything that is being done in linear algebra is modeled using that. So that is the big idea. So we spent quite a number of time, quite a number of classes at the beginning studying how to solve systems of equations." In the former example, the instructor described students' connecting common algebraic structures across number systems; in the latter, the instructor described students making connections by recognizing a big idea in Linear Algebra: that systems of equations are used to model "everythign that is being done" in Linear Algebra.

Instructors of Secondary Mathematics Methods emphasized how they could help PSTs make connections within algebra. An instructor at Great Lakes, for example, reported that "my focus a lot of times is on thinking about how they can make connections within the algebra themselves, how they can consolidate those ideas." He continued, "I'm the one who's making the connection. I feel much more comfortable that you make the connection." That is, his emphasis was on supporting PSTs to make their own connections rather than simply being told about connections. Similarly, an instructor at Midwestern Urban described that students made representational connections within algebra: "having students make connections among graph, different representations. So graphs, tables, words and symbols." Other instructors also mentioned different ways of engaging PSTs by using tasks and discussions that address algebraic connections.

Of the connections between algebra and other mathematics, examples vary depending on topics that can be connected to algebra. A Linear Algebra instructor at Midwestern Research, for example, mentioned concepts around a tangent: "When you're doing calculus you're essentially approximating a graph by its tangent line, finding its tangent line, and then you use that to approximate and that generalizes to a tangent plane, of a surface, or tangent space of a manifold." Hence, the students would connect a basic algebraic idea of linear functions to ideas in Calculus. An Abstract Algebra instructor at Southeastern Research discussed algebraic connections to geometric topics: "One of the things in this course, really the culminating section of the course talks about the non-constructability of certain geometric objects…You can't square the circle, you can't double the cube, you can't trisect angles and that's something that is a connection with high school geometry." A Secondary Mathematics Methods instructor at Great Lakes provided a broader role of algebra: "We connect to geometry, probability, measurement, statistics. One of the conceptions of algebra that we talk about is algebra as kind of -- especially symbolic algebra -- as kind of the written language of mathematics and how being able to make a symbolic representation of an idea or a relationship gives us access to so many other tools -- that's a powerful problem-solving tool."

Connections between algebra and non-mathematics were also discussed, making connections to subjects other than mathematics or to real-life situations. A Linear Algebra instructor at Great Lakes discussed building relationships between algebra and computer science when PSTs studied population dynamics. An Abstract Algebra instructor at Midwestern Research mentioned algebraic connections to cryptography: "Algebra and this cryptography is probably a connection between algebra and other fields because cryptography was done mostly by electrical engineers who are actually building machines." A Secondary Mathematics Methods instructor at Great Lakes discussed connecting algebra to real-life situations, such as the price for a car wash: "Someone was looking at systems of linear equations and they were really struggling. I said, 'I saw there was a gas station that was offering, it was this price for regular without a car wash and it was this price for regular if it was a car wash. Would something like that be helpful?'" Secondary Mathematics Methods instructors at other universities also discussed different examples of real-world connections, including the border problem at Midwestern Urban (generalizing the context using variables) and connections to other subject areas (e.g., geography) at Midwestern Research.

Lastly, connections between school and college algebra were discussed by only mathematics instructors. A Linear Algebra instructor at Southeastern Research provided a specific example of making connections between eigenvalues of matrices and polynomials: "When we went to find the eigenvalues of this matrix, so that came finding the characteristic polynomial which in this case was this [writing on board]. And then finding its roots so using the quadrant so there's a bunch of high school algebra, finding this polynomial, figuring out its roots, so those are x equal 1 plus or minus root 5 over 2." Abstract Algebra instructors discussed such connections around topics of polynomials and set theory. An instructor at Great Lakes said, "We talk about polynomials, for instance, we talk about the relationships between problems that we might ask at this level and the corresponding problems at the high school level." Another instructor at Midwestern Urban remarked, "I mainly see connections between is the college-level algebra and school algebra and this abstract notion of algebra in terms of let's start with number systems you're familiar with and then expand it to these more abstract settings." Such connections were not reported by Secondary Mathematics Methods instructors, but shared by Mathematics for Teachers instructors (These results are discussed in other publications.)

Purposes or ways of providing opportunities related to connections. Several purposes of making connections were described by the instructors: (a) to emphasize the application aspect of algebra, (b) to address the usefulness of algebraic connections, (c) to help PSTs teach connections to their students, and (d) to develop PSTs' conceptual understanding of algebraic concepts. The instructors also discussed diverse ways of providing such opportunities, including the use of previous chapters or other subject areas connected to algebra, the use of concepts or experiences that are familiar to PSTs, and discussions around tasks and textbooks.

Of the Linear Algebra instructors, two instructors (at Midwestern Urban and Southeastern Research Universities) reported using connections for showing its applications in other mathematics. Instructor at Southeastern Research, for example, said, "Certainly algebra with other mathematical field, the reason we do Linear Algebra at this point in their career is that it has applications in so many other parts of math. And I bring those up whenever I can." Instructors also described different ways of providing opportunities related to connections. An instructor at Midwestern Research described the use of related chapters to make connections. He reported, "The beginning chapter is building up the theory, understanding what a linear transformation is, its kernel, its image, being able to do row operations to answer various questions. The later chapter always use that stuff, it's always talking in terms of that language that we've learned about." An instructor at Great Lakes mentioned making connections by using relationships between algebra and computer science. He remarked, "we study population dynamics. We use this as kind of a model for dynamical systems." Lastly, an instructor at Southeastern Research described a way to connect trigonometry with the eigenvalues of matrix. These examples are unique in that each Linear Algebra instructor reported different ways of providing opportunities related to connections.

The Abstract Algebra instructors at Midwestern Urban and Midwestern Research universities reported the usefulness of algebraic concepts by making connections to other mathematical fields or real-life situations. For example, the instructor at Midwestern Urban said, "In terms of between algebra and other mathematical fields, I think they see the usefulness of number theory in the course. They see the usefulness of set theory." An instructor at Midwestern Research reported, "my goal is to introduce how the modern algebra is used in real life." A notable way to teach connections was to teach concepts that PSTs are familiar with. An instructor at Midwestern Urban said, "I have them think about what it means to solve for x in an equation they're familiar with, which is from something they're familiar with (college algebra, previous math classes) and then going to the abstract notion of what we mean by a group." Another way of teaching connections was to promote discussions around relationships between school and college algebra. An instructor at Great Lakes reported, "We talk about the relationships between problems that we might ask at this level and the corresponding problems at the high school level. And the same thing with the integers." The instructor also described how to connect the machinery in the division algorithm with the way that kids learn about division.

In Secondary Mathematics Methods, examples of making connections for PSTs' future students were shown in Great Lakes and Southeastern Research universities. Instructors described why making connections in college level is important in helping their students. A Secondary Mathematics Methods II instructor at Southeastern Research, for example, said, "We tried to help our students to be a little bit creative and try to find the connections and make it coherent for their students." As a way to achieve this goal, the instructor described that "We talked about making connections between algebra and geometry to help students understand what is going on within the curriculum here in this State." Another purpose of making connections reported by Secondary Mathematics Methods instructors was to develop PSTs conceptual understanding of concepts. A Secondary Mathematics Methods instructor at

Southeastern Research said, “We’ve focused so much on the cognitive demand and the conceptual understanding we try to show the connections to our students and bring it in and have them the investigations I try to have the kids go through is investigating ways that they can generalize so they’re not just memorizing rules.” An instructor at Great Lakes explained the ways that he helped PSTs make connections. He reported, “The connections that I’m hoping that they’re going to make are based on some of the workshops that they’ll do, the reading workshops as they’re doing that and seeing the connection to their own experience what’s going on in the classroom.” Other instructors also mentioned several ways of providing opportunities, such as discussions around mathematical tasks and textbooks (Midwestern Research) and discussions after watching a video tape that involves population growth (Midwestern Urban).

Technologies

In analyzing PSTs’ encounters with technology in learning algebra or to learning to teach algebra, we considered the types of technologies that instructors of the three courses reported using, their descriptions of their purposes in using particular technologies, and their descriptions of the ways that they or the course students used technologies. In considering how technologies were used, we thought about whether they were used for pragmatic use, to enhance learning, or to support critical thinking about the use of technologies.

Types of Technologies. For four universities, the widest variety of technologies used occurred in Secondary Mathematics Methods courses. Of the Linear Algebra courses, only Great Lakes and Midwestern Urban instructors reported using technologies for class. At Great Lakes University, the Linear Algebra course had a computer lab component, where the class met in a computer lab one day each week; they used graphing calculators, Java applets created by the instructor, and Maple software. At Midwestern Urban University, the Linear Algebra instructor reported use of graphing calculators; at Midwestern Research, the instructor said he encouraged students to do some work using their favorite technology outside of class and also gave them access to *Mathematica* if they chose to use it, but said, “I’m interested in how this works, the brain, not how that [technology] works, so I don’t need to see the results of their computations.” At Southeastern Research University, the instructor said, “You’re not even allowed a calculator in the exams. Because I think it dulls the mind. Makes them rely on it instead of doing, learning mental arithmetic.”

Of the Abstract Algebra instructors, three instructors (at Great Lakes, Midwestern Urban, and Southeastern Research Universities) reported using a classroom management system for organization and communication of the course. Beyond that, the types of technologies varied: the Great Lakes instructor described use of GoogleDocs, Midwestern Research – any calculators, Midwestern Urban – Wolfram Demonstrations Project, and Southeastern Research – an iPad App called “Show Me.”

In comparison, Secondary Mathematics Methods instructors reported a wide range of technologies including mathematics websites (i.e., Wolfram|Alpha, GeoGebra, Khan Academy), virtual manipulatives or applets (i.e., National Library of Virtual Manipulatives, National Council of Teachers of Mathematics: Illuminations), mathematics software (i.e., Geometer’s SketchPad, TinkerPlots, Fathom, GeoGebra, Excel), teaching websites or resources (i.e., TIMSS videos, classroom videos, Moodle), and hardware (i.e., SmartBoards, tablets).

Ways of Using. We saw examples of each of our three categories of using technology: as a practical expedient, to enhance learning, and to support thinking critically about technology use.

In Linear Algebra, an example of using technology as a practical expedient was allowing students to perform row reduction operations on matrices using a calculator instead of by hand. Great Lakes and Midwestern Urban University instructors reported encouraging students to use graphing calculators (Great Lakes and Midwestern Urban) or Maple (Great Lakes). The Southeastern Research University instructor also encouraged students to row-reduce matrices "using their favorite technology," but instead of asking students to report only their final answer, he said he asked students to explain or justify their answers. In Abstract Algebra courses, Great Lakes, Midwestern Urban, and Southeastern Research University instructors reported using course management systems for organization.

As examples to enhance learning, Abstract Algebra instructors at two universities described their use of technology as supporting students' exploration of and experimentation with mathematical ideas. At Midwestern Urban University, the instructor explained that he chose particular representations from Wolfram Demonstrations Project to support students in exploring symmetries and to "clearly understand what the different operations do." At Midwestern Research University, the instructors asked students to use any calculator to perform experiments and said the use of calculators gave students a "better chance of seeing the pattern and coming up with better conjectures." At Great Lakes University, a Secondary Mathematics Methods instructor also described using Wolfram|Alpha as a tool for student experimentation: "you're making conjectures, you're gathering data, and now you're trying to go about proving it." The Midwestern Research Secondary Mathematics Methods instructor described a big idea of his course as using "technology as a tool for learning."

The Secondary Mathematics Methods instructors at Great Lakes, Midwestern Research, Midwestern Urban, and Southeastern Research described opportunities PSTs had to think critically about using technology in algebra through use of different tasks and activities. At Great Lakes, Midwestern Research, and Southeastern Research Universities, instructors described discussions with PSTs focused on consideration of how different schools provide access to different technologies, so considering what is or is not available and how to consider why and how to use technology to support learning. The Great Lakes instructor described discussions with students asking, "what technology is available [at a school] and what can you do with it? And why use it?" Similarly, the Midwestern Research instructor had discussions asking "What does GSP [Geometers SketchPad] afford? What does – what can you do if you don't have something like this? In terms of developing ideas about co-variation of quantity as a basis for functions." The Southeastern Research instructor explained, "I feel like we try to emphasize not using the technology and the resources for the sake of using them but making sure that there is a purpose and a reason behind why are we using this." The Midwestern Urban instructor described one activity that PSTs engaged in as choosing a particular technology and writing a lesson plan that would use the technology.

Discussion

Our preliminary results show different types of opportunities that PSTs were provided related to the learning of algebraic connections and the use of technology to learn and learn to teach algebra. There was a wide range of opportunities that instructors provided related to algebraic connections: some instructors provided lists of topics and ways that they made connections (e.g., Linear Algebra at Great Lakes); others reported specific activities that engaged PSTs to make connections (e.g., Secondary Mathematics Methods at Midwestern Urban). At

Great Lakes University, mathematics instructors described how they emphasized different types of connections, while the mathematics education instructor focused on how PSTs made connections in his class. At Midwestern Urban University, instructors described connections among not only algebraic topics (e.g., systems of equations, variables), but also practices that can be used in different courses and grade levels (e.g., proofs, generalization), along with how technology can be used to make such connections (e.g., Linear Algebra instructor).

We heard concerns from both mathematics and mathematics education instructors that technology could impede PSTs' learning. Some mathematics education instructors argued, to the contrary, that use of technology enabled PSTs to increase their understanding of algebra topics in ways that were not possible otherwise. At each university there was at least one opportunity for PSTs to think critically about their future educational use of technology, but experiences varied.

Endnote

This study comes from the *Preparing to Teach Algebra* project, a collaborative project between groups at Michigan State (PI: Sharon Senk) and Purdue (co-PIs: Yukiko Maeda and Jill Newton) Universities. This research is supported by the National Science Foundation grant numbers DRL-1109256/1109239 and by the National Science Foundation, Spencer Foundation.

Examining the role of a secondary teacher's image of instructional constraints on his enacted subject matter knowledge

Michael A. Tallman
Oklahoma State University

I present the results of a study designed to determine if there were incongruities between a secondary teacher's mathematical knowledge and the mathematical knowledge he leveraged in the context of teaching, and if so, to ascertain how the teacher's enacted subject matter knowledge was conditioned by his conscious responses to the circumstances he appraised as constraints on his practice. To address this focus, I conducted three semi-structured clinical interviews that elicited the teacher's rationale for instructional occasions in which the mathematical ways of understanding he conveyed in his teaching differed from the ways of understanding he demonstrated during a series of task-based clinical interviews. My analysis revealed that that the occasions in which the teacher conveyed/demonstrated inconsistent ways of understanding were not occasioned by his reacting to instructional constraints, but were instead a consequence of his unawareness of the mental activity involved in constructing particular ways of understanding mathematical ideas.

Key words: Mathematical Knowledge for Teaching; Enacted Knowledge; Instructional Constraints; Trigonometry.

Introduction

> [S]tudents' mathematical learning is the reason our profession exists. Everything we do as mathematics educators is, directly or indirectly, to improve the learning attained by anyone who studies mathematics. Our efforts to improve curricula and instruction, our efforts to improve teacher education, our efforts to improve in-service professional development are all done with the aim that students learn a mathematics worth knowing, learn it well, and experience value in what they learn. So, in the final analysis, the value of our contributions derives from how they feed into a system for improving and sustaining students' high quality mathematical learning (Thompson, 2008, p. 31).

Research in the area of teacher knowledge in mathematics education has progressed significantly since Shulman's conception of *pedagogical content knowledge* (Shulman, 1986). However, this domain of mathematics education scholarship still has much to contribute to the development of instructional, curricular, and pedagogical innovations that seek "to improve the learning attained by anyone who studies mathematics" (ibid.). The overwhelming majority of research in this area has attended to one, or more, of the following foci: (1) characterizing the nature of mathematical and pedagogical knowledge teachers must possess to support students' conceptual mathematical learning (e.g., Ball, Thames, & Phelps, 2008; Fennema & Franke, 1992; Rowland, Huckstep, & Thwaites, 2005; Shulman, 1986, 1887); (2) understanding the experiences by which teachers might construct such knowledge (e.g., Harel, 2008; Harel & Lim, 2004; Silverman & Thompson, 2008); (3) developing assessments to measure teachers' knowledge (e.g., Hill, Ball, & Schilling, 2008; Herbst & Kosko, 2014, Thompson, 2015), and (4) demonstrating the causal link between teacher knowledge and student achievement (e.g., Baumert et al., 2010; Campbell et al., 2014; Hill, Rowan, & Ball, 2005) or instructional quality (e.g., Charalambous & Hill, 2012; Copur-Gencturk, 2015; Even & Tirosh, 1995; Hill et al., 2008). Stated succinctly, research on teacher knowledge in mathematics education has largely focused on what teachers need to know, how they might come to know it, how one might measure it, and the effect of this knowledge on instructional quality and student performance. While these seemingly comprehensive foci are essential to the enterprise of improving students' mathematical learning, they neither identify nor characterize the effect of the factors that mediate the enactment of teachers' knowledge in instructional contexts, which is the only knowledge that has the potential to affect our field's raison d'être: *the mathematics students have the opportunity to learn*. A focus on characterizing, developing, assessing, and discerning the effect of teachers' professional knowledge without attending to the factors that compromise its enactment, while necessary, is not sufficient for ensuring "that students learn a mathematics worth knowing, learn it well, and experience value in what they learn" (ibid.).

The knowledge teachers leverage in the context of practice is regulated by a host of cognitive and affective processes that have thus far not received sufficient attention in the literature on teacher knowledge in mathematics education. Identifying the influences that condition the knowledge teachers utilize in the context of practice, and ascertaining the effect of such influences on the nature and quality of teachers' enacted knowledge, is imperative for satisfying Thompson's (2008) exacting proposal that our research contributions should "feed into a system for improving and sustaining students' high quality mathematical learning" (p. 31). For current scholarship on mathematics teacher knowledge to realize its intended effect of ensuring teachers are equipped to engage students in experiences that support their construction of rich mathematical ways of understanding and their development of productive ways of thinking, it is crucial to apprehend the effect of those factors that condition the enactment of the knowledge teachers *do* possess in addition to characterizing the knowledge teachers *should* possess. Ascertaining the factors that mediate the knowledge that resides in teachers' minds and the knowledge they bring to bear to support students' mathematical learning is indispensible for fashioning well-informed teacher preparation programs and professional development initiatives that take seriously the effect of teacher knowledge and those influences that compromise it. The present study seeks to contribute to this end.

In this paper, I present the results of a study in which I examined the effect of an experienced secondary mathematics teacher's image[1] of instructional constraints on the nature and quality of his enacted subject matter knowledge of trigonometric functions. While there are many factors that potentially mediate the enactment of teachers' professional knowledge, my decision to focus specifically on an in-service teacher's image of instructional constraints was motivated by the well-documented pervasiveness of teachers' resistance to contemporary educational reform initiatives, particularly within British and American educational systems. Such initiatives are often championed by those who conclude that deficits in teacher aptitude and motivation lie at the heart of modest student achievement. Opponents of this perspective contend that teachers operate under progressively crippling circumstances—many of which they consider occasioned by current reforms—that severely obstruct teachers' ability to engage students in high quality learning experiences. For instance, one often hears it said, at least in the United States, that engrained cultural practices, an overreliance on high-stakes testing and accountability, policymakers' aspirations to privatize education, decaying teacher-student relationships, the de-professionalization of teaching, unsupportive administrators and colleagues, insufficient emphasis on early childhood education, inadequate instructional and curricular resources, increasing proportions of students living in poverty, and the escalation of unsupportive parents all impose obstacles that severely limit what many teachers believe they can achieve in the classroom (Hargreaves

[1] The "image of" qualifier suggests my constructivist approach to defining instructional constraints, which I discuss in the section entitled, "Theoretical Framing."

& Shirley, 2009; Nichols & Berliner, 2007; Ravitch, 2010, 2013; Sahlberg, 2004, 2006, 2011; Stigler & Hiebert, 1999). However, the specific ways in which mathematics teachers' appraisal of, and accommodations for, such instructional constraints inhibits them from enacting the full extent of their professional knowledge to support students' learning has not yet been characterized. To address this limitation, the present study explored the following research questions:

RQ 1: Are there incongruities between an in-service secondary mathematics teacher's subject matter knowledge and the subject matter knowledge he enacted while teaching?[2]

RQ 2: If so, in what ways did the teacher's image of instructional constraints condition the nature and quality of his enacted subject matter knowledge?

It is essential in the contemporary climate of mathematics education to apprehend whether teachers do indeed teach what they know. When mathematics teacher educators assume teachers leverage the full extent of their professional knowledge in an uncompromised way, they design preparation programs and professional development experiences that focus on supporting teachers in constructing more advanced knowledge structures—knowledge that ultimately might not inform teachers' instructional practices and thus the mathematics students have the opportunity to learn. A focus on the factors that condition the enactment of teachers' knowledge has the potential to inform instructional and curricular designs that seek not only to advance teachers' knowledge but also to equip them with skills and strategies to minimize the unfavorable effects of such factors.

Theoretical Framing

The "image of" qualifier in the title of this paper suggests my radical constructivist approach to defining instructional constraints. I take the position that environmental circumstances per se in the absence of a teacher's construal of them cannot constrain his or her practice, but the teacher's construction and appraisal of environmental circumstances can and often does. For this reason, I contend that particular circumstances cannot maintain an ontological designation as instructional constraints, however consensual are teachers' construction and appraisal of such circumstances. Therefore, in consonance with radical constructivism's skeptical position on reality, I define instructional constraints as an individual teacher's subjective construction of the circumstances that impede the teacher's capacity to achieve his or her instructional goals and objectives. Such subjective constructions are the only "constraints" that maintain the potential to influence teachers' instructional actions. Accordingly, I locate instructional constraints in the mind of individuals, not the environment. This conceptualization stands in stark contrast to the common perception of instructional constraints as external pressures that exert influence on the quality of teachers' instruction. According to this view, the pressure comes from without instead of from within. My interest in understanding how a secondary teacher's image of instructional constraints conditioned the mathematical ways of understanding and ways of thinking he utilized in the context of teaching necessitated my constructing a model of the teacher's construction of those circumstances he appraised as constraints on his practice.

As a result of my view that instructional constraints are subjective constructions that reside in the minds of teachers, I consider anything that a teacher appraises as an imposition

[2] I note that the identification of incongruities between the teacher's subject matter knowledge and the subject matter knowledge he enacts while teaching is from my perspective. Similarly, characterizing the effect of a teacher's image of instructional constraints on his enacted mathematical knowledge is also a characterization from my perspective.

to achieving his or her instructional goals and objectives to be an instructional constraint. The appraisal need not even be of an external circumstance. A teacher may appraise internal characteristics such as his or her mathematical self-efficacy, social endowments, creativity, tolerance, attitude, perseverance, temperament, empathy, confidence, etc., as imposing limits on the quality of his or her instruction. Since a teacher's appraisal of such intrinsic characteristics is a subjective construction in the same way that a teacher's appraisal of external circumstances is, both types of appraisals have the capacity to influence teachers' practice in the same way.

Methods

My experimental methods proceeded in three phases. In the first phase, I conducted a series of nine task-based clinical interviews (TBCIs) (Clement, 2000; Goldin, 1997; Hunting, 1997) that allowed me to construct a model of the participating teacher's (David's) mathematical knowledge of various topics associated with trigonometric functions. In the second data collection phase, I used video data from 37 classroom observations to construct a model of the mathematical knowledge David utilized in the context of classroom practice. Finally, I employed a phase of three semi-structured clinical interviews to construct a model of David's perception of instructional constraints and to discern the role of this image on the quality of his enacted mathematical knowledge.

The goal of the series of task-based clinical interviews was to facilitate my construction of a model of David's *ways of understanding* and *ways of thinking* (Harel, 2008) relative to angle measure, the outputs and graphical representation of sine and cosine, and the period of sine and cosine. Constructing a model of an individual's cognition by projecting or imputing one's cognitive schemes to the individual constitutes developing a *first-order model* (Steffe & Thompson, 2000). This is in contrast to developing a *second-order model*, in which the researcher attempts to make sense of the individual's actions by interpreting them through the lens of his or her model of the individual, not through his or her own cognitive schemes (ibid.). It is important to note that the goal of the series of task-based clinical interviews I conducted was to construct a second-order model of David's mathematical knowledge. Although I constructed a second-order model of David's mathematics, this model does not constitute a direct representation of David's knowledge, but rather a viable characterization of plausible mental activity from which his language and observable actions may have derived. Constructing such a model involved my generating prior to, within, and among task-based clinical interviews tentative hypotheses of David's ways of understanding that explained my interpretation of the observable products of his reasoning. I developed these provisional hypotheses by attending to David's language and actions and abductively postulating the meanings that may lie behind them. I designed and modified tasks for subsequent interviews to test, extend, articulate, and refine my tentative hypotheses of David's mathematical knowledge.

All task-based clinical interviews took place in David's classroom after school on the days that best suited his schedule. I attempted to schedule the interviews so that there was at least one day between each to accommodate for ongoing analysis, and accomplished this with the exception of the last two task-based clinical interviews. In each interview, I obtained video recordings that captured David's writing, expressions, and gestures. I also created videos of my computer screen via *QuickTime Player* to capture the *didactic objects* (Thompson, 2002) David and I discussed as well as any work David completed on the computer. Additionally, I collected and scanned all written work that David produced during the interviews.

I collected daily video recordings of two of David's Honors Algebra II class sessions over a seven-and-a-half-week period, which resulted in 37 videos of classroom teaching. The only days I did not intend to collect videos of David's teaching were those days students were testing or the days David was teaching content unrelated to the angle measure, sine, or cosine. While the classroom observations did not demand the type of ongoing analysis that was part and parcel of the series of task-based clinical interviews, I documented, in the form of memos, the mathematical understandings and ways of thinking David afforded his students the opportunity to construct. I must emphasize that I characterized the ways of understanding and ways of thinking David *allowed* his students to construct, and not the understandings and ways of thinking his students *actually* constructed. In essence, I documented the understandings that I would be able to construct, and the ways of thinking that I would be able to develop, were I an engaged student in the class with sufficient background knowledge, uninhibited by unproductive understandings or disadvantageous ways of thinking.

The objective of the third phase of my experimental methodology was to obtain data that allowed me to construct a model of David's image of those aspects of his environmental context that he appraised as constraints on the quality of his instruction, and to determine the way in which this image conditioned the mathematical knowledge he employed in the context of teaching. Constructing such a model and determining the effect that David's image of instructional constraints had on his enacted subject matter knowledge involved my conducting a series of three semi-structured clinical interviews after David completed his instruction of trigonometric functions.

The content of these semi-structured clinical interviews was heavily informed by my analysis of the data I obtained from the series of task-based clinical interviews as well as from David's teaching. Based on my analysis of this data, I selected video clips to discuss with David during the clinical interview sessions to discern the role of David's image of instructional constraints on the quality of his enacted mathematical knowledge. I devoted particular attention to ascertaining David's rationale for those instructional actions in which the mathematics he allowed students to construct differed from the mathematical ways of understanding he demonstrated during the series of task-based clinical interviews. It is essential to point out that I did not assume David recognized the discrepancies I noticed in the videos excerpts I selected to discuss. Therefore, after having presented pairs of videos to David that I believed demonstrated him conveying/supporting discrepant meanings, I asked him to compare the ways of understanding he communicated in both videos. My rationale for doing so was to determine if David recognized the same inconsistencies that I noticed in the ways of understanding he demonstrated/conveyed.

Analytical Framework

I leveraged explicit formalizations of *quantitative reasoning* (Smith & Thompson, 2007; Thompson, 1990, 2011) in the design of the present study and my analysis of its data. A growing body of research (e.g., Castillo-Garsow, 2010; Ellis, 2007; Moore, 2012, 2014; Moore & Carlson, 2012; Oehrtman, Carlson, & Thompson, 2008; Thompson 1994, 2011) has identified quantitative reasoning as a particularly advantageous way of thinking for supporting students' learning of a wide variety of pre- and post-secondary mathematics concepts. Additionally, this body of research has demonstrated the diagnostic and explanatory utility of quantitative reasoning as a theory for how one may conceptualize quantitative situations.

Quantitative reasoning is a characterization of the mental actions involved in conceptualizing situations in terms of *quantities* and *quantitative relationships*. A *quantity* is an attribute, or quality, of an object that admits a measurement process (Thompson, 1990). One has conceptualized a quantity when she has identified a particular quality of an object and has in mind a process by which she may assign a numerical value to this quality in an appropriate unit (Thompson, 1994). It is important to note that quantities do not reside in objects or situations, but are instead constructed in the mind of an individual perceiving and interpreting an object or situation. Quantities are therefore conceptual entities (Thompson, 2011).

Conceptualizing a quantity does not require that one assign a numerical value to a particular attribute of an object. Instead, it is sufficient to simply have a measurement process in mind and to have conceived, either implicitly or explicitly, an appropriate unit. *Quantification* is the process by which one assigns numerical values to some quality of an object (Thompson, 1990). Note that one need not engage in a quantification process in order to have conceived a quantity, but must have in mind a quantification process whereby she may assign numerical values to the quantity (Thompson, 1994). Defining a process by which one may assign numerical values to a quantity often involves an operation on two other quantities. In such cases we say that the new quantity results from a *quantitative operation*—its conception involved an operation on two other quantities. Quantitative operations result in a conception of a single quantity while also defining the relationship among the quantity produced and the quantities operated upon to produce it (Thompson, 1990, p. 12). It is for this reason that quantitative operations assist in one's comprehension of a situation (Thompson, 1994). It is important to note the distinction between a quantitative operation and a numerical or *arithmetic operation*. Arithmetic operations are used to calculate a quantity's value whereas quantitative operations define the relationship between a new quantity and the quantities operated upon to conceive it (Thompson, 1990).

Results

On several occasions David demonstrated ways of understanding during the series of task-based clinical interviews (TBCIs) that were inconsistent or incompatible with the ways of understanding his instruction supported. I selected three such occasions to discuss with David during a phase of clinical interviews I conducted after David completed his instruction of trigonometric functions. Specifically, I presented David with three pairs of videos, each containing an excerpt from the series of task-based clinical interviews and an excerpt from his classroom teaching. From my perspective, these pairs of videos exemplified David communicating discrepant mathematical meanings. My purpose in presenting David with these pairs of videos was to determine if he willingly compromised the quality of his enacted mathematical knowledge in response to the circumstances and events he appraised as instructional constraints. The following is a presentation of my analysis of our conversation around two of these three pairs of video excerpts. I do not discuss my analysis of David's and my conversation around the third pair of video excerpts since the conclusions drawn therefrom are consistent with those I present below.

I presented David with a video excerpt from Lesson 1 in which he explained that the measure of an angle is unit-less since the standard linear units one uses to measure the length of the subtended arc and the circumference of the circle containing the subtended arc "cancel" when one computes the ratio of these lengths (see Excerpt 1). During this episode David was discussing the image displayed in Figure 1.

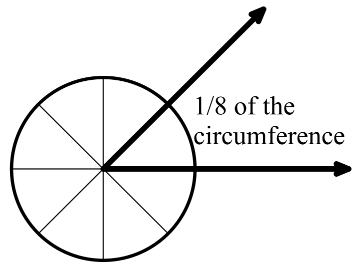

Figure 1. Angle measure as a fraction of the circle's circumference.

Excerpt 1

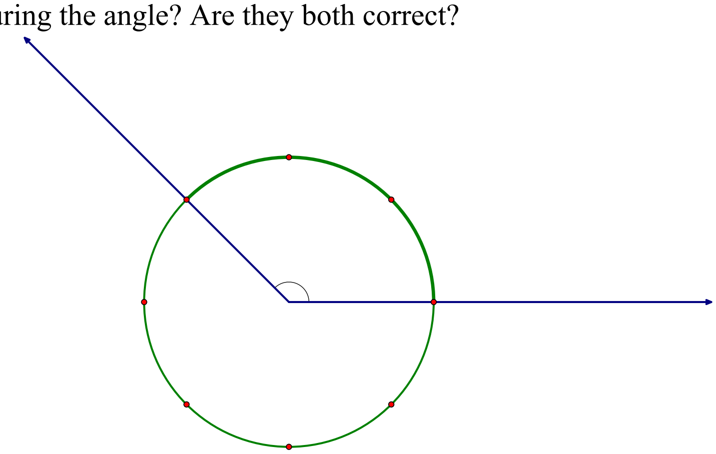
David:	So the angle subtends $1/8^{th}$ of the circumference of the circle. (*Pause*) Now do units matter here? … Why do units not matter here?
Student:	'Cause you're using a proportion.
David:	Why does that matter? …
Student:	Because even though you're making the radius larger you're also making the whole circle larger.
David:	So what happens when you do your proportion? Think in science class. (*Long pause*) 'Cause we're comparing it to our circumference, right? We're comparing arc length to circumference? What would happen to the units then? (*Long pause*) So lets just say for the sake of argument $1/8^{th}$ could be a circumference of, uh, a circumference of 16, that would mean that the arc length would be two, if it's an eighth. So two inches divided by 16 inches is?
Student:	One-eighth.
David:	One-eighth. What are the units now? (*Long pause*) What happens when you put—and again think in terms of science class—what happens when you put two inches divided by 16 inches (*writes* "2in/16in"), your science teacher would say that's $1/8^{th}$. What are the units?
Student:	It doesn't matter.
David:	It does matter. What are the units?
Student:	Inches.
David:	Inches divided by inches give you inches?
Student:	No.
David:	What does it give you?
Student:	One-eighth.
David:	What are the units?
Student:	It doesn't have units.
David:	It doesn't have units? Why not?
Student:	Because the inches cancel.
David:	'Cause inches cancel inches! … 'Cause I'm not just measuring arc length. What am I measuring? I'm measuring arc length and comparing it to what?
Student:	Circumference.
David:	Circumference! How am I comparing them?
Student:	By length.
David:	By length? What operation is going on here? Am I subtracting the circumference? (*Pause*) It's division! We're creating a ratio! Then do the units matter?
Student:	No. …

David:	What happens when we do the ratio? The units stop mattering, right? Because the units end up canceling. We're interested in the ratio. We're not interested in the units from the ratio because the units are going to reduce.

Excerpt 1 demonstrates that David did not provide students with an opportunity to interpret the division of subtended arc length and circumference as the numerator measured in units of the denominator but rather as the ratio of two values. David therefore supported students' understanding of the ratio of subtended arc length to circumference as an arithmetic operation as opposed to a quantitative operation. After showing David the video, I asked him to describe the meaning he conveyed. David's response, "Because we're comparing proportions of arc length to circumference, then we no longer care about the units of measure" led me to believe that he interpreted the video in the way I expected him to. I then showed David a video excerpt from TBCI 3 in which he responded to the task in Table 1. Excerpt 2 contains David's response to the task.

Table 1
Task 5 from TBCI 3

Nick claims that the measure of the angle shown is $3/8^{\text{ths}}$ and Meghan claims that the measure of this angle is three. How is Nick thinking about measuring this angle? How is Meghan thinking about measuring the angle? Are they both correct?



Excerpt 2

Michael:	Taking a look at this picture, what do you see in this picture here?
David:	Uh, I see an, a central angle inscribed inside a circle. Uh, we have an arc, um, that seems to be in a bolder line that, um, subtends the circle and that would be our angle measure.
Michael:	Okay. What about the red dots?
David:	Uh, the red dots seem to be evenly spaced around the, um, around the circle. So it appears that we have basically divided the circle into, um, eight pieces. …
Michael:	Okay. So let's assume that that's the case. Let's assume that these red dots are evenly spaced around the circumference of the circle so that we're splitting up the circumference into eight equal pieces. And let's suppose that Nick claims that the measure of this angle is $3/8^{\text{ths}}$ and let's say that Meghan claims that the measure of this angle is three. Um, how might Nick, who claimed that the measure of the angle is $3/8^{\text{ths}}$, how might he be thinking about measuring this angle?

David:	(*Pause*) Well if he's thinking of it as 3/8^{ths} then he is thinking that the arc is 3/8^{ths} of the whole. So his unit of measure is not the red dots, his unit of measure is the full circumference. Uh, so, um, where Meghan is saying it's three so her unit of measure is the, um, individual, um, arc lengths, uh, between the dots. And so she's saying that the arc is three units of measure where eight units of measure, where eight make up the whole. And he is saying it's 3/8^{ths} of the whole. And so his unit of measure is the whole not the parts.
Michael:	So are they both correct in their, in saying that the measure of this angle is, in Nick's case 3/8^{ths} and in Meghan's case three?
David:	Yes. It's just that they're using different units.

David's remarks in Excerpt 2 suggest that he recognized that Nick measured the subtended arc length in units of circumference and Meghan measured the subtended arc length in units of 1/8^{ths} of the circumference. David therefore assimilated Nick and Meghan's claims as two different instantiations of the same process—measuring the subtended arc length in a particular unit—and in doing so demonstrated a quantitative way of understanding angle measure. After having watched the video clip in which he responded to the task in Table 1, David reluctantly made the remark in Excerpt 3.

Excerpt 3

David:	Now that I'm thinking about it and listening to what I said, I'm not even sure if I would call the full circle a unit. I think he's thinking more in terms of a proportion of the whole. I'm not really even sure if I want to call it a unit. … Meghan is using a unit; she's using three quips or whatever. … He's thinking of it as a proportion. Like I said I'm not sure if I would even want to call it a unit.

After having reflected for a few minutes, David recognized, "The only units that 3/8^{ths} could go with is circumference. It's 3/8^{ths} of circumference. That's the only unit, if we were to assign it a unit that's the only unit that I can think of that would be appropriate." David's hesitation and reluctance suggests that his interpretation of the way of understanding he conveyed in his response to the task in Table 1 was not entirely consistent with my interpretation. David nonetheless acknowledged that the circumference is only unit to which Nick's measure of 3/8^{ths} could refer.

Once I assessed the extent to which David's interpretation of the video excerpts was consistent with mine, I asked him determine whether the ways of understanding he conveyed in the video clip from Lesson 1 (wherein he explained that angle measures are unit-less because units cancel when one computes the ratio of subtended arc length to circumference) was consistent with the way of understanding he conveyed in the video clip from TBCI 3 (in which he recognized that both Nick and Meghan measured the length of the subtended arc, albeit in different *units*).

Excerpt 4

Michael:	Is the way of understanding that you discuss in this clip (*TBCI 3*) consistent with the way of understanding you conveyed in this one here (*Lesson 1*)?
David:	Um, yeah because we're trying to get to like Nick's way of thinking. So like Nick was just talking about the proportion and how he like didn't really kind of have units. … So we were kind of leading to Nick's way of thinking about it so it does kind of match along with Nick's way of thinking.

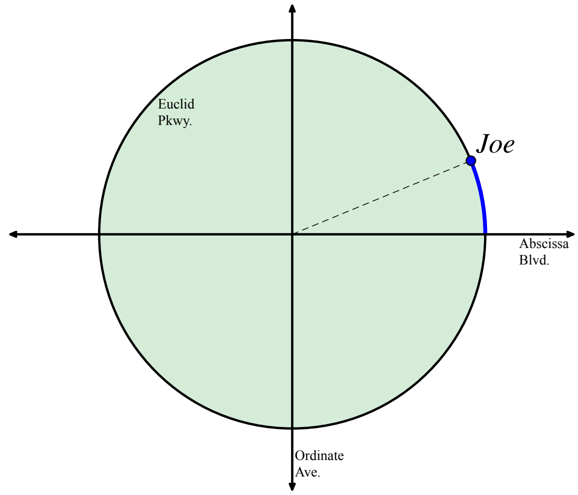
David's response in Excerpt 4 reveals that he did not recognize the discrepancy I noticed in the way of understanding angle measure he conveyed in both video excerpts. David interpreted 3/8^{ths}, the measure of the angle Nick proposed, as being a unit-less measure, which is consistent with the way of understanding he emphasized in the video clip from Lesson 1. I subsequently asked David to describe what he would change about the instructional episode depicted in the video excerpt from Lesson 1. David responded, "I don't know if I would actually change any of it because I do like the fact that when we get to radians that radians are kind of without units. So I do like the fact that we're talking about the units kind of canceling." David's failure to recognize that he conveyed what I consider vastly different meanings of angle measure in the two video excerpts, as well as his assertion that he would not change anything about his instruction from the Lesson 1 video, even after having seen a video in which he demonstrated a productive way of understanding, suggests that David was not consciously aware of the mental actions that comprise the meanings he intended to promote in his instruction. Such conscious awareness would likely have equipped David with the cognitive schemes to recognize the discrepant and incompatible ways of understanding he conveyed in both video excerpts.

I subsequently presented David with a video from the fourth task-based clinical interview in which he used an applet (see Table 2) to successfully approximate the values of sin(0.5) and cos(¾). During this interview David interpreted the task of approximating the value of sin(0.5) as, "Estimate how many radius lengths is Joe north of Abscissa Boulevard when the angle traced out by his path is 0.5 radians." In particular, David interpreted the 0.5 as representing the number of radius lengths that Joe had traveled along Euclid Parkway and sin(0.5) as representing Joe's distance north of Abscissa Boulevard in units of radius lengths. David similarly interpreted the task of approximating the value of cos(¾) in the following way: "Estimate how many radius lengths Joe is to the east of Ordinate Avenue when his path has traversed an arc that is 3/4^{ths} times as long as the radius of Flatville." David's response to the task of using the applet in Table 1 to approximate the values of sin(0.5) and cos(¾) suggests that he had constructed the outputs of sine and cosine as quantities; that is, as measurable attributes of a geometric object. After David watched the video except from the fourth task-based clinical interview, he described the way of understanding he demonstrated in a way that was consistent with my interpretation.

Table 2

Applet Designed to Support a Quantitative Understanding of Sine and Cosine Values

Suppose Joe is riding his bike on Euclid Parkway, a perfectly circular road that defines the city limits of Flatville. Ordinate Avenue is a road running vertically (north and south) through the center of Flatville and Abscissa Boulevard is a road running horizontally (east and west) through the center of Flatville. Assume Joe begins riding his bike at the east intersection of Euclid Parkway and Abscissa Boulevard in the counterclockwise direction.



After David watched the video excerpt from the fourth task-based clinical interview, I presented him with a video excerpt from Lesson 7 (which occurred four days after the fourth task-based clinical interview) in which he defined the outputs of sine and cosine relative to the following two cases: (1) when the radius of the circle centered at the vertex of an angle has a measure of one unit and (2) when this radius does not have a measure of one unit. Specifically, in the video excerpt David claimed that if the radius of the circle has a measure of one unit, then the sine and cosine values of the angle's measure are respectively equal to the y- and x-coordinates of the terminus of the subtended arc. David then explained that if the radius of the circle centered at the angle's vertex does not have a measure of one unit, then the values of sine and cosine are given by the respective ratios of the y- and x-coordinate of the terminal point to the length of the radius. It is noteworthy that David's explanation did *not* support students in conceptualizing sine and cosine values as the measure of a quantity in a particular unit. In other words, David's explanation in Lesson 7 did not support students in being able to answer the question, "What are the attributes to which sine and cosine values may respectively be applied as measures and in what unit are these attributes being measured?" In contrast to the quantitative way of understanding the outputs of sine and cosine David demonstrated in the fourth task-based clinical interview, during Lesson 7 David conveyed sine and cosine values as respectively representing y- and x-coordinates of the terminal point, or as arithmetic operations (i.e., $\sin(\theta) = y/r$ and $\cos(\theta) = x/r$).

After David viewed the two video excerpts, I asked him to determine if the way of understanding he supported in the excerpt from Lesson 7 differed from the understanding he employed to approximate the value of sin(0.5) and cos(¾) in the excerpt from the fourth task-based clinical interview (Excerpt 5).

Excerpt 5

Michael:	Is there any way that the understanding of sine and cosine you convey in this clip (*Lesson 7*) is different from what you did here (*Task-Based Clinical Interview 4*)?
David:	Only in the units of measure that we started with to obtain the ratio, but in the end we end up with an output that is a proportion of the entire radius. So in the end, no [they aren't different]. In the end they end up giving me the same thing.

David did not appear to recognize the way of understanding he demonstrated in the first video excerpt as being fundamentally different from the way of understanding he conveyed in the second. David's remark in Excerpt focused primarily on the outcome of his application of two discrepant (from my perspective) ways of understanding instead of attending to the ways of understanding themselves. Like several occasions in other interviews in which David demonstrated an incapacity to attend to ways of understanding—either his own or his students'—his remarks in Excerpt demonstrate that he had not achieved clarity relative to the mental activity involved in his own ways of understanding, nor of those he intended to support in his teaching. Had David done so, he would likely have been positioned to notice the discrepant meanings he conveyed in the videos I presented. David similarly failed to identify the inconsistent meanings he communicated in the other two pairs of video excerpts I presented to him.

Discussion

To investigate the role of David's image of instructional constraints on his enacted subject matter knowledge, I provided opportunities for him to rationalize occasions in which the ways of understanding he supported in his teaching differed from the ways of understanding he demonstrated during a series of task-based clinical interviews. My analysis of our conversation around all three pairs of video excerpts revealed that David failed to notice the discrepancy in the ways of understanding he conveyed/demonstrated in these excerpts. David's inability to recognize such discrepancies suggests that he was not consciously aware of the mental actions that comprise the meanings he intended to promote in his teaching, as such awareness would likely have equipped David with the cognitive schemes necessary to recognize the inconsistent and often incompatible ways of understanding he conveyed in the excerpts we discussed. My analysis further revealed that the occasions in which David conveyed/demonstrated discrepant, inconsistent, or incompatible ways of understanding were not occasioned by his responding to or accommodating for the circumstances and events he appraised as constraints on his practice, but were rather a consequence of his unawareness of the mental activity involved in constructing particular ways of understanding mathematical ideas.

The results of this study suggest that inconsistencies between mathematics teachers' subject matter knowledge and their enacted subject matter knowledge do not necessarily result from teachers' making conscious concessions to the quality of their enacted knowledge in the process of accommodating for the circumstances and events they appraise as constraints on their practice. Such inconsistencies might be a byproduct of teachers' unawareness of the mental activity that constitute their ways of understanding mathematical ideas. Accordingly, the main findings of this study suggest that the mathematical knowledge required for effective teaching involves more than powerful understandings of mathematical ideas; it involves an awareness of the mental actions and operations that constitute these understandings. Therefore, what might be called *mathematical content knowledge for teaching* entails both strong subject matter knowledge as well as an awareness of the mental processes that characterize such knowledge. Pre-service mathematics teacher educators and in-service professional development specialists should thus make an effort to provide opportunities for teachers to have explicit answers to questions like, "When my students read the symbols 'sin(θ)' what do I want them to imagine?" and "When my students look at an angle and think about measuring it in radians, what do I want them to visualize?" While it is beyond the scope of this paper to substantiate this claim, I believe that Piaget's (2001) notion of *reflected abstraction* can be leveraged as a particularly powerful instructional design principle for supporting teachers in becoming consciously aware of the mental processes that comprise their own ways of understanding mathematical ideas. Providing opportunities for teachers to achieve such conscious awareness of the mental activity involved in particular ways of understanding might minimize the potential that teachers will not leverage the full extent of their subject matter knowledge to support students' mathematics learning.

Mathematicians' ideas when formulating proof in real analysis

Melissa Troudt
University of Northern Colorado

This report presents some findings from a study that investigated the ideas professional mathematicians find useful in developing mathematical proofs in real analysis. This research sought to describe the ideas the mathematicians developed that they deemed useful in moving their arguments toward a final proof, the context surrounding the development of these ideas in terms of Dewey's theory of inquiry, and the evolving structure of the personal argument utilizing Toulmin's argumentation scheme. Three research mathematicians completed tasks in real analysis thinking aloud in interview and at-home settings and their work was captured via video and Livescribe technology. The results of open iterative coding as well as the application of Dewey's and Toulmin's frameworks were three categories of ideas that emerged through the mathematicians' purposeful recognition of problems to be solved and their reflective and evaluative actions to solve them.

Key words: proof construction, Toulmin argumentation scheme, inquiry, real analysis, mathematicians

Writings of mathematicians and mathematics education researchers note that the mathematical proving process involves a formulation of ideas; specifically, for mathematicians, there is a reflection, reorganization of ideas and reasoning that "fill in the gaps" so a proof will emerge (Twomey Fosnot & Jacob, 2009). Byers (2007) described an idea as the answer to the question "what's really going on here?", and Raman, Sandefur, Birky, Campbell, and Somers (2009) observed three critical moments in the proving process in which there were opportunities for a proof to move forward. Tall and colleagues (2012) gave a description of proof for professional mathematics that "involves thinking about new situations, focusing on significant aspects, using previous knowledge to put new ideas together in new ways, consider relationships, make conjectures formulate definitions as necessary and to build a valid argument" (p. 15). Rav (1999) stated that the term "proof" can describe the written product used to "*display the mathematical* machinery for solving problems and to justify that a proposed solution to a problem is indeed a solution" (p. 13, italics in original); however the process of constructing proof involves informal and formal arguments to find methods to attack the problem as well as incomplete proof sketches (Aberdein, 2009). Despite these writings, little research describes the context around the formulation of ideas that a professional mathematician finds useful and how these ideas influence the development of the mathematical argument. This study focused on describing mathematicians' development of these ideas when constructing proofs in real analysis made evident in changes in the structure of the argument (Toulmin, 1958/2003) utilizing Dewey's (1938) theory of inquiry to describe the problem situation.

Research Questions

Part of a larger project, this report focuses on the findings for the research questions: What ideas move the argument forward as a professional mathematician's personal argument evolves? What problem situation is the mathematician currently entered into solving when s/he articulates and attains an idea that moves the personal argument forward?

Theoretical Perspective

This research conceived of the mathematical proving process as an evolving personal argument. The *personal argument* is a subset of one's total cognitive structure associated with the proof situation (described as a *statement image* by Selden and Selden (1995)) that the individual deems relevant to making progress in proving the statement. The personal argument is graded in that some aspects of the statement image may be central and others may lie on the periphery. The personal argument evolves or moves forward when an individual develops an idea that s/he sees as useful in making progress in proving the statement. The focus of this study was to describe the ideas incorporated and the inquirential context surrounding that development.

Toulmin's (1958/2003) argumentation model provided a means of describing structurally the evolution of the personal argument as the individual incorporated new ideas. The framework notes the content of the statements given in the argument (either explicitly or not) as well as the purposes that those statements serve. The framework classifies statements of an argument in six different categories. The claim (C) is the statement or conclusion to be asserted. The data (D) are the foundations on which the argument is based. The warrant (W) is the justification of the link between the grounds and the claim. Backing (B) presents further evidence that the warrant appropriately justifies that the data supports the claim. The modal qualifiers (Q) are statements that indicate the degree of certainty that the arguer believes that the warrant justifies the claims. The rebuttals (R) are statements that present the circumstances under which the claim would not hold.

New ideas result from periods of ambiguity or when engaged in non-routine problem solving (Byers, 2007; Lithner, 2008). John Dewey (1938) posited in his theory of inquiry that persons engage in two types of experiences: non-cognitive experiences (everyday life) and inquirential experiences (engagement in the intentional process to resolve doubtful situations). Moreover, the theory of inquiry insists that new knowledge or ideas are developed when one is engaged in active, productive inquiry into a problem. The inquirential process involves the cyclical process reflecting on problem situations to select or create tools to apply to the situation; acting to apply those tools (actively or hypothetically); and evaluating the effectiveness of the tools (Hickman, 1990). The term tool encompasses theories, proposals, actions, or knowledge chosen to be applied to a situation. Persons engaged in everyday, non-inquirential thought may also act and deploy tools; however, choosing and deploying tools is not an experiment requiring reflection and constant evaluation. Dewey's theory provided a framework for understanding the context surrounding the emergence of new ideas from the participant's point of view.

Related Literature

This research followed the lead of other researchers who have conceived of the proof construction process as a particular type of problem solving (i.e. Savic, 2012; 2013; Weber, 2005). Selden and Selden (1995; 2013) maintained that there is a close relationship between problem solving and proof, and that two kinds of problem solving could occur in proof construction: solving the mathematical problems and converting an informal solution into a formal mathematical product. Building upon extensive work in understanding the problem solving process and investigating the problem solving processes of twelve mathematicians, Carlson and Bloom (2005) developed a Multidimensional Problem Solving framework providing a description of the cyclical progression through the phases of problem solving (orientation, planning, executing, and checking), cycling, and problem-solving attributes.

Savic (2013) found that the four phases of Carlson and Bloom's framework could be used to code and describe most portions of the proving process. However, he found some differences including the mathematician cycling back to orienting after a period of incubation and one participant not completing the full cycle; Savic hypothesized additional problem solving phases could be added.

Some research has been conducted and documented the existence of and provided initial descriptions of the types of ideas that this study sought to describe. Raman (2003) characterized three types of ideas involved in the production of a proof: heuristic ideas (ideas based on informal understandings linked to private aspects of proof), procedural ideas (ideas based on logic and formal manipulations), and key ideas (heuristic ideas that can be mapped to formal proofs). In later work Raman and colleagues (Raman, Sandefur, Birky, Campbell, & Somers, 2009) identified the potential for three critical moments when constructing proof (1) attaining a *key idea* (later termed *conceptual insight*; Sandefur, Mason, Stylianides, & Watson, 2012) that gives a sense of why the statement is true; (2) gaining a *technical handle* for communicating a key idea, and (3) the culmination of the argument into a standard form. The potential for a key idea to exist apart from a technical handle exists when a prover is engaged in some informal mathematical reasoning. Sandefur et al. demonstrated how students could achieve alignment amongst the conceptual insight and technical handle when using examples in their proving process. This work as documented critical moments that may occur in the proving process characterized by the generation of certain types of ideas. Sandefur and others later showed how example-use can aid students in developing and utilizing these ideas.

Although they did not describe them as ideas, Inglis, Mejia-Ramos, & Simpson (2007) found mathematics graduate students used warrants based on both formal mathematical deductions (*deductive warrants*) and non-deductive reasoning including inductive reasoning (*inductive warrants)*and intuitive observations or experiments with some kind of mental structure (*structural-intuitive warrants*). Noting these ideas' existence is interesting but calls for further research into descriptions of how these ideas are developed and what kinds of ideas are deemed important when formal or informal reasoning is utilized. It is unclear whether these ideas identified are the only useful ideas. Additionally, there is a need for more description of the thinking and perception of the problem situation surrounding the emergence and evaluation of these ideas, how these ideas are tested and utilized in the development of the argument.

Methods

Three professional mathematicians with faculty appointments at four-year universities who specialized in researching or in teaching courses in real analysis served as the participants for this study. Each participant worked on a task or tasks in a "think-aloud" interview setting, continued to work on the tasks on their own, turned in their at-home work captured via Livescribe technology, participated in a follow-up interview replaying the video and Livescribe capture of their previous work, and repeated this process with new tasks in the next interview. Each participant worked on three to four tasks in total.

Data analysis proceeded in two phases. In the preliminary analysis of the participants' work on the tasks, I noted moments where participants articulated insights, observations, or hypotheses, and these acted as markers in the transcripts. I hypothesized Toulmin models of the participants' personal argument as well as the inquiriential context while these ideas were formulated (perceived problem, contributing actions and tools, and anticipated outcomes of applying the tools) prior to and following these markers. These hypotheses informed the questions asked at the follow-up interview. In the primary analysis, the follow-up interviews provided information to complete and modify the initial analyses. For each task, I wrote stories of the participant's complete work on the task sectioned by the ideas in order to capture the evolution of the argument. I conducted open iterative coding of each idea, the problem situation encountered, the tools that influenced the generation or articulation of the idea, and the anticipated outcome of said tools. Most analysis was inductive; however, I borrowed language from the literature when elements fit the descriptions given by other authors. I analyzed across the ideas of each participant and across participants along the common tasks to look for emerging themes and patterns. This paper reports findings regarding the types of ideas formulated and the problems encountered when ideas were articulated.

Results

In presenting these results, I first give an overview of the characteristics of the ideas that moved the argument forward and then brief descriptions of each idea category and idea type. I illustrate how these ideas developed through one participant's work on a task. Finally, I describe the problems that participants were entered into solving when they developed these ideas.

Ideas that moved the argument forward

The ideas that moved the argument forward either were accompanied by a structural shift in the personal argument captured by a Toulmin diagram, provided a means for the participant to communicate their personal argument in a logical manner, gave a participant a sense that his way of thinking was fitting, or were explicitly referred to by the participant as a useful insight. While pictures, examples, or individual actions were not included as ideas, the insights extracted from performing and reflecting upon these tools or a collection of tools were included. Ideas were coded in terms of the work they did for the participant. In total, I identified fifteen sub-type ideas grouped into three categories: ideas that focus and configure, ideas that connect and justify, and monitoring ideas (see Table 1). Note that three of the idea sub-types that connect and justify are meant to keep in the spirit of the descriptions given by Inglis et al. (2007), *inductive warrants, structural-intuitive warrants, and deductive warrants*.

An action or evaluation of that action from one particular moment could solve multiple problems or give rise to multiple feelings. Therefore, multiple idea-types at times characterized a single moment. For example, an insight that provided a *deductive warrant* could also give the prover a sense of *I can write a proof*.

Dr. C's work on the additive implies continuous task

To illustrate some examples of these idea-types and the mechanism for their development and incorporation into the personal argument, consider Dr. C's work on the task: *Let f be a function on the real numbers where for every x and y in the real numbers, f(x + y)= f(x)+ f(y). Prove or disprove that f is continuous on the real numbers if and only if it is continuous at 0.*

Upon his initial reading of the problem, Dr. C declared that he believed the statement was true for the rational numbers but not generally true for the real numbers.

> Dr. C: I was thinking about the well-known fact that the only continuous linear functions in the reals to the reals are those of the form $y = mx$ for some fixed m. And one shows that those are continuous on the rationals fairly easy, linear functions are continuous on the rationals pretty easily by doing some induction.

Table 1
Descriptions of ideas that moved the argument forward sub-types

Idea sub-type	Description
Ideas that focus and configure	Ideas that gave a sense of what was relevant, what claims to connect to the statement, fitting strategies to achieve connections, and how to structure and articulate the argument
Informing statement image	Ideas that broadened or narrowed the conception of the situation.
Task type	Assessments about what tools or ways of approaching developing connections between the conditions and the claim would be fitting
Truth proposal	Participant-generated conjectures about the validity of a given claim based on a warrant of any type
Identifying necessary conditions	A sense that "The statement can't possibly be true unless this condition is fulfilled"
Envisioned proof path	A proposal of a series of arguments that will lead to a solution that may be missing connections
Logical structure & representation system of proof	Decisions regarding structuring and communicating the formal argument
Ideas that connect and justify	Warrants and backing, the means of connecting data with claims
Deductive warrant*[1]	Reasoning based on generalizable logical statements
Inductive warrant*	Reasoning based on specific examples
Structural-intuitive warrant*	Reasoning based on a feeling that is informed by structure or experience
Syntactic connection	Symbolic manipulations deemed useful to connect given evidence to a claim that may not be supportable by deductive reasoning or attend to the mathematical objects that the symbols represent
Proposed backing	Proposed support for previously identified non-deductive warrants or vague senses of what would underlie a possible warrant
Ideas that monitor the argument evolution	Ideas or feelings about the mathematicians' progress
Truth conviction	Personal belief as to why a statement must be true
"I can write a proof"	A feeling of formulating the connections necessary to communicate the argument in a final proof
Unfruitful line of inquiry	An idea that persuaded the participant that the tools or actions pursued or considered were not optimal for achieving the set goal
Support for line of inquiry	A sense that one's actions were fitting

[1] The asterisks indicate that the titles of idea sub-types of deductive warrant, inductive warrant, and structural-intuitive warrant borrow from the descriptions of reasoning given by Inglis et al. (2007).

Dr. C was reflecting on the problem of determining the truth of the statement. Dr. C based his initial claim about the truth of the statement to be proven on a connection between the additive property of the function and linearity of functions as well as his past experience with linear functions. This was coded a *truth proposal* idea-type based on a *structural-intuitive warrant*. The Toulmin structure is after this utterance is given in Figure.

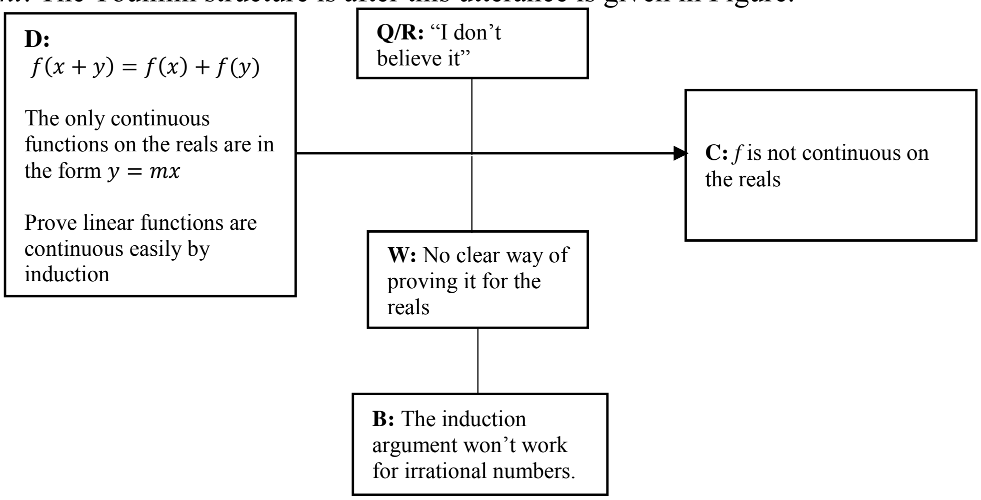

Figure 1. Toulmin model of Dr. C's personal argument with initial truth proposal.

Dr. C then set about the task of determining a means of supporting his initial inclination by looking for a counterexample to the statement. He proposed a counterexample function that was continuous at zero and the rational numbers but discontinuous on the reals, namely, the piecewise defined function that has an output of zero when the input is rational and the value of the input otherwise.

Dr. C: Well, I knew that it had to work for the rationals. So I thought I would try something that had one definition in the rationals and something else in the irrationals. And it seemed to me that *x* in one case and zero in the other case would be the easiest thing to try as a first effort

He then moved to verify the function could serve as a counterexample to the statement by checking to see if it satisfied the additive property. He chose to input two irrational numbers whose sum was rational and found the function not possess the additive property. He paused for a moment while he was working before concluding that the given statement might be true.

Dr. C: It turned out that didn't work. And if the easier ones didn't work, then the harder ones probably wouldn't either. Matter of fact, if the easier one didn't work, then it seemed likely that none of the harder ones would work.

I: Okay. So I was going to ask about that. So after you found that it didn't work, it didn't satisfy it. You paused for a while. Was it because you were trying to think of different examples, or were you convincing yourself that it-

Dr. C: Yeah. I was trying to convince myself that if this didn't work, then nothing would.

Dr. C recognized an *unfruitful line of inquiry*, moved back to the problem of determining the truth of the statement. The deliberation was inaudible but Dr. C reflected on his previous ideas about the types of functions that would not be continuous in light of the results of exploring the example function. He gave a new *truth proposal* which was based on the generated example coupled with his knowledge of functions (an *inductive warrant)*. These moment characterized ideas that moved the argument forward as illustrated in the Toulmin model in Figure.

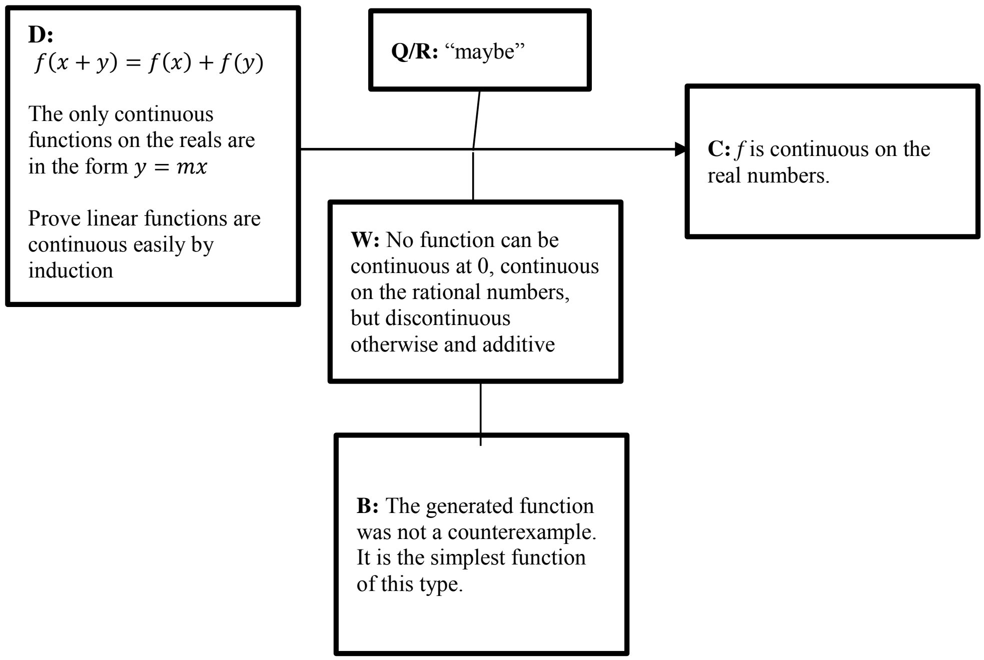

Figure 2. Toulmin model of Dr. C's personal argument after reevaluating his truth proposal.

He then moved to try to prove the statement was true (look for a deductive warrant). In exploring, he developed a string of inequalities based on instantiations of the definition of continuity and logical mathematical deductions, and he identified the *necessary condition* that $\lim_{\varepsilon \to 0} f(\varepsilon) = 0$. He recalled a proof that $f(0) = 0$ and that the function was given to be continuous at zero to fulfill the condition. Dr. C symbolically evaluated that his written assertions were correct and declared a sense that he could now write the proof based on his deductive warrants. Because his work in proving the task was based on deductive warrants within the representation system of proof, the writing of the proof did not require the formulation of any new ideas.

Process of developing ideas: Problems encountered

No distinct pattern involving the types of problems and tools that contributed to the generation of certain ideas. However, the ideas that moved the argument forward were developed as a result of the pattern of a participant proposing or articulating an idea or tool, testing the usefulness of the proposed idea or tool or the prior ideas against the consequences of the new idea, and then articulating a new idea or evaluation. This process involved the passing through, perhaps multiple times, the inquirential cycle of reflecting, acting, and evaluating against the ideas' abilities to solve a perceived problem. The problems posed played a role in the decisions the mathematicians made about what tools or propositions would be useful. The focus of this paper is to elaborate on the problems encountered and tackled when ideas emerged. The participants transitioned through the following four phases of problems to tackle or tasks to complete in order to finish the construction of the proof.

1. Understanding the statement and/or determining truth
2. Determining a warrant of some kind
3. Validating, generalizing, or articulating those warrants
4. Writing the argument formally

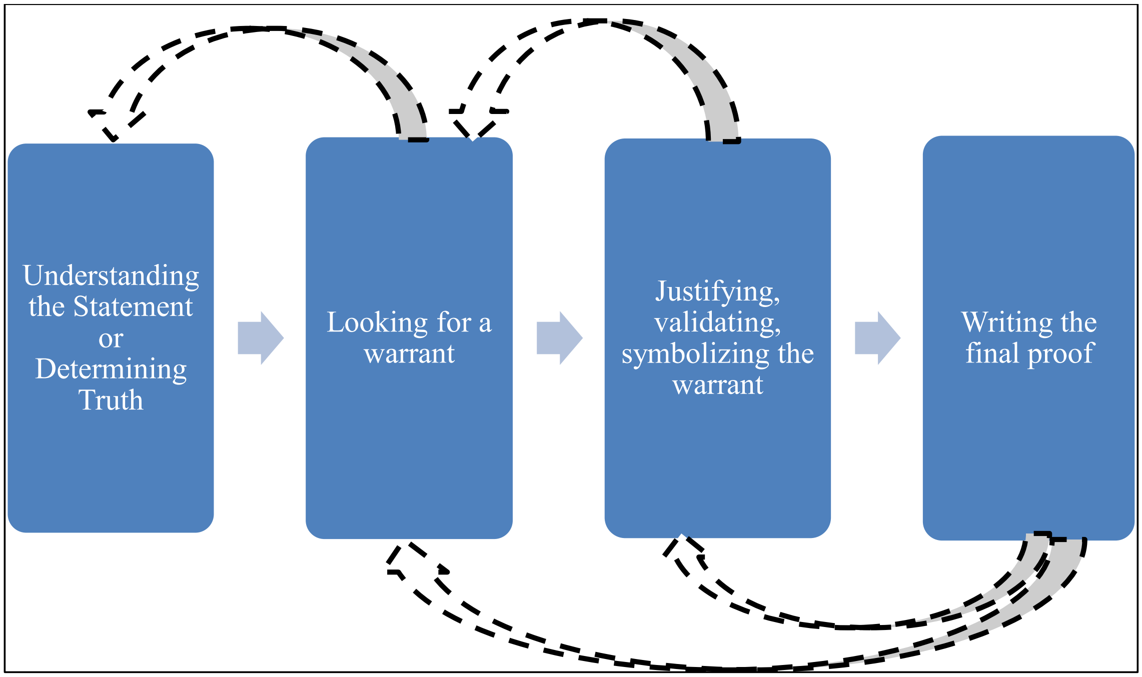

Figure 3. Illustration of the problem phases observed and the potential to cycle back.

The first phase involved the mathematicians engaging in efforts to get a sense of what the statement meant, definitions of objects described in the statement, and how objects in the statement related. On the one "prove or disprove" task, the mathematicians also engaged in determining the truth value of the statement.

The second phase of determining a warrant encompassed work to find a reason that a statement or participant-generated conjecture is true that they could eventually render into a final written proof. In the example above, Dr. C did look for a counterexample which, if found, could have been used in a final, formal proof. However, this phase also encompassed the work to find inductive and structural-intuitive warrants that provided personal feelings about understanding why the statement was true.

Once the mathematicians proposed a warrant, they worked to test the warrant, looked for ways to generalize the warrant, or articulate it in a symbolic or written way. If the warrant found previously was based on logical deductions, then this phase sometimes coincided with writing a rough draft of the proof formally. In the example above, Dr. C tested the function he generated to determine if it could serve as a warrant. Once the mathematicians articulated or felt they could articulate their reasoning for why the statement would be true in general, they indicated they were ready to write the final proof, the fourth phase listed above.

The first three phases listed could coincide with genuine problems for the mathematicians in the inquiriential sense. If a problem was encountered, the participants passed through the cycle of reflecting, acting, and evaluating until an idea that moved the argument forward was developed. Sometimes, however, the mathematicians passed through without problem as they could enact a previous insight or follow symbol manipulation through. For example, once Dr. C had formulated his truth proposal and proposed a possible counterexample, it was not problematic for him to find an efficient way to test the function.

In addition to the four above major problems to solve, the participating mathematicians also tackled problems parallel to or embedded within these problems (phases) such as dealing with a found problem with a tool. Writing the argument formally typically was not problematic for the professional mathematician once they had developed a deductive warrant.

At times the participants proceeded linearly through the four phases; however, there were instances where participants needed to cycle back to a previous phase when a proposed idea or tool was not fitting or if no tool (or proposition) could be found to solve the current problem (see Figure 1). Dr. C's work above provides an example of cycling back from the third phase of validating the warrant to the second phase of determining truth, he began (1) determining the truth of the statement, (2) worked to develop a counterexample (a deductive warrant), (3) worked to validate the warrant and found that he could not. In light of this new information, he cycled back to the first phase as he (1) reevaluated his truth determination. This prompted (2) searching for another warrant for why the statement would be true that he could render into a proof. This study also observed mathematicians cycling back from phase (3) to phase (2) and back from phase (4) to phases (2) or (3).

Discussion and Conclusions

The purpose of this larger research project was to identify ideas that mathematicians generated that pushed their arguments forward and to provide context to the situation when these ideas emerged. Dewey's theory of inquiry was

The mathematicians in this study developed ideas that moved their arguments forward in that their personal arguments structurally evolved upon the development of these ideas. The multiple idea-types are grouped into three categories. Every participant on each task identified ideas from each of the three idea categories. As was described above with Dr. C, the evolution of the personal argument was not linear in identifying focusing and configuring ideas, identifying connections and justifications, and then making monitoring decisions. Instead, multiple idea-types from any or all of these categories could characterize a single moment. The process of articulating ideas, testing the new idea or previous ideas against these new ideas, and then proposing new ideas was apparent. The process of testing ideas varied, but the process involved active, productive inquiry in that ideas were tested against their abilities to do work in solving a perceived problem. Four major types of problems or phases of the process of constructing proof were identified to coincide with the emergence of ideas. The mathematicians progressed through these four phases but needed to cycle back to a previous phase when the ideas that the mathematicians had previously incorporated into the personal argument were insufficient in resolving a situation in a later phase.

The four identified phases of understanding the statement or determining truth, looking for a warrant, working to validate, generalize, justify or articulate their warrant; and writing the formal proof are reminiscent of findings of other researchers. The following aspects have been identified as part of the proof construction process: understanding the statement or described objects (Alcock, 2008; Alcock & Weber, 2010; Carlson & Bloom, 2005; Savic, 2013); determining the truth of the statement (Sandefur et al., 2012); determining why the statement is true (Raman et al., 2009; Sandefur et al., 2012); translating ideas into analytic language (Alcock & Inglis, 2008; Alcock & Weber, 2010; Weber & Alcock, 2004); and justifying a previous idea (Alcock, 2008; Alcock & Weber, 2010).

This research is unique in its specific efforts to identify the problems encountered as participants developed new ideas and in its use of Dewey's theory of inquiry to explain how ideas were developed and tested against these problems. Using Dewey's theory of inquiry as a framework to describe the context surrounding the generation of these ideas focused the research on the question of identifying the problems encountered instead of the actions performed in isolation. We know that students and novice provers can apply heuristic strategies in non-purposeful ways (e.g. Alcock & Weber, 2010), and they may not recognize generated statements as relevant and useful ideas (e.g. Raman et al, 2009). The mathematicians in this study appear to have developed (perhaps unconsciously) a routine for approaching proof problems. There may be value in viewing a proof task as consisting of sub-tasks to be explored and resolved.

The findings presented in this paper are linked to a larger study, and there are limitations. The participants in this study selected some of the tasks. This resulted in imprecise formulations of two instances (out of ten) of tasks used. Additionally, the study was limited to three male mathematicians working in isolation on tasks within the realm of real analysis. The context of the interview situation was not representative of a research mathematician's typical practice. While the tasks presented genuine problem solving situations, they were still "school tasks". Therefore, the participants, informed by their training in school mathematics, brought with them conceptions about "hints" in the statement formulations, what were reasonable expectations for a solution, and what theorems they were allowed to assume.

The choice to conceive of the proof construction process as involving an evolving personal argument was made due to a desire to talk about all the ideas, relationships, concepts, pictures, and so on that an individual personally judges as important to providing a final proof and the relationships amongst these elements at various points in time. This conception allowed for attending to moments when ideas were generated that the prover saw as useful which broke the construction process into significant events to illustrate the story of the argument's evolution. As researching the proving process in this manner is relatively unexplored, many avenues of research are open to explore how these ideas develop, how they are tested, and the consequences their development provides for the evolution of the argument. The findings of this study were descriptive and exploratory and the fifteen idea sub-types found may not be salient in other studies. It is probable that varying the mathematical content area or narrowing the research questions would provide new and clarifying findings to refine the categorizations or provide insight as to how the proof construction process compares across mathematical content.

Exploring pre-service teachers' mental models of "doing math"

Ben Wescoatt
Valdosta State University

This study explored the mental models pre-service teachers hold of doing math. Mental models are cognitive structures people use while reasoning about the world. The mental models related to mathematics would influence a teacher's pedagogical decisions and thus influence the mental model of mathematics that their students would construct. In this study, pre-service elementary teachers drew images of mathematicians doing math. Using comparative judgements, they selected an image that best represented a mathematician doing math. The drawings and participants' responses to prompts were analyzed for common themes. The pre-service teachers generally believed that mathematicians do math through teaching and mathematicians really enjoy doing math. The appearances of the mathematicians generally adhered to stereotypes found in the literature.

Key words: Mental Models, Drawing Research, Pre-service Teacher Mathematics Beliefs, Comparative Judgement

In a recent article of the *MAA FOCUS* magazine, Francis Su, newly installed president of the MAA was asked the following question, "What is your earliest memory of doing mathematics?" Dr. Su spoke of solving arithmetic problems on worksheets, prior to being of kindergarten age, given to him by his father. He further clarified that, at that time, this was what he believed mathematics to be (Peterson, 2015). What does it mean to do math? What does it mean to do math? Due to their early interactions with students and mathematics, better understanding of teachers' perceptions regarding this question is important. This current study aims to explore mental models held by pre-service elementary teachers to better understand their perceptions of what it means to *do* math.

Mental Model Theory

Mental model theory is a theory of how people reason about the world. A mental model is a cognitive structure constructed by an individual as a representation of a possibly real, imaginary, or hypothetical external reality (Gentner, 2002; Jacob & Shaw, 1999; Johnson-Laird, Girotto, & Legrenzi, 1998; Jones, Ross, Lynam, Perez, & Leitch, 2011). Due to cognitive limitations of an individual, models cannot contain every detail of the reality and thus are not complete or technically accurate representations (Gentner, 2002; Jones et al., 2011; Norman, 1983/2014). However, structural relations present in the reality will have analogous representations in the individual's mental model (Johnson-Laird, 1998). Thus, a model will have structural features in common with the represented domain and be as iconic as possible (Johnson-Laird, 2004).

An individual constructs a mental model through experience, by perceiving or imagining the reality, or by understanding discourse and gaining formal knowledge (Jacob & Shaw, 1999; Johnson-Laird et al., 1998; Jones et al., 2011). An individual uses mental models as conceptual frameworks through which to interpret, understand, and reason about the world (Gentner 2002; Jacob & Shaw, 1999). New information filters through the model (Jones et al., 2011), and the individual reasons about situations, leading to predictions and decisions through mental manipulations of the models (Johnson-Laird, 2005). Because of how models are constructed, a mental model is contextually bound, constrained by an individual's experiences with the represented domain (Norman, 1983/2014). In addition to experience, an individual's goals and motives for construction of the model also influence the structural aspects of the reality that end up being represented in the model (Jones et al., 2011).

In addition to representing physical aspects of a particular domain, mental models also incorporate an individual's beliefs related to the domain; thus, mental models are reflective of belief systems (Libarkin, Beilfuss, & Kurdziel, 2003; Norman, 1983/2014). This connection allows an exploration of belief systems through an individual's mental model. Yet, being internal constructs, mental models are difficult to explore. While one method of exploration is the direct questioning of an individual's beliefs, people generally have difficulty clearly articulating their beliefs (Gentner, 2002). As a result, novel methods can be useful in constructing external representations of internal mental models (Jones et al., 2011).

Efforts continue in order to improve methods for constructing such representations. Mental models are more general instances of a mental image. Hence, underlying any mental image is a mental model, with the image being the projection of the mental model's visualizable aspects (Johnson-Laird, 1998; Johnson-Laird, Girotto, & Legrenzi, 1998). Some recent studies have explored mental models via participant-made drawings, which would be physical manifestations of mental images. For example, drawings were analyzed to explored elementary and middle school students' mental models of circuits (Jabot & Henry, 2007), pre-service teachers' mental models of themselves as teachers of science (Thomas, Pederson, & Finson, 2001), pre-service agriculture teachers' mental models of effective teaching (Robinson, Kelsey, & Terry, 2013), and pre-service teachers' mental models of the environment (Moseley, Desjean-Perrotta, & Utley, 2010). While not explicitly using mental model theory, other studies have used a drawing methodology to explore pre-service elementary teachers' visual images of themselves as mathematics teachers (Utley & Showalter, 2007) and middle and secondary students images of mathematicians at work (Aguilar, Rosas, Zavaleta, & Robo-Vazquez, 2014; Picker & Berry, 2000; Rock & Shaw, 2000).

In their work, Picker and Berry (2000) theorized how a stereotypical cultural image of mathematicians and their work is formed. A young learner, someone unfamiliar with the stereotypical cultural view of mathematics, begins school. Through exposure to cultural stereotypes via media, adults, and peers, through interactions with teachers lacking rich images of mathematics, through a pedagogy that reinforces stereotypes, and through the lack of clear intervention by the mathematics community, the student begins forming a deficient image of mathematics. Stereotypes fill the void left vacant by desirable alternatives, and the student's forming mental model is validated through experience. Teachers play a key early role in inculcating students into the stereotypes of mathematics. However, the teachers would need to hold a healthy model of mathematics themselves to have any positive effect, as a teacher's beliefs influence the mathematical experiences they have with their students and so can influence the model that the students form (Mewborn & Cross, 2007). If students do not have healthy images of mathematics, they may choose to pursue other vocations, potentially robbing society of valuable mathematical innovation. Thus, exploring pre-service teachers' mental models related to mathematics is of importance.

Doing **Math**

From a survey of twenty-five post-secondary mathematics professors, Latterell and Wilson (2012) formulated a working definition of doing math, stating that in order to be considered doing math, mathematicians must be *creating* new mathematics. Schoenfeld (1994) stated, "research – what most mathematicians would call *doing* mathematics – consists of making contributions to the mathematical community's knowledge store" (p. 66). As a result of their definition, Latterell and Wilson excluded teachers of mathematics from being considered as mathematicians and only included mathematics professors if they were engaged in research mathematics. However, the general populace does not necessarily hold to this same understanding.

Through a survey of children in grades K-8, Rock and Shaw (2000) determined that the students believed mathematicians did the same kind of math the students did in the classroom, only with larger numbers. Students also tended to believe mathematicians solved the hard problems no one else wanted to do. Many images drawn by the participants showed a mathematician in a classroom setting. Picker and Berry (2000) found similar results when they explored the images that 12-13 year olds had of mathematicians at work. About one-fifth of the drawings were of a teacher. The images of mathematicians adhered to some stereotypes found in the research of images of scientists; most of the images were of men, and some of the drawings resembled Einstein. In a follow-up prompt, the plurality of students mentioned that mathematicians were hired to teach math, suggesting that students actually did not have a clear idea of what mathematicians did. As a result, Picker and Berry suggested that mathematicians and their work were basically invisible to the students.

From a study of images of mathematicians at work created by high-achieving high school students attending a mathematics and science school, Aguilar, Rosas, Zavaleta, and Romo-Vázquez (2014) discovered that while the images were mostly male figures and contained many images of teachers, the students had a richer conception of what mathematicians did. They suggested this richer view developed from more exposure to advanced mathematics. Also, since many of the images contained items found in school settings, the students' limited interactions with math, mainly in the schools, heavily influenced their image of what it means to do math.

Due to the important role that teachers and the school setting play in the formation of a student's mental model of mathematics, this study explored the following question:

What shared mental model of *doing mathematics* is held by pre-service elementary teachers in a mathematics content course?

Theoretical Framework

This study used participant-made drawings in order to explore the mental models preservice teachers have of doing math. The use of drawings to explore concepts has its origins in Goodenough's Draw-a-Man psychological test developed in 1926. The test was adapted through the years, notably as the Draw-a-Scientist test in 1983 by Chambers (Finson, 2002). Participant drawings were analyzed through the Farland-Smith framework (2012) as adapted by Bachman, Berezay, and Tripp (2016). To analyze scientists at work, Farland-Smith (2012) suggested analysis along the dimensions of the appearance of the scientist, the location in which the scientific activity is taking place, and the scientific activity being conducted. In analyzing participant drawings of scientists at work, Farland-Smith used the categories of appearance, location, and activity. Using these categories, Bachman, Berezay, and Tripp coded participant drawings of themselves doing math to analyze students' mathematical affect related to doing math. Including issues of affect makes sense in light of other research into drawings of mathematicians; for example, research into images of mathematicians and mathematics has included extreme images, including images suggesting violence (e.g., Picker & Berry, 2000; Lee & Zeppelin; 2014). Images such as these may have little mathematical content but would contain valuable insight into peoples' beliefs about math and doing math.

In the current study, as the original drawing prompt requested students to draw a picture of a mathematician doing math, analysis of the drawings focused on the mathematician, what the mathematician was doing, and what elements in the drawings could be considered mathematical in nature. Thus, the categories of analysis were *Action*, *Mathematics*, *Appearance*, *Location*, and *Affect*. The action and mathematics categories were a splitting of the activity category from the Farland-Smith framework in order to better capture elements that the participants consider to be mathematical.

The drawings created by the participants were assumed to be external representations of their own mental images, which were in turn the projections of the visualizable aspects of their corresponding internal mental model. An individual's mental model was influenced by the culture (classroom) to which he or she belonged, forming shared mental model, which is an overlapping of mental representations of members of the culture (Van den Bossche, Gijselaers, Segers, Woltjer, & Kirschner, 2011). That is, the formation of the shared mental model occurred in a fashion as described by Picker and Berry (2000).

Methodology

The study was conducted at a regional university in the southeastern United States. Participants, or pre-service teachers (PSTs), in the study were undergraduate students in a teacher preparation program. The PSTs were enrolled in one of three sections of a mathematics content course for pre-service teachers. The course was the third in a sequence of four mathematics content courses required by the program. Forty-six PSTs were enrolled in the sections. The PSTs were divided between two disciplines, early childhood education (31, 67.4%) and special education (15, 32.6%). Of these students, 4 (8.7%) were male and 42 (91.3%) were female. Additionally, 2 were Hispanic (4.3%), 10 were African-American (21.7%), and 34 (73.9%) were Caucasian.

During the sixth week of classes, PSTs responded in an at-home activity consisting of several drawing activities. Germane to this current study was the prompt: Draw a picture of a mathematician doing math. PSTs had approximately one week to create the drawings. The drawings were subsequently collected and scanned to create electronic files. The *Mathematician doing Math* drawings were uploaded to the No More Marking website (nomoremarking.com), a website that facilitates and calculates comparative judgements to explore preferences. Comparative judgement is a method to measure qualities that are subjective in nature, such as individual's beliefs, and is based on the idea that a person assigns a value to a phenomenon; when asked to choose between two phenomena, the person will base the decision on a comparison of the phenomena's values; the values are based upon a shared consensus of those making the judgements (Pollitt, 2012). In other words, with many judges participating, the preference of a phenomena is based upon the shared cultural preferences of the judges. As an example, Jones and Alcock (2014) used comparative judgement to explore whether or not calculus students performed well as peer assessors in the absence of assessment criteria. Through a website, students were presented 20 pairs of student work and asked to judge which one showed better conceptual understanding. The work receiving the highest overall score, determined through appropriate formulae, was the work that showed the most understanding, as judged by the students.

During the ninth week, for an at-home activity, PSTs were invited to perform comparative judgments on the two sets of drawings with the following question: Which best represents a mathematician doing math? Furthermore, PSTs were instructed to compare each drawing and choose the one they believed best answered the questions, to give honest responses, and to not judge the pictures on artistic merit. Each PST made 40 comparisons per data set. Figure 1 shows what the PST would see on his or her screen while judging. The image receiving the highest overall score, estimated by using the Bradley-Terry model and calculated internally on the website, was taken to be the image that best represented a mathematician doing math in the opinion of the participants. That is, the image was taken to

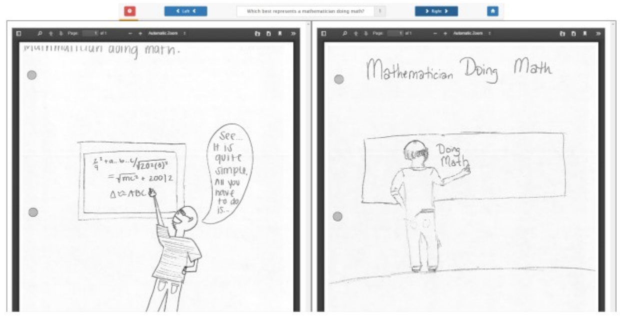

Figure 1. Screen judges while judging at No More Marking website.

represent the ideal image based upon shared standards of the students. Finally, during the twelfth week, for an at-home bonus activity, PSTs were shown the image selected through comparative judgment as the best representative of a *Mathematician doing Math* and answered the following prompts: 1.) Why do you believe this picture was selected as the best representation of a mathematician doing math? 2.) To what extent does this picture align with your beliefs of what it means for a mathematician to do math? 3.) To you, what does it mean to be a mathematician?

The participant drawings of mathematicians doing math were analyzed using the categories of action, mathematics, appearance, location, and affect as modified from the Farland-Smith framework. The drawings were analyzed one category at a time with the analysis focused on commonalities across the drawings. Colored pencils were used to circle common elements across the drawings and then a name was chosen for the subcategories to represent the common themes. The drawings were reanalyzed until elements in the drawings were exhausted. The cyclical process continued for the other categories in the framework.

In order to analyze the responses to the prompts in the bonus activity given during week 12, the participant responses were analyzed using an open coding approach, reading through the responses, then rereading each response and underlining common themes across each response to create categories. Finally, each response was reread and coded according to the themes present, with frequencies in each category tallied. As needed, categories were adjusted until the essence of each response could be categorized.

Results

This section contains the results of the analyses of the drawings and the participant responses to the first prompt on the bonus assignment.

Participant Drawings

Action

The focus of analysis for action found in the participants' drawings was on identifying what a person was doing in the drawing. Thus, a person needed to be visible in the drawing in order to identify an action. Table 1 includes the analysis of the drawings along the action category. Only one drawing did not have a person visible; this drawing showed a construction site with a crane and a building. Thus, this image was not coded for an action. Six categories of action evolved from the analysis. The first four categories were mutually exclusive while the remaining two categories could be action found in tandem with another category action.

Table 1

Actions Performed by Mathematicians

Action Category	Description	Frequency
Writing	The person has finished writing, is in the act of writing, or will be writing in the future. The person is holding a writing implement such as a pencil or a piece of chalk. The writing occurs on a vertical surface such as a chalk board or on a horizontal surface such as a piece of paper.	Vertical: 24/43 (55.8%) Horizontal: 2/43 (4.7%) Total: 26/43 (60.5%)
Pointing	The person uses a pointer or hand to direct the audience's attention to another element in the drawing.	9/43 (20.9%)
Presenting	The person is standing, facing outward to the audience with arms outstretched, in a "ta-da" pose. The person stands in front of some mathematical writing.	4/43 (9.3%)
Manipulating	The person uses physical manipulatives pieces such as those found in elementary mathematics classrooms.	1/43 (2.3%)
Talking	A speech bubble is apparent or a mouth is drawn in a way to suggest speech.	10/43 (23.3%)
Pondering	The person has a thought bubble filled with utterances related to a problem, is in a position identified as related to thought, or other elements related to thinking are present.	9/43 (20.9%)

Mathematics

This category focused on those elements in the picture that could be construed as intending to be mathematical. Two equations well-known in everyday culture, the Pythagorean theorem equation and the energy-mass equation, were present in nearly half of the drawings. The Pythagorean theorem appeared in some form, either being named or as an equation, in 13 out of 43 drawings (30.2%). Ten drawings (23.2%) contained either the equation $E = mc^2$ or the expression mc^2. As 3 drawings contained both equations, about 46.5% of the drawings contain one, the other, or both of the equations. In 12 drawings (27.9%), the person had written an algebraic expression containing alphanumeric symbols, not including the Pythagorean theorem equation, although some drawings had both the Pythagorean theorem equation and other algebraic expressions. Moreover, 28 drawings explicitly included the equal sign, while another 5 drawings contained notions of equivalence, such as geometric congruency or arithmetic problems written in a stacked algorithm, meaning that 76.7% of all drawings conveyed a notion of equivalence. In eight drawings (18.6%), a geometric drawing such as a triangle or a geometric concept such as angle was included. A doubling sum, such as $1 + 1$ occurred in 8 drawings (18.6%), while another 6 drawings (14.0%) contained basic operations involving single-digit whole numbers such as $1 + 2 = 3$. Symbols such as π or ∞ were found in 8 drawings (18.6%). Four drawings (9.3%) contained overly complex mathematics or overly complicated expressions. For example, one drawing contained the formula for a Taylor polynomial, including the remainder term formula. This same image also included the number 1729, written out in its two taxicab decompositions. A calculator could be found in four drawings (9.3%). Finally, 2 drawings (4.7%) had elements of a proof and 2 drawings (4.7%) showed physical manipulatives.

Appearance

The physical appearances of the people present in the drawings were analyzed. One drawing did not contain any people; thus, this image was not analyzed for appearance. One drawing contained seven people, one teacher standing at the front of the room at a board with six students in two rows of desks. The other drawings contain one individual person. In many of the drawings, people were standing (33/43, 76.7%). To be counted as standing, the feet of the person needed to be visible in the drawing. People were sitting in 4 images (9.3%). When standing, the person was nearly always standing near a vertical surface containing writing. The person in the drawing was either drawn in a facing (24/43, 55.8%), profile (10/43, 23.3%), or back position (8/43, 18.6%). To be considered facing, both eyes needed to be visible; in profile, only one eye was visible. Of the 34 drawings in the facing or profile position, in 15 of the drawings (44.1%; 34.9% overall), the person was wearing glasses. The Einstein effect (Picker & Berry, 2000) appeared in 13 drawings (30.2%); 4 drawings were a facsimile of Albert Einstein, and in 9 drawings, the mathematician had a wild hair style, usually sticking upward. To be considered a wild hair style, the upstanding hair needed to have an exaggerated appearance and not merely be due the participants' crude art skills. That is, the exaggerated hair style needed to appear purposeful.

While it appeared that most of the people in the images were male, this facet of analysis was not pursued in more detail as gender in many of the images was ambiguous in nature; additionally, many of the drawings were of stick figures. Furthermore, due to the stick figure nature of many drawings, an analysis of their clothing was not attempted.

Location

The location category contains descriptions of the environment surrounding the mathematician. Physical objects depicted in the drawings were noted and counted. A vertically-positioned rectangle containing some form of symbols was present in 37 drawings (86.0 %). Many of these rectangles represented chalk boards or white boards as they were either named as such in the drawing, a board was present on the rectangle similar to those found on chalk or white boards, or a tray along the bottom of the rectangle containing erasers, chalk, and/or markers was drawn. Seven drawings contain either a table or a desk (16.3%). As previously mentioned, one drawing was of a classroom setting with both a teacher and students present; this drawing contained both a vertical board and desks. Paper with writing was usually present on the tables/desks (5/43, 11.6%). Books were not present in any of the drawings.

Affect

Each drawing was analyzed for affective factors related to the doing of mathematics. One aspect analyzed was the mouth on each person that was facing or in profile, totaling 34 drawings. Of these 34 drawings, 24 contained a person with a smiling mouth (64.7%);

omitted from these possibilities were those drawings in which the person was determined to be talking. Additionally, 4 drawings contained the people saying or thinking positive words about math or their abilities. “Math is easy” & “I love Pi” and “Doubles, doubles, I can do doubles!” were written in thought bubbles with smiling people, while “See…it is quite simple” and “I’ve almost got it” were in a speech bubble and not already counted. Furthermore, 2 drawings contained positive writing on boards; “I love Math!” was written on the board with a smiling person, and the phrases “Woohoo,” “so much fun,” and “I love math” are written on the board with a person in a back position. Potentially negative elements in the drawings were scant. One board in a drawing of a smiling person contained the writing “Math…Blah Blah Blah.” The classroom setting drawing showed a sleeping student, with “zzz” emanating from the head of the student. Some of the pictures showing a pondering person were neither positive nor negative in nature; instead, these drawings depicted the struggle involved while solving problems. In two drawings, the person had question marks in thought bubbles, while another drawing showed the person saying, “Hmm,” with a tilde for a mouth. A more extreme pondering drawing showed perspiration dripping from the head of the person as he slumped his head forward into his hands. Overall, 26 of the 43 (55.8%) drawings contained positive elements, 4 of the 43 (9.3%) depicted the uncertainty and struggle in problem solving, 1 drawing had both positive and negative elements, 1 drawing had only negative elements, and 12 drawings were not coded for affect elements due to either a back position, talking, or no discernible affect elements (including the 1 drawing without a person).

Extra Credit Prompt

The image in figure 2 was selected as the drawing that best represented a mathematician doing math. A reliability of 0.89 was achieved, suggesting a stability of the results. Furthermore, the interrater reliability was 0.77. In the first extra credit response, participants explained why they believed the particular drawing was chosen as the best drawing through comparative judgement. Through these responses to the prompt, students commented on five aspects of the drawing: *Artistic merit*, *Stereotypes*, *Teaching activity*, *Affect*, and *Mathematical content*.

Artistic merit

Despite being asked to not judge the drawings on artistic quality, 20 out of 37 participant responses commented about the artistic quantity. Comments were similar to the following examples: “For one, I have to say that the drawing is really good” and “I believe the artist is really talented at drawing and the depiction is detailed, realistic and aesthetically pleasing.”

Figure 2. Image selected as best representing a mathematician doing math.

Stereotypes

Participants expressed a belief that stereotypes about mathematicians were found in the drawing. Specifically, they commented that the mathematician was male, he was wearing glasses, and that he was dressed in a specific manner. Of the 37 responses, 18 (48.6%) mentioned the fact the mathematician wore glasses. Additionally, some participants added that the glasses made the mathematician appear smart, implying intelligence was a quality needed in a mathematician. For example, one participant stated, "It includes the standard picture of a man with glasses, which is a stereotype for smart people." Another said, "He also is wearing glasses, and we tend to think that people who wear glasses are smarter."

To be counted as a male stereotype, the participants had to specifically mention the choice due to being male and not just refer to the mathematician as a man. Thirteen participants (35.1%) mentioned the male stereotype. Example comments included, "I think of mathematicians as a male," "This mathematician is a man, which we sometimes automatically think of when we think of a mathematician," and "The person is a guy and generally when you think of a mathematician, it is a guy."

Furthermore, eleven participants (29.7%) commented that the person was dressed in the way a mathematician would dress, explaining that the mathematician was dressed in a fashion that was stereotypical. For example, one participant claimed, "The mathematician looks how a lot of people think a mathematician does look, with the glasses, buttoned up shirt, and sweater vest." "The character appears to be conservatively dressed which indicates an organized approach to problem solving," another participant stated.

Teaching activity

When responding to why they believe the drawing was chosen as the best representation of a mathematician doing math, 21 of the 37 participants specifically mentioned that the mathematician was teaching (56.8%). Here are some example comments:

> To me, the picture looks like that of a teacher and we also perceive our math teachers as mathematicians.
>
> I think the first example of a mathematician that comes to our minds is a math teacher so that would be one of the first things we would draw.
>
> I also see him at a board and it looks like he is teaching math. I see a mathematician as someone who not only works out math problems but teaches as well.
>
> I believe that this picture was chosen because, not only do mathematicians sit there and solve math problems all day in an office, but they also share their solutions and findings with the world. … Most math teachers that I have experienced get very excited about specific topics because that is what makes them happy and they cannot wait to share it with the world.

In these statements, participants professed the belief that teachers of math were mathematicians and thus doing math, and vice versa.

Affect

Of the 37 participant responses, 20 (54.1%) of them commented on the positive elements found in the drawing, suggesting that overall, mathematicians enjoy doing mathematics. Common words appearing in the responses were *enjoy*, *smile*, *happy*, and *excited*. Comments displaying the joy of math were similar to the following:

> Math makes mathematicians happy.
>
> The man is also smiling, and it looks like he is enjoying teaching the math.
>
> Mathematicians obviously love doing math, and this person [the illustrator] wanted to show that.

> I think that in order to be a mathematician, the mathematician must enjoy doing the math. Then with the smile, it makes me believe that this individual is sharing his knowledge and teaching it to others.
> There is a smile on his face meaning that he is excited to teach the class about math and enjoy the subject overall. This mathematician seems happy to be able to teach his children the things that he has planned on the board.

Mathematical content

Participants commented on the fact that the mathematician was working with formulas or mathematical content, leading to the conclusion that the person was a mathematician doing math. More specifically, several participants commented on the familiarity of the material on the board. For example, one participant commented, "Our class was learning about the things on the board." Another comment read, "I also believe it was picked because of the familiar formulas he is depicting." Similarly, a participant commented on choosing drawings with familiar mathematics, stating, "Many of us may have felt a connection to the mathematical concept being presented on the chalkboard since we recently discussed Euler's formula. It appears we picked what we were the most familiar to."

Discussion and Implications

This study explored the shared or cultural mental models pre-service teachers have of doing mathematics by analyzing participant-made drawings and analyzing student commentary of a prototypical mathematician doing math drawing selected through comparative judgement. The results of the analyses of the participant drawings and prompt responses were used to draw conclusions about the PSTs mental models.

One of the themes of the analysis was that familiarity breeds comfort. Martin and Gourley-Delaney (2014) suggested that students will consider activities more mathematical in nature if they have actual experience with the activity. Thus, many students comments on being familiar with the math in the prototypical drawing. Furthermore, much of the mathematics in the drawings was basic in nature or very common equations in everyday culture such as the Pythagorean theorem equation or the energy-mass equation. Moreover, pre-service teachers would generally have had limited experience with mathematicians. As their experiences in what they consider math up to this point in their lives has occurred in school settings, the only people they could possibly consider to be mathematical would be teachers.

The other possible exposure to mathematicians would be in popular culture such as television or movies in which mathematicians generally adhere to the stereotypes named by the participants. This exposure to mathematics through culture could also explain the phenomena of the Einstein effect, including Einstein as a mathematician. With a limited knowledge of mathematicians and what they do, Einstein could be a ready placeholder. Regardless, PSTs' mental models appear to contain stereotypes of mathematicians and limitations on the power of mathematics.

Another explanation for choosing teachers of mathematics as mathematicians was mentioned by several participants and best encapsulated by the following comment: "I believe that this picture was chosen because, not only do mathematicians sit there and solve math problems all day in an office, but they also share their solutions and findings with the world." Thus, according to the PSTs, a mathematician is a teacher; he or she solves difficult problems and then must effectively communicate this knowledge to others. Hence, part of doing math is teaching math, passing along knowledge. That PSTs emphasized the teaching aspect recalls the communication process standard of the NCTM. That is, mathematics is not merely solving problems, reasoning, proving, connecting, and representing. Communication is important, and communicating appeared to be a necessary facet of the PSTs' mental model of doing math.

The PSTs also believed that mathematicians loved interacting with mathematics and reveled in the joy of mathematics. As one participant wrote, "Math makes mathematicians happy." This facet of the mental model could be a bit troubling. If people do not feel joy when doing math, then perhaps they would believe they could not be a mathematician, or perhaps they are not doing math at all. While these last statements are a bit speculative, that strong, positive feelings for doing mathematics is an important feature of the mental model cannot be denied.

While more data would need to be collected from different populations, there does appear to be some misalignment between the mathematics community and the general population regarding doing math. Perhaps discussion within the mathematics and education communities would be warranted in order to help PSTs develop a mental model of math that would encourage robust models within students. If students view doing math as just teaching math, then they may become discouraged from entering the mathematics field. Or perhaps a new definition of doing mathematics should be promoted. For example, Chick and Stacey (2013) explained that mathematics teachers act as applied mathematicians in order to solve teaching problems. Such a definition would align with the results of this study.

Overall, the pre-service teachers were sensitive to the importance of mathematics in the world and their future place in facilitating a positive of mathematics in there students. As one participant so eloquently put it:

> A mathematician is someone that does not only deal with numbers, equations, or solutions. A mathematician is a contributor to the world; whether they are a teacher, an engineer, or a scientist. They share their ideas with the entire world, all the way from a 6th grade student to an elderly man reading a research article. They never stop questioning the world around us and are always looking for new ways to solve problems. When a mathematician is a teacher, all they are doing is trying to instill the passion they have for their career into a student, so they will hopefully go on and question ideas, and maybe one day discover something nobody knew existed, or maybe inspire a student to be a mathematician.

Assessing student-learning gains from video lessons in a flipped calculus course

Cassandra Williams
James Madison University

John (Zig) Siegfried
James Madison University

Abstract

The flipped classroom has garnered attention in post-secondary mathematics in the past few years, but much of the research on this model has been on student perceptions rather than its effect on the attainment of learning goals. Instead of comparing to a "traditional" model, in this study we investigated student-learning gains in two flipped sections of Calculus I. In this paper, we focus on the question of determining learning gains from delivering content via video outside of the classroom. In particular, we compare student-learning gains after watching more conceptual videos versus more procedural ones. We share qualitative and quantitative data gathered from surveys and quizzes, as well as results from in-class assessments. We conclude by sharing some implications for future research.

Keywords: Flipped Classroom, Video Lessons, Learner-Centered Teaching, Calculus

Background

Learner-centered or active classrooms are those which change the role of the instructor from "sage on the stage" to "guide on the side" and encourage students to construct their own meaning while engaging in authentic problem-solving. Recent research has consistently showed that active classrooms improve student learning in a variety of fields. For example, in 2014 the National Academy of Sciences published a meta-study of 225 studies on student performance and failure rates in undergraduate science, technology, engineering, and mathematics [STEM] classrooms employing active learning components. Their analysis suggests that students in traditional lecture classrooms are 1.5 times more likely to fail than students in classrooms including any type of active learning technique, and failure rates in lecture classrooms are 55% higher than in active classrooms (Freeman et al., 2014). In addition, a 2013 report from the President's Council of Advisors on Science and Technology [PCAST] called for 1 million more college graduates in STEM over the next decade (PCAST STEM Undergraduate Working Group, 2013). Given the current retention rate in STEM majors during the first two years of college and the decreased failure rate in active learning classrooms reported in Freeman et al. (2014), a majority of this goal could be met by employing more active learning and less lecturing during classroom time.

The *flipped* (or *inverted*) classroom structure is one example of an active learning method that has become increasingly popular. This classroom structure takes on many forms, but the common trait is that most of the initial content delivery happens outside of the classroom while in-class time is spent solving problems, often in small groups, to assimilate the new knowledge and to deepen understanding. Some instructors deliver content through assigned readings from a text or other source, while others use videos curated from those available online or create their own videos. The core idea is to use classroom time for challenging problem-solving where students can draw support from their peers and instructor; this design more effectively uses the experience and knowledge of the instructor to guide students through the topic at hand.

Literature Review

Much of the initial literature on flipped classrooms only described the varying structures of such classrooms or the particular technologies employed by teachers using a flipped classroom. The controlled studies published on this classroom model have often focused on student perceptions of and attitudes towards the structure rather than its effect on the attainment of learning goals. For example, Foertsch, Moses, Strikwerda, and Litzkow (2002) described the use of a specific video streaming software in an engineering classroom, and reported student opinions of the videos and software, and Ford (2015) described the activity structure in a math content course for pre-service elementary teachers. Strayer (2007) gathered data on a traditional and flipped introductory statistics classroom to evaluate the learning environment of each structure, and found that students enjoyed the innovation and cooperation in the flipped class, but had a low "comfortability" with the learning activities in this environment. Roach (2014) found that 76% of students in an economics class believed that video lectures helped them learn, and the same percentage would take another class using the flipped format. Bishop and Verlager (2013) did a meta-analysis of the literature on flipped classrooms in all areas of STEM, as well as economics and sociology, and found that there were few studies examining student achievement and advocated for more controlled research.

While lecturing has been a staple of academia for close to a millennium, the flipped classroom structure might be seen as a return to an even older system of teaching where classroom time was centered around academic debate and discussion rather than the transmission of information. Modern flipped classrooms are now returning to this classroom structure and also taking advantage of newer technologies like video and the Internet. This recent resurgence dates to at least the mid-1990s when Eric Mazur, a physics professor at Harvard, started using team learning and in-class activities as ways to stop lecturing (Mazur, 1996). Jonathan Bergmann and Aaron Sams (2012) started using video lectures in the mid-2000s and are often credited with pioneering the flipped classroom and its current popularity. Since then, many educators in a variety of fields and at a wide range of institutions have started using this structure. For example, Gaughn (2014) wrote about their experiences running a flipped history classroom, and Findlay-Thompson and Mombourquette (2014) published research from their flipped business classroom. Additionally, research has been done on flipped classrooms at levels ranging from from high school (Johnson, 2013; Moore, Gillett, & Steele, 2014) to upper division medical courses (Sharma, Lau, Doherty, & Harbutt, 2015). Education-focused video repositories like Khan Academy are available on the web, and many have spoken about their experiences with various forms of the flipped classroom at local and national professional meetings (e.g., in 2014 the Joint Mathematics Meetings included a session titled *Flipping the Classroom* with 37 different talks).

As the flipped classroom has gained popularity among undergraduate STEM educators, more research studies are using classroom data to evaluate the success of flipped classrooms. Lape et al. (2014) and Mason, Shuman, and Cook (2013) compare grades on individual assessment questions in engineering between flipped and traditional sections of the same course and found few cases of statistically significantly higher scores in the flipped classroom, but no cases where students in a lecture section outperformed students in a flipped section. Similarly, Day and Foley (2006) compared grades on several course components in a senior level computer science elective and found that the flipped section earned higher average scores on every component of the grade, with statistically significant differences in the case of homework based on lectures/video lectures. Moravec et al. (2010) found statistically significant score increases over previous years in matched exam questions related to topics delivered in an inverted fashion in a large introductory biology course.

In mathematics in particular, McGivney-Burelle and Xue (2013) flipped a unit in a Calculus II course and showed that student grades on exams and homework were higher for the flipped section than the traditional section. Wilson (2013) found that students in a flipped section of statistics outperformed their lecture counterparts on exams and the course post-test. Love, Hodge, Grandgenett, and Swift (2014) found that students in a flipped linear algebra course had greater improvement in exam scores than those in a traditional section, and had higher averages on the final exam. Additionally, Problems, Resources, and Issues in Mathematics Undergraduate Studies (PRIMUS) has a forthcoming special issue on research in flipped classrooms that will increase the literature within mathematics education.

Some researchers have also considered the format, use, and effectiveness of video lectures, both in flipped classrooms and in general. For example Zappe, Leicht, Messner, Litzinger, and Lee (2009) investigated how students used online lecture videos to learn in an undergraduate engineering course, including the percentage of videos watched, students reviewing unclear segments, and time spent per video. Mayer and colleagues have published a number of papers considering specific attributes of videos, like the use of graphics and animations, or the style and tone of the voice in the video, and how they help or hinder student learning (e.g., Mayer, Hegarty, Mayer, & Campbell, 2005; Mayer, Sobko, & Mautone, 2003).

Research Question

Since students in the flipped classroom model do introductory learning of topics outside of the classroom, it is prudent to investigate the effectiveness of the content delivery method. The classroom in our study most often introduced new content outside of class through the use of the instructor's own video-recorded lessons. In this study we investigate the effectiveness of these videos on the learning gains made by students enrolled in two sections of a standard first semester undergraduate calculus course. In particular, we explore student-learning gains from watching videos outside the classroom to determine students' development of conceptual understanding and procedural skills in calculus.

Methods

Participants

The participants were undergraduate students in a first semester calculus course at a large comprehensive public university in the Mid-Atlantic United States. Of the 59 students in the study, 51 (86%) were freshmen, 5 (8%) were sophomores, 2 were juniors, and 1 was a senior. The majority of the students were male (64% male, 36% female). Four students withdrew from the course before the end of the semester. More than 80% of the students had previously had a course in calculus, generally in high school. The majority of the students were majoring in STEM fields. The students were divided into two sections (34 students in one section, 25 in the other) and generally covered the same material on the same days.

Classroom

The data was collected during the instructor's third semester running a flipped Calculus I classroom. Before each class, students had a pre-class assignment, such as watching a video or completing a reading. Nearly all class sessions started off with a short open-note quiz related to their pre-class assignment. The majority of class time was spent on group-work activities.

These activities were often sets of questions designed to reinforce, clarify, deepen, and extend the content in the pre-class assignment, address misconceptions, and provide practice. At times throughout the semester, activity were discovery or guided-inquiry, meant to allow students to develop a key concept or idea on their own through the use of a carefully chosen set of leading questions and problems. The students worked in groups of two to four students and the instructor would interact with the groups one-on-one. Students were also given homework and practice problems to be completed outside of class.

Data Sources

Over the course of the semester, we gathered qualitative data from the students, including student feedback about specific video lectures (for example, questions like "What did you find confusing?" or "What helped clear up confusion?"), student answers to post-video or post-activity questions or problems (calculus content questions to evaluate learning gains), and student surveys about their perceptions of the class structure and their learning gains. Aggregate quantitative data, such as assessment scores and exam grades, were also recorded. We used video recording on certain class days to help the instructor objectively evaluate and improve student-teacher interactions in the classroom. Collected data was used to make changes to course structure and activities in order to increase potential learning gains.

Analysis

We created rubrics to analyze the students' responses to assessment questions. For example, the rubric shown in Table 1 was used to analyze responses to a conceptual question asking students to describe L'Hôpital's Rule. We then used two-tailed pairwise comparisons ($\alpha = 0.05$) to compare groups of students (e.g., students who had previously viewed a more conceptual video about the mathematical content versus students who had viewed a more procedural video) or to compare pre- and post-assessment results. Written responses were also categorized so that we could view trends in the data.

Table 1.
Rubric Used for Scoring Responses to Conceptual L'Hôpital's Rule Question

Score	Explanation
0	Answer was blank or made no mention of tangent lines.
1	Answers either lack "functions act like their tangent lines", or say something about tangent lines but neither "slope" nor "compare".
2	Answer states that functions act like their tangent lines near a point, and that one can find limits of $f(x)/g(x)$ (or compare $f(x)$ and $g(x)$) which have indeterminate forms by comparing the slopes of their tangent lines.

Students were also given in-class surveys consisting of Likert-scale and multiple-choice questions. The surveys generally asked students about their perceptions of the class structure and their learning gains. Their answers were categorized to look for trends in the responses. Aggregate quantitative data, such as scores on specific questions from class assessments, were also used as a measure of student learning gains.

Results

In this section we share a subset of results from our larger study. In particular, we share students' overall opinions about video use and data on content learning for three individual topics, including one class period specifically designed to help us see differences in the ways students learn conceptual and procedural content via video.

First, we share data on the students' beliefs about video usage. Several times throughout the semester, students were given surveys where they could voice their opinions about the structure of the class. When asked to compare learning a new topic outside of class via reading assignment versus watching a video, students overwhelming preferred videos (86%). However, when asked what part of their class structure had the greatest positive impact on their learning, 56% of students said the pre-class videos and readings, whereas 46% said the in-class activities and interactions.[1] We also asked the students to state their beliefs on how the videos increased both their conceptual understanding and computational skills in the class (see Table 2). For both questions, the majority of the class believed the videos greatly or significantly helped their mathematical understanding and skills, although more of the students found video helpful for their conceptual understanding than their computational skills.

Table 2.
Students' Beliefs About Video Usage

	Greatly	**Significantly**	**Moderately**	**Slightly**
Conceptual understanding	38%	38%	24%	0%
Procedural skills	20%	40%	30%	10%

The data suggests that the students believed the videos contributed to their content learning, but what objective evidence for learning gains can be seen in the students' work in the classroom? Prior to an in-class activity about L'Hôpital's Rule, we had the students watch an introductory video about the topic. However, we split the classes into two groups: one group watched a more conceptual video, and the other watched a more procedural video (n = 23 for each group). At the beginning of class, the students were given a content-driven assessment about L'Hôpital's Rule, with one question asking for a more conceptual explanation ("Describe how L'Hôpital's Rule works geometrically.") and the other asking for a more procedural explanation ("How does one calculate a limit using L'Hôpital's Rule?"). We then assigned the students to groups of two to three so that each group contained at least one student who had watched each video. We videotaped the class session to capture the students' interactions with and explanations to each other. At the end of class, students were given the same assessment as before to measure what changes in their understanding occurred due to their group discussions.

We scored their responses to the pre/post assessment using rubrics similar to the one described above (0–2 scale). The students' average results can be found in Table 3. The results indicate that students who watched the more conceptual video were able to answer the more conceptual question on the pre-class assessment, but were not able to answer the more procedural question. The opposite was true for the students who had watched the procedural video.

Table 3.
Average Scores on L'Hôpital's Rule Assessment

	Conceptual Question		**Procedural Question**	
Group	Pre	Post	Pre	Post

[1] Percentages add up to more than 100% because students could choose more than one answer.

Watched conceptual video	1.39	1.48	0.09	1.26
Watched procedural video	0.04	1.35	1.74	1.57
Significantly different? (p-value)	Yes $p < 0.001$	No $p = 0.210$	Yes $p < 0.001$	No (barely) $p = 0.057$
Effect Size (r)	0.839	0.119	0.909	0.235

After working with their peers, both groups of students were generally able to answer the conceptual and procedural questions. No statistically significant differences were found in the two groups' post-class assessment average scores. However, the difference in their post-assessment scores for the procedural question was just barely insignificant. (We will discuss this finding further in the next section.) These are preliminary analyses, but they seem to indicate that students gained mathematical knowledge from watching the videos and were able to share that knowledge with other students.

We also found that the learning gains from the L'Hôpital's Rule videos were similar to the gains from other videos in the class. For example, two of the videos the students watched covered the formal definition of the limit and the intermediate value theorem. After each, the students had an in-class activity to explore the topic in more depth. This was similar to how the students were introduced to L'Hôpital's Rule

After watching each of these two videos, students took post-video surveys. For the definition of the limit, they were asked to write the definition in their own words. For the intermediate value theorem, students were asked to explain the importance of assuming continuity in the statement of the theorem. We created rubrics (0–2 scale) and scored their responses on these items (see Table 4). The average score on the limit definition survey was 1.07, and the average score on the intermediate value theorem survey was 1.26. However, these scores may hide the range of solutions given by the students. For example, on the limit definition survey more than 75% of the students had at least some understanding of the limit definition. In both cases, students exhibited at least moderate content learning gains after only watching the videos.

Table 4.
Score Distribution for Two Surveys

Score	**0**	**1**	**2**
Limit Definition survey	18%	57%	25%
IVT survey	10%	43%	36%

For the limit definition and for L'Hôpital's rule, we gave the students an additional assessment question after they had watched the video and discussed the topic in class. (For the limit definition, this was an exam question, and for L'Hôpital's rule this was the post-activity assessment.) We found the students had similar results on these assessments, with an average score of 71% on the L'Hôpital's Rule question and 75% on the definition of limit question.

Last, we compared the students' solutions to specific questions on their final exam (see Table 5). We looked at the results from the final exam about three different topics from the course: two of which were introduced via video and one of which was introduced via a guided-inquiry activity, the second most common form of content delivery in this classroom. Topics in this table are listed in the order they were covered in the course. The students' final exam scores on these three topics were virtually identical, which seems to indicate learning gains for these two methods of content delivery are nearly equivalent for these students.

Table 5.
Final Exam Results

Topic	Delivery Method	Percent
Definition of Limits	Video	76%
Definition of Derivatives	Guided-Inquiry Activity	78%
L'Hôpital's Rule	Video	75%

In summary, the results from our data imply that students are gaining at least some conceptual and procedural understanding of the mathematical content from video lessons. In the next section we discuss some possible implications of these results, along with areas of future research.

Discussion

Our study contains many different types of research data that may at first seem disconnected. This was our first attempt to quantify student learning gains in a flipped calculus classroom, specifically via video lectures. We collected data from a wide range of sources to help narrow down the research questions we wanted to explore in more depth in later studies. As such, this data may give us an initial overall picture of student learning gains through the semester but it does not allow us to go into depth for any one topic. However, we will use this data to help us design future studies to investigate the role that video lectures play in student learning in a flipped classroom.

In reviewing the results of the pre-activity assessment for the videos on L'Hôpital's Rule, we were not surprised by how well the students did on the question that related to the video they had viewed. However, more than 80% of the students in the class had taken at least one calculus class before, so we predicted that some students would initially be able to answer both questions successfully, which was not the case. Also, we were surprised by the students' improvement in both conceptual and procedural understanding after working in groups. Our results seem to indicate that students learned conceptual and procedural content from the videos and were able to share that knowledge effectively with their peers.

There are still some open questions from the data. The L'Hôpital's Rule post-activity assessment scores between the two groups of students on the procedural question were just barely insignificantly different and students felt the videos helped them more with conceptual knowledge than with learning procedures. This could mean we need to take into consideration what content educators deliver via video. However, because of the small number of students in this study, more research needs to be done to determine if there is a statistically significant difference in learning gains from more procedural videos than more conceptual ones.

One result that stands out is the low average on the post-video assessment on the limit definition. While in most other cases, the average scores were typically 65–75% on post-video assessments, in this case the average was just over 50%. As this topic is one of the most difficult and most conceptual of the entire course regardless of delivery method, this may not be as surprising as it initially seemed. It is also significant to note that this topic appeared early in the course, and it is possible that students had not yet developed productive ways of interacting with the video.

There are two important caveats to our findings. First, we had no control group against which to compare our results from the flipped course. We can anecdotally compare to our prior experiences teaching Calculus I at other institutions and with our colleagues' experiences in other sections of this course, but the goal of this study was not to make comparisons. Instead, we wanted to investigate learning gains in the flipped classroom, although we do advocate for research comparing learning gains from different pedagogical techniques. Second, while we attempted to specifically investigate learning gains from videos watched outside the classroom, we must remember the videos were not used in isolation. In some of our data, such as exam data, the effect of the videos on the students' understanding is difficult to separate from the effects of the other learning activities that happen afterwards (e.g., in-class discussion and activities, homework, office hours, studying for exams). As we continue our research, we hope to be able to isolate the learning gains from videos and also investigate how the structure of the video-watching experience affects student learning, which we will discuss in more detail below.

Last, teachers thinking about using videos in their classes should know that students will at least get a basic understanding from videos, whether the videos are more conceptual or procedural. Moreover, some may be disappointed that our results indicate that introducing material via video does not necessarily improve learning gains as compared to learning via other methods. However, our data does seem to indicate that student content learning gains from video are at least equivalent to those from the other content delivery methods used in this course.

Implications for Future Research

While the results of this preliminary study seem to indicate that students can and do learn mathematical content from video lessons, our data have also opened other lines of future inquiry. For example, one might investigate what balance of conceptual and procedural videos should be used to have the greatest impact on student-learning gains, or the effect of video-recorded lessons on specific student demographics. Another possible avenue of investigation would be to determine the effect of this classroom structure on student communities of learning. Anecdotal evidence suggests that students may form cohorts within a flipped classroom that persist in future courses.

It is important to note that flipped classrooms do not consist solely of video lessons. Moving primary instruction out of the classroom creates time in class for students to clarify and reinforce content through discussion with peers and to actively participate in authentic problem-solving. This inversion allows instructors to be present while students engage with deep mathematical ideas, which is a more effect use of their knowledge and instructional abilities.

In future research we plan to focus specifically on the ways in which students interact with videos. We want to determine if they are actively engaging with the video lessons or passively listening as though they are in a lecture. We are also curious about their video-watching habits and what they do when they are confused during a video. One of our primary goals is to find ways to structure the video-watching experience to improve student learning, including helping them build mathematical integrity (knowing what you do and do not know about mathematics). If students can accurately assess what they do and do not understand from the videos *before* each class session, the instructor can more productively run the class session. The results of this research could provide instructors with ways to make videos more effective and help students interact with videos more productively.

Impact of Abstract Algebra Knowledge on the Teaching and Learning of Secondary Mathematics

Matthew Wright	Eileen Murray	Debasmita Basu
Montclair State University	Montclair State University	Montclair State University

This study explores how in- and pre-service teachers make connections between advanced mathematics, specifically abstract algebra, and secondary mathematics. To better understand these connections, we draw on three areas of research: mathematical knowledge for teaching (e.g., Ball, Thames, & Phelps, 2008), mathematical practices (e.g., Council of Chief State School Officers [CCSSO], 2010; RAND, 2003) and habits of mind (e.g., Cuoco, Goldenberg, & Mark, 1996). In order to investigate how exposure to and instruction in abstract algebra impact the way teachers understand secondary mathematics and approach instruction, this study utilizes two main frameworks. To characterize mathematics understanding, we used the action, process, object, and schema (APOS) framework (Asiala, 1997). To unpack approaches to discussion, we use the construct of knowledge of content and teaching, part of pedagogical content knowledge in mathematical knowledge for teaching (Ball, Thames, & Phelps, 2008). Our analysis uncovered two broad themes related to understanding and approach to instruction—understanding and interpreting inverse, and use of mathematical language.

Keywords: Algebra and Algebraic Thinking, Teacher Knowledge, Advanced Mathematical Thinking.

There has been a longstanding debate in the mathematics and mathematics education communities concerning the knowledge secondary mathematics teachers need to provide effective instruction. Central to this debate is what content knowledge secondary teachers should have in order to communicate mathematics to their students, assess student thinking, and make curricular and instructional decisions. Many researchers believe that mathematics teachers should have a strong mathematical foundation along with the knowledge of how advanced mathematics is connected to secondary mathematics (Papick, 2011). But according to others, more mathematics preparation does not necessarily improve instruction (Darling-Hammond, 2000; Monk, 1994). Therefore, it is important that, as a field, we investigate the nature of the present mathematics content courses offered to (and required of) prospective secondary mathematics teachers to gain a better understanding of which concepts positively impact teachers' instructional practice.

The Mathematics Education of Teachers II (MET-II) (Conference Board of the Mathematical Sciences [CBMS], 2012) calls for prospective mathematics teachers to have opportunities to examine the connections between the mathematics taken at the university level and the mathematics taught in high school. The importance of understanding such connections is highlighted by the fact that in order for secondary school teachers to be able to develop mathematical reasoning skills in their students, they must themselves have a coherent view of the structure of mathematics and the way in which new knowledge can be connected to and develop from prior knowledge (CBMS, 2012). However, while many have defended this idea that the mathematics education for future secondary teachers must involve "seeing the discipline as a coherent body of connected results derived from a parsimonious collection of assumptions and definitions" (CBMS, 2012, p. 56), less is known about how this might happen in traditional mathematics courses, such as abstract algebra.

This exploratory study aims to advance our understanding of how prospective mathematics teachers make sense of and understand mathematical connections between secondary mathematics and abstract algebra. This work furthers the field's understanding of what connections could be leveraged to positively impact teachers' knowledge of the structure of mathematics as well as their ability to use such structure to develop their own students' mathematical reasoning skills. The research questions for this study are as follows: (1) How does exposure to and instruction in abstract algebra impact the way teachers understand secondary mathematics? (2) How does exposure to and instruction in abstract algebra impact the way teachers approach secondary classroom instruction?

Background

We consider connections between advanced and secondary mathematics to be ones that encompass both mathematical content and ways of thinking about and engaging with that content. To better understand these connections, we draw on three areas of research: mathematical knowledge for teaching (e.g., Ball, Thames, & Phelps, 2008), mathematical practices (e.g., Council of Chief State School Officers [CCSSO], 2010) and habits of mind (e.g., Cuoco, Goldenberg, & Mark, 1996).

Since Shulman's seminal work on content and pedagogical content knowledge (Shulman, 1986), researchers and policy-makers have been investigating how teachers' understand the mathematics they teach, and how this understanding can help them clearly present it to students. Because of the growing interest in teacher knowledge and its relation to student learning (e.g., Bolyard & Moyer-Packenham, 2008; Hill, Rowan, & Ball, 2005; Piccolo, 2008), teacher education programs in the U.S. have begun to include a variety of courses designed specifically to improve teachers' content and pedagogical content knowledge.

Secondary mathematics teachers are generally required to complete the equivalent of an undergraduate degree in mathematics for certification. However, research has shown that more mathematics preparation does not necessarily improve instruction (Darling-Hammond, 2000; Monk, 1994). In fact, some research has shown that more mathematics preparation may hinder a person's ability to predict student difficulties with mathematics (Nathan & Koedinger, 2000; Nathan & Petrosino, 2003). Even so, many still believe that mathematics teachers should have a strong content foundation that includes understanding connections within and between mathematical topics (Papick, 2011). But questions remain about what secondary content stems from advanced connections, which connections are important, and how knowledge of such connections may impact classroom practice.

Mathematical knowledge for teaching (MKT) (Ball et al., 2008) incorporates both subject-matter knowledge and pedagogical content knowledge. One component in the larger domain of subject-matter knowledge we focus on is *horizon content knowledge* (HCK). We believe this specific aspect of MKT is particularly useful for thinking about what advanced content knowledge prospective mathematics teachers at the secondary level need for teaching. HCK focuses on the relation of a sequence of mathematical concepts and considers how understanding is intended to progress across a curriculum.

One component in the larger domain of pedagogical content knowledge we focus on is *knowledge of content and teaching* (KCT) (Ball et al., 2008). This particular component highlights the interaction between specific mathematical knowledge and a teacher's understanding of pedagogical issues that could impact a student's learning. In particular, teachers need to draw on their mathematical knowledge to make decisions about sequencing content for instruction, choosing examples, and evaluating "the instructional advantages and disadvantages of representations used to teach a specific idea and identify what different methods and procedures afford instructionally" (Ball et al., p. 401). This knowledge is also important as teachers facilitate classroom discussions. That is, teachers draw on their KCT to make decisions regarding when they need to ask for clarification of a student's understanding or offer alternative explanations. Each of these requires an "interaction between specific mathematical understanding and an understanding of pedagogical issues that affect student learning" (Ball et al., 2008, p. 9).

To expand the notion of MKT, it is also useful for us to consider what secondary teachers need to know beyond content and concepts and to encompass mathematical habits of mind (e.g., Cuoco et al., 1996) and engagement in mathematical practices (e.g., CCSSO, 2010). These include looking for patterns, making conjectures, attending to precision, utilizing visualizations, and connecting representations. Such habits and practices in mathematical thinking and learning extend across content areas and levels of mathematical study. Therefore, as we consider how advanced mathematical content impacts teachers' knowledge and understanding of the teaching and learning of secondary mathematics, it is important for us to consider habits and practices that may also influence how advanced ideas are learned and interpreted for teaching.

We drew on these tasks to engage practicing middle school mathematics teachers in mathematics tasks highlighting a particular connection between abstract algebra and secondary mathematics. This study seeks to show how connections can be not only mathematical in nature and relate directly to subject-matter knowledge, but to also illustrate how connections can go beyond knowledge *of* mathematics and encompass engagement *in* mathematics through the lens of mathematical knowledge for teaching, mathematical habits of mind, and mathematical practices.

Analytical Framework

Teacher Understanding of Specific Content

When considering a course such as abstract algebra, a course typically required in a traditional mathematics major, Cuoco and Rotman (2013) have argued that topics such as groups, rings, and fields are not well connected to high school mathematics in university courses. One possible explanation is that university professors are unaware of the connections between the content they teach and secondary mathematics (Hodge, Gerberry, Moss, & Staples, 2010). Therefore, in order to build prospective teachers' content knowledge in a way that could support their teaching, courses such as abstract algebra should provide occasion to encounter links between advanced and secondary mathematics (Blömeke & Delaney, 2012).

In order to investigate how exposure to and instruction in abstract algebra impact the way teachers understand secondary mathematics, this study utilizes the action, process, object, and schema (APOS) framework (Asiala, Brown, DeVries, Dubinsky, Mathews, & Thomas, 1997). APOS characterizes the learning and understanding of mathematics according to four levels of mathematical understanding. The most fundamental level of understanding of a mathematical concept is referred to as an *action*—a transformation of mathematical objects which are perceived to be, at least in part, external to the individual. Actions are composed of previously constructed mental or physical objects. For the purpose of our study, these objects are the set of numbers and mathematical symbols that comprise mathematical language. Any operation carried out on these mathematical objects is done in response to external cues; an individual simply manipulates the given objects to form another object. When an individual can perform these operations mentally, not necessarily according to a prescribed algorithm, these actions have been interiorized, marking the attainment of the *process* level of understanding (Breidenbach, Dubinsky, Hawks, & Nichols, 1992).

At the process level, a learner is carrying out operations while simultaneously considering the object produced by these operations. Another characteristic of process-level understanding is the ability to reverse an action by decomposing an object produced by a binary operation back into the original objects and operation. When an individual is able to transform a process by using actions, they are said to have *encapsulated* the process, thereby transforming it into an *object* (Clark et al., 1997). At object-level understanding, a learner is able to view processes in terms of both its operational and elemental components.

The highest level of understanding for a mathematical concept is the *schema* level, or the "individual's collection of actions, processes, objects, and other schemas which are linked by some general principles to form a framework in the individual's' mind that may be brought to bear upon a problem situation involving that concept" (Dubinsky & McDonald, 2001, p. 3). This approach towards inverse, in form of function, is also aligned to the perception of 'undoing' to reach a certain outcome. Thus, the different perspective of inverse laid confusion regarding the different methods of determining inverse. In elementary and middle school, when students are primarily familiar with four basic operations, then inverse is determined an operation nullifying the effect of another, but with advanced grade level, the operational approach changes to functional approach. According to Wasserman (2016), it is the responsibility of the teachers to develop the overarching theme of inverse despite the different ways inverse is referred to during different course level of study. Below we discuss how the APOS framework can be used to unpack one's understanding of inverse, identity, and binary operation, the building blocks of the important structures at the core of abstract algebra.

Understanding inverse, identity, and binary operation

The conceptual understanding of inverse changes as students progress through grade levels. In elementary school, children learn the fundamental arithmetic operations of addition, subtraction, multiplication and division and the relationship between them. In considering the relationships between addition and subtraction, and multiplication and division, this is perhaps the first time that children are introduced to the concept of inverse operation. According to Wasserman (2016), the primary focus of elementary school education is to develop and refine students' procedural skills as well as their ability to justify mathematical results. Gilmore and Bryant (2008) stated, "Improvements in conceptual understanding can lead to advances in procedural skill and vice versa" (p. 302). This bidirectional relationship between procedural skill and conceptual understanding constructs the foreground of students' conception of inverse.

In middle school, students' perception of number systems faces a challenge with the introduction of negative and rational numbers and mathematical operations on these numbers (Wasserman, 2016). During this time, the inverse operation of subtraction, taking one positive number from itself, (e.g., $8 - 8$), tends to be reconsidered as the equivalent operation of adding one positive number with its opposite, (e.g., $8 + {}^{-}8$). Under such circumstances, though the operations are different, the ultimate outcome is same. At this time, students often struggle with the transition of the concept of inverse operation to inverse element. Eventually, students become familiar with one of the most ubiquitous components of secondary mathematics, the concept of function. A function and its inverse are connected to each other in several ways. For example, the domain of the function is the range of the inverse function and vice versa. Also, if we consider composition as the binary operation associated with the set of functions, inverse elements become inverse functions.

Advanced content knowledge helps teachers understand the different applications and conceptions of inverses. Advanced knowledge can also help teachers and students further their conceptual understanding of inverse beyond action and process levels towards understanding inverse as "objects in a set based on connecting inverse function to abstract algebra"

(Wasserman, 2015, p. 22).

Language in the Mathematics Classroom

As presented above, a teacher's knowledge of content and teaching plays a role in the decision-making a teacher needs to sequence and choose examples and tasks and facilitate classroom discussions. Therefore, as we consider how exposure to and instruction in abstract algebra impact the way teachers may approach secondary classroom instruction; we use the construct of KCT and its relation to the use of language in the classroom.

A widely held belief about mathematics knowledge is that it is precise and unambiguous. This view extends to the language in the mathematics classroom. According to Barwell (2005), when it comes to mathematical language, "Any ambiguity, that is, any possibility of more than one interpretation for a mathematical expression arises from sloppy use of language rather than any uncertainty of mathematical ideas" (p. 118). However, Barwell argues that as students explore mathematical ideas, they are better able to participate in mathematical practices and further develop their mathematical thinking. In this way, ambiguity "acts as an important resource for students and teachers, serving as a means of articulating between thinking and discourse" (p. 125).

Hauk, Toney, Jackson, Nair, and Tsay (2014) use the idea of discourse in the mathematics classroom as a central tenet of an expanded model of PCK for secondary and postsecondary mathematics focused on the use of language. This expanded model aims to bring attention to "mathematical appropriateness, clarity, and precision that are integral to thinking, learning, and communicating, especially in advanced mathematics" (p. A24). In their framework, Hauk et al. connect the elements of PCK to *knowledge of discourse*, to help address the fundamental question: "What is the interplay among advanced mathematical understandings, teaching, and culturally mediated communication in defining and growing pedagogical content knowledge" (p. A21). This knowledge of discourse helps relate PCK components to ways of thinking. In particular, KCT is connected to knowledge of discourse through *implementation thinking*. Implementation thinking draws on knowledge of discourse and mathematics-specific instructional practices, such as questioning, as a teacher adapts teaching based on content and classroom context.

For example, Hauk et al. (2014) present vignettes of a novice undergraduate instructor, Pat, to illustrate his development in implementation thinking. In his first semester, Pat's implementation thinking focuses on students getting the correct answer. He evaluates students' contributions and student-to-student interaction as less important. In Pat's fifth semester of teaching, he begins to attend to student thinking and works to make sense of and reason about the mathematics content with his students, which indicates growth in his implementation thinking. The goal of presenting these vignettes is to illustrate how effective teaching needs to extend "beyond precise and accurate transmission of facts or uptake by students of information and includes taking into account the background and experiences (mathematical and otherwise) of the people in the room" (p. A34).

As we consider the relationship between approaches to instruction, KCT, and implementation thinking, we work to uncover how language in the classroom can impact the teaching and learning of mathematics. In particular, we consider how exposure to and instruction in abstract algebra may change one's perspective on their use of language, and thus alter how one draws on discourse to inform the sequencing and choice of examples and tasks and the facilitation of classroom discussions.

Methods

To explore how exposure to and instruction in abstract algebra impact teachers' understanding of secondary mathematics and approach to instruction, we conducted a pilot study with pre- and in-service teachers enrolled in a mathematics master degree program with a concentration in mathematics education. In this pilot, we developed an instructional unit focused on solving equations. The goals of the unit were to have participants consider mathematical properties used when solving equations and how these properties were related to algebraic structures. One of the researchers, Murray, used this unit to teach one 2.5-hour class session. The class was videotaped and all written artifacts were collected. A more detailed description of the participants, data collection, and data analysis follows.

Participants

Participants were 12 students in a mathematics education course, titled *Selected Topics in Mathematics Education*, which focuses on topics often taught during high school or the early years of college. Students in this course are exposed to subject matter viewpoints from advanced college-level mathematics courses such as abstract algebra, geometry, number theory, and analysis. The class met once a week for 2.5 hours over a 15-week semester. Of the 12 participants, four were male and eight were female with zero to fifteen years teaching experience. One out of the twelve participants was a special education teacher, two were pre-service teachers, and nine were in-service high school and middle school mathematics teachers.

Data Collection

We relied upon three data sources: audio and video classroom data, written artifacts, and participant interviews. The instructional unit began by engaging participants in an investigation of the mathematical properties used to solve three different linear equations. Participants were asked to provide rationale for every step used to solve the equations. The purpose of this section was to challenge teachers' understanding of mathematical properties used for solving equations and to consider how attention to the algebraic structures and their properties may inform procedures and solutions.

After conversation of the initial problems, Murray facilitated a discussion on abstract algebra, specifically groups, rings, fields and their properties. Throughout the class, participants were encouraged to engage in small group discussions and explore different aspects of each algebraic structure with the help of various examples. Every small-group discussion was followed by whole-class discussion where participants shared their own solutions and rationale supporting their answers. The session was filmed to capture participant responses for future analysis. At the end of the session, participants reflected upon their classroom experience by answering a series of four questions asking about the impact the class might have on their perception of solving equations.

Following the classroom lesson, participants were emailed a request to participate in a follow-up interview; the purpose of which was to clarify ideas discussed in class and to probe participants' thinking on the impact of tertiary knowledge on the understanding of secondary mathematics and instruction. Only one participant volunteered for the interview session and his replies were recorded for future analysis.

Data Analysis

Due to the exploratory nature of this study, we used qualitative methods to analyze the data. APOS theory is well-suited to characterize conceptual understanding of mathematics; for our purposes, we used this framework to describe teachers' knowledge of secondary mathematics, particularly with regard to the concept of inverse. Having the ability to assess teachers' understanding helped us to answer our first research question, as it provided a starting point from which to discern changes in participants' understanding of the use of inverses before and after exposure to and instruction in abstract algebra. We additionally employed the MKT framework, and specifically KCT, to address our second research question. In particular, we used this framework to investigate how participants discussed secondary mathematics instruction after exposure to and instruction in abstract algebra.

We conducted preliminary analysis of the audio and video data with the intention of isolating episodes that contained connections between abstract algebra and secondary mathematics. For the initial analysis, we independently reviewed the video data and isolated episodes where connections were believed to have occurred. The researchers then came together to discuss the isolated portions of data. Once the significance of these episodes was mutually ratified, the segments were transcribed. The segments of data were then re-analyzed by reading through the transcripts. Initial or "open" coding methods were used, searching for words or phrases that showed evidence of participants' understanding of secondary mathematics or connections between secondary mathematics and abstract algebra. Although the analysis of our transcribed data was guided by our initial research questions, open coding was the preferred method of initial analysis as it allowed for the development of tentative codes that led to further inquiry, thereby allowing the study to take direction organically (Saldana, 2009).

Once initial codes had been elicited from the transcribed data, the codes were refined by employing inductive, constant-comparative methods (Merriam, 2009). This structural coding was particularly well-suited for our study as the study was exploratory in nature, incorporated multiple participants, and elicited data via semi-structured data-gathering protocols. We were able to assign more focused codes that served as a labeling and indexing device for our preliminary analysis. Finally, we used axial coding to categorize and organize the codes that had been generated during the initial and secondary coding phases. This coding resulted in two broad themes related to abstract algebra and teachers' understanding of secondary mathematics—*understanding and interpreting inverse*, and *use of mathematical language*.

Results

We report results from classroom data, e.g., transcriptions from the video-taped lesson and written artifacts. Although we also interviewed one participant after the instructional unit, this data continues to be analyzed, and will not be discussed here.

Impact on Understanding Secondary Mathematics

In considering how exposure to and instruction in abstract algebra impact the way secondary teachers understand secondary mathematics, we found some participants moving from an action or process-level of understanding towards an object-level of understanding. To illustrate this change in understanding, or lack thereof, we present evidence from the data focused on the concept of inverse. To explain this characterization of participant knowledge, we adapted the definitions from the APOS framework for the concept of inverse (see Table 1).

	Definition (Asiala, Cottrill, Dubinsky, & Schwingendorf, 1997, p. 400).	Our Characterization
Action	[A]n *action* is a transformation of mathematical objects that is performed by an individual according to some explicit algorithm and hence is seen by the subject as externally driven.	An *action* conception of inverse involves being able to use inverses to perform particular mathematical tasks. In the case of this study, we began by discussing the use of inverses to solve equations. In this instance, when the students saw addition or multiplication as an external cue, they thought subtraction or division in response. That is, they were using the inverse to isolate the variable and determine the solution to a problem.

Process	When the individual reflects on the action and constructs an internal operation that performs the same transformation, then we say that the action has been interiorized as a process.	A *process* conception of inverse involves more generally thinking about inverses, so that an inverse is an operation, as well as a mathematical property that one can use in a variety of situations. For example, inverses were being thought of as operations and the students discuss properties of equality as a way to think about solving equations.
Object	When it becomes necessary to perform actions on a process, the subject must encapsulate it to become a total entity, or an *object*. In many mathematical operations, it is necessary to de- encapsulate an object and work with the process from which it came.	An *object* conception of inverse involves seeing the inverse as an element of a set, consisting of elements and a binary operation. Here, students think about the inverses as being elements in the set, but then are able to use the process to determine what that element is for each specific member of the group.
Schema	A *schema* is a coherent collection of processes, objects and previously constructed schemas that are invoked to deal with a mathematical problem situation. As with encapsulated processes, an object is created when a schema is *thematized* to become another kind of object, which can also be *de-thematized* to obtain the original contents of the schema.	The *schema* conception of inverse includes acceptance of the operational/elemental duality of inverses. The utility of inverses as not only an element with an associated binary operation, but also its relation to other mathematical properties and applications to problem solving are understood.

Table 1: *Characterization of Student Understanding of Inverse According to the APOS Framework*.

In the sections to follow, we illustrate how before exposure to and instruction in abstract algebra, participants relied on external cues within problem structure to determine and describe solution strategies. Some participants possessed a more generalized view of inverses and were able to establish a connection between the use of operational inverses and existing properties of equality. After the unit on abstract algebra, some participants were able to demonstrate characteristics of object-level understanding, yet still tended to rely on process to participate in the tasks. In all cases, conversation on inverses predominantly centered around the operational aspect; those students who attempted to reconcile the operational-elemental duality of inverses were viewed to demonstrate essential characteristics of object-level understanding and reasoning.

Understanding Prior to Exposure to Abstract Algebra

To begin the lesson, participants were provided three linear equations, $x+5=12$, $3x=12$, and $5x+7=3+2x$, with worked out solutions. They were asked to describe the steps and properties used to solve the equations. For the first example, participants cited the mathematical properties of "inverse of addition" and the "subtraction property of equality" to justify the step of subtracting 5 from both sides of the equation. [Author] followed up by asking, "Are those two things different?" Participants replied both yes and no, which led to the follow-up question of why they might be different.

P1: I think they are different because, um…the, calling it an additive inverse is referring to why they chose subtraction. Subtraction property of equality refers to the fact that its subtraction on both sides.

P2: That's, that's true.

Murray: So how are they the same then?

P1: They're both subtracting. I mean, if you're calling it the inverse of addition, that's subtraction, and the subtraction property of equality is obviously subtraction.

This brief episode at the beginning of the lesson sheds light on the participants' prior knowledge of secondary mathematics, particularly with respect to the use of inverses as an aspect of performing algebraic operations. In stating, "additive inverse is referring to why they chose subtraction," participants used the presence of addition as an indicator within the structure of the equation to employ subtraction as a solution step. Reliance on external cues embedded in the problem demonstrated an action-level understanding of inverse. The participants also viewed the inverse of addition as the subtraction property of equality, an established mathematical property, thereby signifying an understanding of the utility of inverses beyond that of an external process for 'undoing'. This interpretation indicates a more general perception of inverse and shows that some viewed inverses as serving an algebraic application other than reversing an operation, indicating a process-level of understanding.

The steps used to solve the second equation, $3x=12$, were viewed similarly. When asked to describe the step of dividing by 3 students replied,

P1: Division property of inequality, equality?
Murray: Division property of equality. Anyone calling it anything different than that?
P2: Inverse multiplication?
Murray: Inverse multiplication. So, is that the same thing what just happened with the…
P2: Mmhm.
Murray: So, when you talk about the inverse property, so you said inverse property of, what?
P2: Multiplication.
Murray: Of multiplication. So, what's the inverse?
P2: Division?
Murray: Ok. So you are saying, you are saying that because multiplication division are inverse operations? All right. Is that how other people are interpreting that?
P3: Multiplied by the reciprocal.
Murray: We are multiplying by the reciprocal. What's the reciprocal?
P3: Of three it's one-third.
Murray: One-third. So will that look different if I was thinking about it as multiplying by the reciprocal?
P3: Same thing. It's dividing by three.
P4: It will look, it would look different written in the equational form, obviously because instead of having the division sign it is having the multiplication sign.

As in the first problem, participants demonstrated a reliance on cues within the equation's structure to describe operations. In this equation, students observed that 3 and x were multiplied together to yield 12; the use of multiplication prompted the participants to employ division to reverse multiplication. When considering the use of the multiplicative inverse as an alternative to division, one participants stated, "it would look different written in the equational form, obviously because instead of having the division sign it is having the multiplication sign," demonstrating that some were still concerned with differences in notation in equivalent solution steps. According to our framework, the reliance on external cues to select or justify an operation indicates that the participants demonstrate an action-level of understanding of inverse.

Continuing the discussion, the students posit that the equation can be solved in two ways, by dividing both sides by three or multiplying by the multiplicative inverse. Although there was still some confusion over exact language use, all participants agreed that the outcome, or the object produced by either action would be the same. By arriving at the same result through the use of different actions, participants demonstrate a process-level understanding of inverse.

For the equation, $5x+7=3+2x$ participants were asked to justify the operation of subtracting

$2x$. As they discussed this step, rather than discussing additive inverse as before, a new idea came to light.

Murray: Ok then for the last one, what happens…what are we doing there? So for the first side we are subtracting the $2x$, what's that?

P1: Combining like terms.

Murray: Combining the like terms? What would other people say about that?

P2: It's still subtraction property of equality.

Murray: Ok. So it's still subtraction. So, what makes it different than the last problem? Like why it…why would combined like terms maybe pop-up there?

P3: Because it is a variable?

Murray: Still they look different right? So, we are kind of combining like terms but in order to do that we have to use the property.

P2: I only use combining like terms when things are on the same side of the equal sign, maybe it's my preference in my class, but like I, I try to distinguish them because when I say combining like terms I mean there are things on the same side of the equal sign that can be combined. And then when we are moving things from side to side, I use subtraction property or addition property just so that they know kind of distinction I am trying to make. But I also teach pre-algebra kids, so I try to create the distinction.

Unlike the discussion of the first two problems, in this segment we did not find any discussion of the use of inverses. Instead one participant explained this step as "combining like terms." There was no mention of using subtraction to reverse the operation of adding $2x$, nor was there mention of the additive inverse, $-2x$. Students viewed this problem as structurally different than the first two because they performed actions on a variable rather than a constant term. By performing intermediate steps to isolate the variable or combine like terms, students did not recognize they were utilizing the same properties as the first problem, namely inverse of addition. By slightly altering the structure of the problem and requiring students to reconcile operations on a variable term, at least one participant thought differently about essentially the same operations. The participants' perception that a different idea must be used in this situation showed reliance on external cues within the structure of the problem, evidencing action-level reasoning. In summary, prior to the introduction of abstract algebra content there is evidence that most participants possess an action and/or process-level understanding of inverses.

Understanding After Exposure to Abstract Algebra

After the introduction to abstract algebra, participants were prompted to explain the nature of inverse operations within a group structure. During this conversation, some participants displayed an object-level understanding of inverse, while others continued to show understanding of inverse at an action-level. Below is an exchange that illustrates the object level of understanding.

P1: We said when you were talking about a group that each element needs an inverse element and that in order to find an inverse element, you are thinking about an inverse operation.

Murray: So it means something different, when I say inverse operation I mean something different than when I say additive inverse.

P1: Sort of. When we are talking about the set of integers not that a specific element like 2, and I want to find its inverse, I am thinking about subtraction in a way to come up with additive inverse, I am thinking about the inverse operation.

The requirement that each element in the group has a corresponding inverse element is a property unique to the group structure, and knowledge of this requirement changed the direction of discourse on inverses. For the first time, participants discussed whether an inverse may or may not exist. Participants attended to the relationship between an element, its inverse, and the associated binary operation. By contemplating the existence of an inverse element for a given element with respect to a single operation, participants began to consider the elemental-operational duality of inverses. Within the APOS framework, by accommodating the notion that inverses consist of both an elemental and operational component, some participants were able to encapsulate the concept of inverse and demonstrate object-level understanding. These participants continued to display object-level understanding in a later activity in the unit.

One of the final activities included solving linear and quadratic equations in Z_5 and Z_6. For solving the linear equations, most participants used a guess-and-check method by either referring to the Cayley tables they generated or solving the equations over the set of real number and determining the solutions' equivalence class in Z_5 or Z_6. During small group discussion, however, Murray encouraged participants to consider using properties to solve the equation $x+5=1$ in Z_6:

P1: Like I can use the additive inverse of 5 on both sides or something. Is that what you are saying?
Murray: Maybe. Yeah. So if you did that...
P2: You want something that's one. Ah, well, but that's…
P1: Because that would give me a zero, which is what I was looking at.
Murray: So you're just saying, so she was like, if I added the additive inverse to both sides.
P2: Of five.
Murray: Of five. Yeah.
P1: Which, I have to think about.
Murray: Yeah.
P2: Because the additive inverse of five in six will be
P1: Is one?
P2: One.
Murray: One. So, if I did $x+5$,
P2: Add one to both sides.
P1: So add one to both sides.
Murray: Which would give me this.
P1: And get me x plus zero equals two.

In this discussion, participants considered the implications of adding the additive inverse of 5 to 1 in Z_6, which would result in x plus the additive identity on the left side of the equation, and a new object - the solution on the right. Furthermore, the participants considered what the solution would look like within the domain of Z_6 rather than on the set of real numbers. This indicated an object-level understanding of inverse as participants were thinking about the inverse as an element of Z_6, but were using a process to determine the solution.

However, not all participants were able to develop this level of understanding. In another activity, participants were asked to determine if Z_5 or Z_6 satisfied the field axioms. One participant, Steven (pseudonym), observed that multiplicative commutativity held for all elements within Z_5 and Z_6. But confusion arose around a discussion of the inverses. Steven claimed "The inverse is zero. Both the additive and multiplicative inverse is the same. 0 times a is 0." A few moments later Steven continued, "here they are saying, the inverse of a times a is the additive identity.” In testing Z_5 and Z_6 against the field axioms, Steven seemed to be emphasizing the importance of the operations, but ignoring the significance of the objects created by these operations. It appeared that Steven misread the multiplicative inverse axiom, taking *e* to be the additive identity. Steven remained focused on the operation to be performed, in this instance—multiplication, but ignored the fact that the axiom was dedicated to producing the *multiplicative* identity by multiplying an element with its *multiplicative* inverse.

When determining if Z_5 and Z_6 satisfy the multiplicative commutativity and identity axioms, Steven relied heavily on the notation within the axioms to analyze the structure of these residue classes. In all field axioms, the binary operation is multiplication, however; Steven failed to realize that multiplying *a'* and *a* should yield the multiplicative identity. Steven attended to the operations prescribed by the axioms without regard for the resultant object, thereby overlooking the fact that *e* represented different elements depending on the operation. The application of operations without consideration of the object produced provided evidence of action-level understanding.

Impact on Approaches to the Use of Language in Secondary Classroom Instruction

In considering how exposure to and instruction in abstract algebra impact the way teachers may approach secondary classroom instruction, we found participants focusing on language use in the classroom. To illustrate this focus, we present evidence from the data primarily after the introduction of a particular classroom scenario about solving quadratic equations.

It is interesting to note that throughout the instructional unit, Murray tried to engage participants in discussion about the influence of advanced mathematical concepts on secondary school mathematics. For example, after the extensive discussion about inverse operation and inverse elements associated with different groups, Murray stated:

> “So, when I talk about inverse operation, I wonder how much that maybe helps or hinders students’ ideas about what an inverse is. [W]e have all these inverses, right? I have additive inverse. I have multiplicative inverse. I have functional inverse…So this word inverse keeps coming up over and over and over again, but it means different things in different situations.”

Even with prompting comments such as this, participants did not seem to consider the impact of abstract algebra on their instruction until the final activities in the unit.

Recall that as participants solved linear and quadratic equations in Z_5 and Z_6, we saw some moving towards an object understanding of inverse. While solving quadratics, participants realized was there were four solutions in Z_6; namely the zero divisors in the ring. Immediately following discussion about the nature of the quadratic solutions for Z_5 and Z_6, [Author] introduced a vignette about a high school algebra teacher, Clark Freeman. The scenario below appeared in the instructional unit:

> *Clark Freeman is teaching in an Algebra classroom. He has mostly first year high school students, but there are some second and third year students repeating the course. The class has been discussing quadratic functions for a week, and has discussed finding the x-intercepts, y-intercept, and axis of symmetry. During one class, Mr. Clark is presenting solving simple quadratic equations. He first shows the students how to solve $x^2 - 4=0$. He describes adding four to both sides to obtain $x^2=4$, then takes the square root of each side to obtain $x = 2, {}^{-}2$. He then shows the students $x^2+4=0$. He describes subtracting four from both sides to obtain $x^2={}^{-}4$. He says, “When we try to take the square root of both sides, we have to take the square root of a negative number, which we can’t do, so there are no solutions.”*

Participants then considered the questions: (1) What do you think of Clark’s presentation?

(2) What does Clark mean by "no solution?", and (3) Is there any situation where the equation, $x^2+4=0$ would have a solution?

By connecting their experience of finding four solutions for the quadratic equation $x^2+2x+3=0$ in Z_6 to Mr. Freeman's instruction, participants considered the struggle students go through when first introduced to quadratic equations with complex solutions. Specifically, participants agreed that it is the responsibility of the teachers to choose, make, and use mathematical representations effectively (Ball et al., 2008), and use mathematical language in the classrooms carefully to avoid conflicts in students' understanding of mathematical concepts. One participant stated, "There's gotta be a distinction between 'no solution' and 'no real solution'. The wording has to be a little more precise."

Additionally, within the written responses at the conclusion of the unit, participants reacted to the question, "In what ways, if any, have these discussions impacted your thinking about instruction of solving equations for students?" Several responses indicated a focus on language use in the classroom and its impact on student learning. Comments included, "to be careful with wording of answers—consider all possibilities and their perspectives," "I care about words a lot and will think about that more," and "[there is a] difference of having absolutely no solution and having a complex number as a solution."

Conclusions and Implications

Prior to the instructional unit on abstract algebra, participants demonstrated action and/or process-level understanding of inverses. In most cases, participants viewed the inverse as an operation that could be used to undo another operation performed on the unknown variable. This indicated that use of inverse was prompted by cues within the structure of the equation, evidencing action-level understanding. Some participants saw the link between inverses and established properties of equality, demonstrating the algebraic utility of inverses as a problem-solving tool, which showed process-level understanding.

Post-instructional unit, some participants exhibited object-level understanding, while some remained at action or process-level. None of the participants displayed schema-level understanding. Specifically, when solving $x+5=1$ on Z_6, participants attended to inverses with respect to a binary operation, solution elements in the domain of Z_6, and the additive identity. The incorporation of the operational and elemental aspects of inverse along with contemplation of the object created as a result of the operation showed object-level understanding. Participants' knowledge of group structure, an essential component of abstract algebra, caused them to consider inverse elements with respect to a given binary operation, facilitating the transition from action/process-level understanding to object-level understanding. According to Wasserman (2016), this movement from an action/process-level of understanding of inverses towards viewing inverses as objects in a set reflects the APOS framework. This illustration of object-level understanding was indicative of the participants expanding their sense of number and operation. In fact, we claim the participants who were able to transition from the action/process-level of understanding toward an object-level understanding were able to do so because they began to view inverses as elements rather than operations.

We also found that participants were not concerned about the existence of solutions until they themselves were baffled by four solutions of the quadratic equation, $x^2+2x+3=0$, in Z_6. This result is opposed to the Fundamental Theorem of Algebra, according to which a polynomial of degree n should have at most n roots. The contradiction of this mathematical theorem, that participants themselves have used since middle school, challenged them. Later, when Murray put forward the story of Mr. Clark, participants realized the conflict faced by students of secondary mathematics as they accommodated a new, unfamiliar number system. By the end of the study, we found our participants became aware of the importance of maintaining a proper progression of related mathematical concepts for effective teaching and learning practice. This realization about sequencing mathematical concepts is aligned with KCT (Ball et al., 2008). According to KCT, effective teaching is the outcome of the perfect combination of knowledge of teaching and content. Teachers should be able to "choose which examples to start with and which examples to use to take students deeper into the content" (Ball et al., 2008, p. 401).

Even so, there are benefits to ambiguous language in the mathematics classroom for the continued development of concepts (Barwell, 2005). In fact, it may not necessarily be a problem that students are exposed to ambiguities, such as "no solution" versus "no real solution". Rather, it is up to the teacher to confront ambiguities in productive ways that allows students to develop a deeper understanding of a concept. In the context of solutions, this could mean that students themselves can question the idea of no solution and come to understanding that solutions to equations are closely related to the domain over which the equation is being solved. Therefore, while it is not surprising that our participants were questioning the use of language as they themselves experienced disequilibrium around the number of solutions, we claim that their students should have the opportunity to expand upon and alter their understandings of particular words, like solution, as their mathematical knowledge increases.

In this exploratory study, we investigated the impact of exposure to and instruction in abstract algebra on mathematics teachers understanding of secondary mathematics and approach to instruction. Many researchers of mathematics and mathematics education may intuitively understand how secondary mathematics teachers' deep knowledge of mathematics is related to the ability to be an effective mathematics instructor in secondary schools. However, the field still lacks deep understanding of how secondary teachers use their knowledge of tertiary mathematics during instruction. This understanding could lead to a better sense of the kinds of mathematics courses that can provide teachers with the content and pedagogical content knowledge they need to make best use of these connections to improve their own understanding and during classroom instruction.

Service-learning in a precalculus class: Tutoring improves the course performance of the tutor

Ekaterina Yurasovskaya
Seattle University

We have introduced an experiment: as part of a Precalculus class, university students have been tutoring algebra prerequisites to students from the community via an academic service-learning program. The goal of the experiment was to improve university students' mastery of basic algebra and to quantitatively describe benefits of service-learning to students' performance in mathematics. At the end of the experiment, we observed 59% decrease of basic algebraic errors between experimental and control sections. The setup and analysis of the study have been informed by existing research on tutor learning and cross-age tutoring, as well as mathematical pedagogy for social justice.

Key words: Precalculus, design experiment, service-learning

Introduction and Research Questions

Academic service-learning consists of two integral components: a useful service to the community, and a meaningful learning opportunity to the students, which is relevant to the material covered in the course (Hadlock, 2013). The type of service is largely determined by the needs of the target community, and can range from a one-time day-long event to a project that spans several months. Service experience is linked directly to an academic course, and is guided by the course instructor, as well as by the supervisors from the community. While providing service, students practice and directly apply skills and knowledge acquired in the course, and bring to the classroom a real-life perspective on the material which they may have until now viewed as purely theoretical. Astin, Vogelsang, Lori, Ikeda, and Yee (2000) found that service-learning showed positive effects on academic performance (GPA, writing and critical thinking skills) and values of participating students.

Academic service-learning has traditionally been associated with social sciences, psychology, counseling, and social work, while service-learning in mathematics courses has recently been gaining prominence (Hadlock, 2005). By engaging in mathematical service-learning, students are meeting the needs of the community by providing mathematical and statistical modeling to local organizations, by offering tutoring in the fields of mathematics and STEM disciplines, or by organizing Math Fests for schoolchildren. Our present study was motivated in part by the need for a quantitative analysis of the benefits of service-learning to students' mathematical performance.

Our second motivation was the ever-present need to improve student success and retention in Calculus in effort to increase attrition in STEM disciplines (Bressoud, Mesa & Rasmussen, 2015). Results from a recent national study show that "a total of 48 percent of bachelor's degree students and 69 percent of associate's degree students who entered STEM fields between 2003 and 2009 had left these fields by spring 2009. Roughly one-half of these leavers switched their major to a non-STEM field, and the rest of them left STEM fields by exiting college before earning a degree or certificate" (U.S. Department of Education, 2013). Edge and Friedberg (1984) show that solid algebra skills are one of the main factors determining success in Calculus. Success of the service-learning project raises students' fluency in algebra and leads to a stronger chance of their mastering Calculus, and staying within their chosen technical field. At the same time, students in the community receive additional mathematical one-on-one instruction, raising their chances of high school graduation. University students, especially athletes, often serve as role models for those who may consider going to university.

Our study explored the following research questions:

Question 1: Will students who engage in tutoring algebra pre-requisites to middle-school and returning students demonstrate fewer 'fundamental' mistakes than students from the control section without the tutoring experience? By 'fundamental' mistakes we mean the following:

1. *Mistakes that result from misunderstanding the addition/subtraction algorithm of*
    a. *numerical fractions*
    b. *rational expressions*
2. *Cancellation mistakes in*
    a. *numerical fraction arithmetic*
    b. *rational expressions*
3. *Mistakes in operations on radicals*
4. *Mistakes in operations with exponents.*
5. *Mistakes in basic factoring using formulas.*
6. *Other – may be added after consultations with other mathematics faculty, or after marking the final exam.*

Question 2: What will be the reaction of students to the service-learning experience introduced in a scientific course that has not traditionally been associated with community work at this and other institutions?

Theoretical Perspective

Our framework for the present study follows a standard pseudo-experimental setup as described by McKnight, Magid, Murphy, and McKnight (2000): baseline performance for experimental and control sections is determined via a diagnostic test; the two sections receive equivalent instruction for the duration of the course, except for the difference in the tutoring service-learning component. The two sections are given identical final exam, and their performance is analyzed via a rubric. Qualitative data is also compared. To our knowledge ours is the first study that quantitatively analyses benefit to mathematical performance of service-learning students engaged in tutoring.

In designing the course and analyzing the results of the experiment, we consider sources in literature on understanding the phenomenon of tutor learning. Our idea to use tutoring as a means to help student-tutors learn mathematics starts with a well-known saying 'I hear and I forget. I see and I remember. I do and I understand'. We rely on work of Allen and Feldman (1976), as well as Gartner, Kohler, and Riessman (1971), who show that cognitively demanding tasks of organizing subject matter knowledge, as well as explaining and questioning in the process of working with a tutee, contribute to tutor knowledge. In designing reflective mathematical journal activities to reinforce tutoring experience, we rely on the work of Roscoe and Chi (2007), who name reflective knowledge-building, "which includes self-monitoring of comprehension", as fundamental to tutor learning.

Inspired by the stated mission of Seattle University to promote justice, our overall study is situated in the context of teaching and learning mathematics for social justice, as described by Gutstein (2006).

When designing and implementing the service-learning structure, we closely follow the suggestions and project design outlined in the Special Issue on Service-Learning in Mathematics, PRIMUS: Problems, Resources, and Issues in Mathematics Undergraduate

Studies (2013), particularly Schulteis' (2013) experience of building a course with university students' satisfying the tutoring needs of local institutions and non-profit organizations.

Methodology

Our work took place at Seattle University: a medium-sized urban Catholic university in the heart of Seattle, WA, with a long tradition of incorporating service-learning and community work into students' coursework and extra-curricular education. University's Center for Community Engagement runs Seattle University Youth Initiative which has provided tutoring to schools in close proximity to the University. In years 2014-2015, 112 members of Seattle University faculty implemented academic service-learning in their courses. Such high participation rate is largely due to the Center for Community Engagement that carries most of the administrative work in organizing student placements and in establishing effective communication with community partners.

Mathematics Department at Seattle University has traditionally been involved in outreach activities. Annually, several sections of a standard Mathematics Core course for students majoring in humanities involve a social justice service-learning component with university students tutoring math to elementary school students. The course was first developed and implemented by Allison Henrich, who demonstrated a decrease in math anxiety in participating university students (Henrich & Lee, 2011). Seattle University mathematics professor Leanne Robertson runs Seattle University Math Corps: a highly successful mathematics outreach program that employs mathematics majors and provides tutoring to local elementary school students. No STEM-related courses at the Mathematics Department have yet involved an academic service learning component as part of mathematics course curriculum except for the Precalculus course described below.

Experimental Design

The setting for our study was two sections of a standard Precalculus course that served as a pre-requisite for the science and engineering track Calculus sequence. The course focused on algebra material and served as a mathematics refresher for students whose ACT and SAT scores would not allow them to be placed directly into a Calculus I course.

Topics covered in the course included quadratic, radical, and rational equations and inequalities, functions, inverses, and graphing, roots of higher-degree polynomials, exponential and logarithmic functions, as well as applications of all the above topics. Course audience in both sections consisted of first- and second-year university students of traditional age, majoring in a variety of fields: engineering, nursing, biology, business. Students' prior mathematical background varied: some students may have difficulty with basic exponents, while others are comfortable solving standard radical and rational equations.

Both experimental and control sections numbered 21 students each. The experimental section of the Precalculus course involved a service-learning component, while the other section served as control and consisted of standard in-class instruction only.

All students in the experimental section took part in the SU Service Learning program. Over the course of the quarter, they spent 2-3 hours per week tutoring basic algebra and sometimes arithmetic to middle school and high-school students, as well as adults returning to obtain their GED. The students put in a total 18-21 hours of tutoring work over the duration of the quarter. Service-learning component constituted 10% of students' grade, while homework, web-work, tests, and in-class participation made up the remaining 90%. On the first day of class, students in the experimental section received an overview of the service experience as community partners introduced their respective organizations and described the target populations that used their services. Representatives from Seattle

University Center for Community Engagement distributed necessary paper-work, explained the process and the timeline of contacting community partners, and conducted an interactive presentation on aspects of cultural competency that could be relevant in work with diverse populations.

During the first week of the quarter, students in the experimental section contacted the community partners of their choice, filled out various clearance documents, received training, and started tutoring. In the meantime, mathematical part of the course started as it usually would, with lectures, homework, and class-work. Tutoring continued through the quarter, and ended on the last week of the course, to give students time to prepare for the final exams.

The control section was identical to the service-learning section in every aspect of the course syllabus, such as the topics covered, the number of exams, attendance and make-up policy, etc. The only difference was the lack of the tutoring component in the control section, as well as a slight difference in grading weights assigned to exams and homework. The control section also received some amount of extra homework intended to balance the additional workload faced by experimental section.

Diagnostic test

We established a baseline of the students' prior knowledge and preparation by using a diagnostic pre-test. The pre-test was given to both sections on the first day of class and covered the pre-requisite material including arithmetic with fractions and radicals, basic factoring, and solving basic equations. In order to make sure the task was taken seriously, the students received a small amount of credit for completing the pre-test.

Written Reflection

In order to fully benefit from the service-learning experience, students must have an opportunity to engage in structured reflection and connect for themselves the tutoring experience with the content of the course (Bringle & Hatcher, 1999). An integral part of the experimental service-learning section was a weekly guided reflective diary of tutoring experiences, helping students analyze mathematical, as well as social and pedagogical, aspects of their work with the students from the community.

Each journal entry included a mathematical and a non-mathematical component. Mathematical reflection helped the students engage with and analyze the mathematical aspect of the tutoring experience and reflect on the following and similar questions:

- What is the topic that your student is studying? With which component did the student need help?
- What problem did you discuss with your student? What mathematical concept did you address?
- What piece of knowledge was missing from the students' understanding that prevented them from moving forward?
- What method did you use to approach the solution and how did you explain the material?
- Can you predict which future mathematical topics will rely on the problem you discussed with the student?
- Did you discover any gaps in your own mathematical knowledge? What steps did you take to address them?
- Did you discover any parallels between the topics you tutored and our mathematical lectures and problems from class?

Mathematical part of the journal became a place for conceptual analysis of mathematics discussed in the tutoring sessions, as well as an aid in reflective teaching.

The free-form non-mathematical reflection was intended to help the students process the human aspect of their experience with service-learning and tutoring. The following guiding questions were suggested to the students: "You may think about your pedagogical observation of your student. What do you think is holding this student back and what can be done to help the student succeed? How was your tutoring week? What non-mathematical problems did you encounter? Any thoughts on what you are seeing and experiencing while tutoring? Any questions you would like to ask me, or your fellow students, or the management of the organizations where you tutor?"

The non-mathematical part of reflection was optional, reserved for the time when students wanted to share a personal experience, however, most of the time students chose to write down their observations of service sites and of people they met there. Service-learning journal served as an effective communication tool between students and instructor, and readily alerted the latter as to potential problems or issues at the service sites.

In-class reflection

In addition to completing reflective journal entries, the experimental section held two in-class reflection meetings. Students split in groups according to their respective tutoring sites, which gave them opportunity to meet others who worked at the same location, exchange information, and discuss common issues, such as transportation, time commitment, and communication with the community partners.

In-class reflection meetings offered the participants an opportunity to discuss the pedagogical issues raised by the students themselves, through the journals or in class: How do you motivate an unmotivated student? How do you explain a concept of a variable? Of an equation? How do you guide a student through word problems? How do you deal with discipline problems?

Everyone was asked to contribute, and students from different tutoring groups offered valuable pedagogical suggestions, arriving on their own at well-known mathematics education techniques: the need to build on the basics (arithmetic) before proceeding to algebra, to move from concrete to abstract in explanations of material, to ensure that the given and the unknown were clearly identified before a word problem can be solved.

> What I have noticed most after tutoring at Seattle Central is that if you truly want to succeed you need to master the basics if you even want to excel at the next level of math. Barely grasping the concept is not enough to get through that current level of math, never mind the next. (post-meeting journal entry)

Reflection meetings fostered a sense of a community in the classroom, brought out a shared experience, and helped create a common bond among the students.

Anonymous end-of-term reflection

At the end of the course, the students submitted a typed anonymous reflection where they were free to comment on any aspect of their experience, to offer suggestions for improvement, and to voice any additional concerns regarding the course. Results of anonymous reflection are discussed in the Results section below.

End-of-term examination.

At the end of the quarter, both sections took a standard final exam with identical questions. Relevant statistics were computed and compared for both sections. The number of fundamental mistakes (see Introduction) was determined via a special rubric, which we will describe in the Results section along with the data obtained from the exams.

Results

Our diagnostic pre-test indicated that the experimental and control sections were comparable in preparation and abilities and showed similar score distributions, with the experimental section showing a slightly better average, but the difference between the two sections not being statistically significant.

Research question 1 was answered affirmatively. We compared the number of fundamental mistakes in the final exams for both sections: there were only 13 fundamental mistakes made by the 21 students of the experimental section, while the 21 students of the control section made 32 fundamental mistakes. Thus, there were 59% fewer fundamental mistakes in the experimental section than in the control one.

The following error types were analyzed and recorded via a grading rubric. In the list below, the shorthand Error Code is followed by an explanation of the mathematical error.

Arithmetic:

- R1: Subtracting polynomials without use of parentheses
- R2: leave square roots unsimplified
- S1: signs remain unchanged when a term is moved from one side of equation to another
- P1: failing to distribute multiplicative term to all terms in parentheses
- C1: mistakes in longer arithmetic calculations performed without a calculator.
- R3: miscellaneous errors in calculating square roots of real numbers.
- E1: failing to apply laws of exponents correctly

Algebra:

- A1: distributing exponents over sum or difference; ex: square of sum equals sum of squares
- A2: miscellaneous errors in algebra of radicals.
- A3: splitting radicals over sum/difference
- A4: reluctance to use formulas: ex: foiling every time instead of applying formula: $(a+b)^2 = (a+b)(a+b) = a^2 + ab + ba + b^2$
- A5: fundamental misunderstanding of formulas and reasoning behind them, leading to algebraic mistakes: ex: in applying square of difference $(a-b)^2 = a^2 - 2ab + b^2$ to example $(a-3)^2$, b is assumed to be (-3), not 3. Applying above formula leads to result $(a-3)^2 = a^2 + 6a + 9$

The following table summarizes final exam errors from experimental and control sections:

Error Code	Error Type	Experimental Section	Control Section
Arithmetic			
R1	If y=a+b then x-y=x- a + b	3	4
R2	leave $\sqrt{\frac{125}{4}}$ unsimplified		1
S1	x= - 2 equivalent to x-2=0		2
P1	4(a-b)=4a-b	1	4
C1	Mistakes in longer arithmetic computations w/o calculator	5	7
R3	R^2=d^2/2		1
E1	3^2=8		1
Algebra			
A1	$(a+b)^2$=a^2+b^2	1	6
A2	Root misc	3	3
A3	$\sqrt{a+b}=\sqrt{a}+\sqrt{b}$		1
A4	Foil without use of formula: $(a+b)^2=(a+b)(a+b)=a^2+ab+ba+b^2$		1
A5	$(a-b)^2=a^2+2ab+b^2$		1
Totals:		**13**	**32**

The course average for the experimental section was higher, due to the difference in the weights given to individual course components.

Data from the reflective diaries and the end-of-term anonymous reflection indicate that the answer to the second research question was also positive: out of 21 submitted anonymous reflections, 20 were positive, reflecting a sense of accomplishment and a clear understanding of the privilege of university education, as well as the appreciation of new friendships.

> I learned how to better explain everything and how important it is to verbalize the why and not just the how. I also think learning how to deal with children, and learn patience is essential in growing up. (end-of-term anonymous student-tutor reflection)

Similarly to Butler (2013), we observed a number of service-learning benefits that went far beyond the original goal of the project, including an increased level of confidence in oral communication skills mentioned by the international students. After the quarter ended, several students voluntarily continued their work with the community partners.

In their diaries, the students frequently pointed out multiple connections between the mathematical concepts covered in class and the topics they had explained in the tutoring sessions.

> Another mathematical challenge he is facing is remembering to flip the sign of the inequality when you multiply or divide by a negative number. This draws incredible parallels to what we are studying in class. Just today we learned the exact same thing while working with inequalities except that we use non-linear equations and my student only uses linear equations. Sometimes I have to be careful to remember this step as well so it is good practice for both of us. (weekly student-tutor journal entry)

> …The topic of focus for the week was helping Alfred understand the variables of a linear equation. We covered what "y = mx + b" represented (a linear graph) and discussed how to find the slope and y-intercept using just two coordinate points. This was actually coincidentally perfect, because we have been learning about the coordinate plane in our pre-calculus class. Although I was already very familiar with linear equations and the coordinate plane, analyzing the comparisons and contrasts between how I had explained it to Alfred versus how professor explained it to the class helped me to gain perspective. In listening to your explanations and taking notes, I was able to learn better ways that I could explain the linear graph to help Alfred understand it better. So, I started out by presenting him with the definition that "a graph is a drawing that represents all of the solutions of a linear equation."… Since Alfred already knew the basics of drawing a graph, we used his graphing abilities to understand how the slop (m) of the equation corresponded to the rise over run of the graph and how the y-intercept represented the "b" variable. (weekly student-tutor journal entry)

Many students rediscovered for themselves that the underlying concepts and definitions were in fact the same for the polynomial graphs and the radical equations covered in class, and the basic linear graphs and equations their tutees had studied in middle school. As Roscoe and Chi (2007) point out, peer tutors manifest highest levels of tutor learning as a result of explaining conceptual rather than process-based questions to the tutees. In our case, reflection diaries worked as a tool to reinforce mathematical knowledge gains made by the tutor as a result of the tutoring session.

In the non-mathematical section of their journals, the students often spoke of various life circumstances faced by their tutees and were able to directly observe complex interplay of social position and education and their often cyclical effect on each other.

> One thing that is clearly holding my student back in math is a language barrier. Since English is not his first language, it is difficult for him to read and interpret the word problems in his math workbook. It is also sometimes challenging for him to read explanations of how to do problems in the book. This makes the process of learning math more laborious and time consuming. On a positive note though, my student seems very determined to learn math so that he can pass his GED test and hopefully go to college later. He is very optimistic and likes to practice math on his own outside his tutoring sessions. I am excited to help him as much as I can next week. (weekly student-tutor journal entry)

Another Precalculus student watched her adult pupil miss more and more tutoring sessions and classes due to family problems, putting the GED further out of reach.

> Tutoring at Seattle Central Community College is really eye opening. It's really made me think of my blessings and truly be grateful for them…Recently one of the people I tutor (let's call her Hana) has dropped out of school. This was a woman that I admired and looked up to from the moment I met her. I took a while to really put my thoughts together on how to go about to write about this because when she told me of her decision over the

> phone, I was surprised by how big the blow was to me. She was a 57 year old woman aiming to be a nurse. She showed me how determined a person can be even when the odds and/or circumstances are against them. She had dropped out due to medical reasons which really upset me due to how well she was picking up on her material in class. (weekly student-tutor journal entry)

As instructor, it was a privilege to be part of student experience and to hear their thoughts and impressions of what they saw and experienced. Running a service-learning course can be an extremely rewarding experience for all involved, however, instructor who wishes to implement such an experiment, should be aware of potentially high time commitment that is involved. Seattle University faculty is deeply grateful for the work of the Center for Community Engagement that establishes contacts with community partners, finds placements for students, and largely takes care of the administrative overhead involved.

Ongoing project work

At the time of writing, academic service-learning experiment in pre-calculus course is ongoing, and we are still collecting and analyzing data.

Further projects may include:

- Introducing optional service-learning component into a regular pre-calculus course, with student given an option to participate. Instructor will introduce advantages of service-learning to mathematical knowledge. Course grade for participating students will be computed using a different grading scheme, giving students an option to earn a higher mark.
- Repeating service-learning experiment in pre-calculus, with university students tutoring elementary school kids. Difference in mathematical gains will be compared with the present results.
- Repeating Allison Henrich' service-learning experiment in the mathematics course for students of humanities (Henrich & Lee, 2011) and measuring mathematical gains of students involved.
- Measuring potential shift in attitudes towards mathematics in all participating and non-participating university students.

Conclusions and Implications for Mathematics Education

Our research statistically establishes a number of tangible benefits of service-learning to students' mathematical performance in class. The non-mathematical benefits have been widely explored, and they are confirmed by our study. Our research opens venues to further exploration of the long-term academic and non-academic benefits of service-learning to the university students, as well as to students from the community. Service-learning requires commitment of time and sometimes additional funding: our findings may encourage Mathematics departments and university administration to promote service-learning in mathematics courses.

Eliciting mathematicians' pedagogical reasoning

Christine Andrews-Larson
Florida State University

Valerie Peterson
University of Portland

Rachel Keller
Virginia Tech

Given the prevalence of work in the RUME community to examine student thinking and develop instructional materials based on this research, we argue it is important to document the ways in which undergraduate mathematics instructors make sense of this research to inform their own teaching. We draw on Horn's notion of pedagogical reasoning in order to analyze video recorded conversations of over twenty mathematicians who elected to attend a workshop on inquiry-oriented instruction at a large national mathematics conference. In this context, we examine the questions: (1) How do undergraduate mathematics instructors engage in efforts to make sense of inquiry-oriented instruction? (2) How does variation in facilitation relate to instructors' reasoning about these issues? Preliminary findings suggest that differences in facilitation relate to how participants engaged in the mathematics, and that the nature of participants' engagement with the mathematics was related to their subsequent pedagogical reasoning.

Key words: mathematicians, pedagogical reasoning, inquiry-oriented instruction

Given the prevalence of work in the RUME community to examine student thinking and develop instructional materials based on this research (e.g. Wawro et. al., 2013; Larsen, Johnson & Bartlo, 2013; Rasmussen & Kwon, 2007), we argue it is essential that our community consider issues related to the dissemination and use of findings from our research. This work aims to serve that goal by examining our efforts to engage practitioners (instructors of undergraduate mathematics) in thinking about research-based, inquiry-oriented instructional materials for undergraduate mathematics courses. In this preliminary report, we begin to explore two research questions: (1) How do instructors of undergraduate mathematics (who are interested in inquiry-oriented instruction) reason about instructional issues, particularly in the context of inquiry-oriented mathematics instruction? (2) How does variation in facilitation relate to the ways in which instructors engage in reasoning about these instructional issues?

Theoretical Framing and Literature

National organizations have called for instructional change in undergraduate STEM courses, relating poor instructional quality to a lack of student interest and persistence (e.g., Fairweather, 2008; PCAST, 2012; Rasmussen & Ellis, 2013). Researchers from a range of STEM fields have developed and documented student-centered instructional approaches that result in greater conceptual learning gains and student attitudes when compared with classes in which lecture is the dominant form of instruction (e.g. Kogan & Laursen, 2013; Kwon, Rasmussen, & Allen, 2005; Larsen, Johnson, & Bartlo, 2013). While it is well-documented that instructional change is difficult to achieve at scale (Henderson et. al., 2011), there is evidence that suggests a sizable number of faculty in undergraduate STEM fields are making efforts to offer their students the kinds of student-centered learning experiences supported by these studies. Indeed, though 61% of STEM faculty report they use extensive lecturing when they teach, a full 49% of STEM faculty report they incorporate cooperative learning into their courses (Hurtado et. al., 2012). Given the rates at which STEM faculty now report use of cooperative learning in their instruction, we argue that there is a pressing need to document and leverage the pedagogical reasoning of those faculty who are working to implement these kinds of instructional approaches.

In this work, we follow Rasmussen & Kwon's (2007) characterization of inquiry-oriented instruction in which students are actively inquiring into the mathematics (e.g. by developing, justifying, and generalizing their own solution methods to open ended problems) and instructors are actively inquiring into students' thinking about the mathematics so as to build on students informal and intuitive ideas to help them make sense of and engage in more formal and conventional forms of mathematical reasoning.

We take a situated perspective, in which we view knowledge and learning to be evidenced in the interactions among members of a community (Lave & Wenger, 1991) – in this case, the community of instructors of undergraduate mathematics. As such, we look to document mathematicians' pedagogical reasoning by examining their conversations about instruction. We follow Horn's (2007) characterization of pedagogical reasoning, considering it to be instructors' reasoning about issues or questions about teaching "that are accompanied by some elaboration of reasons, explanations, or justifications" (p. 46). Analytically, we draw on the vertices of the instructional triangle (teaching, students, and mathematics) as a conceptual tool for organizing our analysis of these conversations about instructional issues.

Data Sources and Methods of Analysis

The data under consideration in this study were collected from a workshop conducted as part of a national mathematics conference, and these data are part of a broader project that is developing and analyzing a set of instructional supports for undergraduate mathematics instructors interested in implementing inquiry-oriented instruction. The workshop focused on implementing inquiry-oriented instruction, and was organized around research-based curricula that have been developed in the areas of linear algebra, abstract algebra, and differential equations. The workshop lasted a total of four hours, which was split across two 2-hour sessions on consecutive days. On each day, about half of the time was devoted to content-specific work in breakout groups (self-selected by the participants), and the other half of the time was spent discussing issues of inquiry-oriented instruction that cut across all three curricula. On Day 1, facilitators planned to engage participants with an overview of inquiry-oriented instruction, followed by time to engage in mathematical tasks from the curricula in the area of their selected breakout group. On Day 2, the focus was to be on student thinking related to the day 1 tasks and instructional moves designed to help instructors implement inquiry-oriented curricula.

The workshop included 25 participants, 21 of which responded to a workshop pre-survey that provided us with information about their background and home institutions. All participants except one were housed in Mathematics departments, and the group represented a diverse group of institutions and positions (see Figure 1). Less than a third of survey respondents reported that they prefer to lecture most of the time, and more than 70% reported that they like to have students work in groups on problems in class, and more than 60% report they frequently ask students to explain their thinking to the whole class when they teach. This was significant to our research because it suggests our sample is part of the sizable subset of undergraduate STEM faculty working to teach in student-centered ways, and the choice to attend the workshop also points to an interest, outside the RUME community, in research-based instructional approaches.

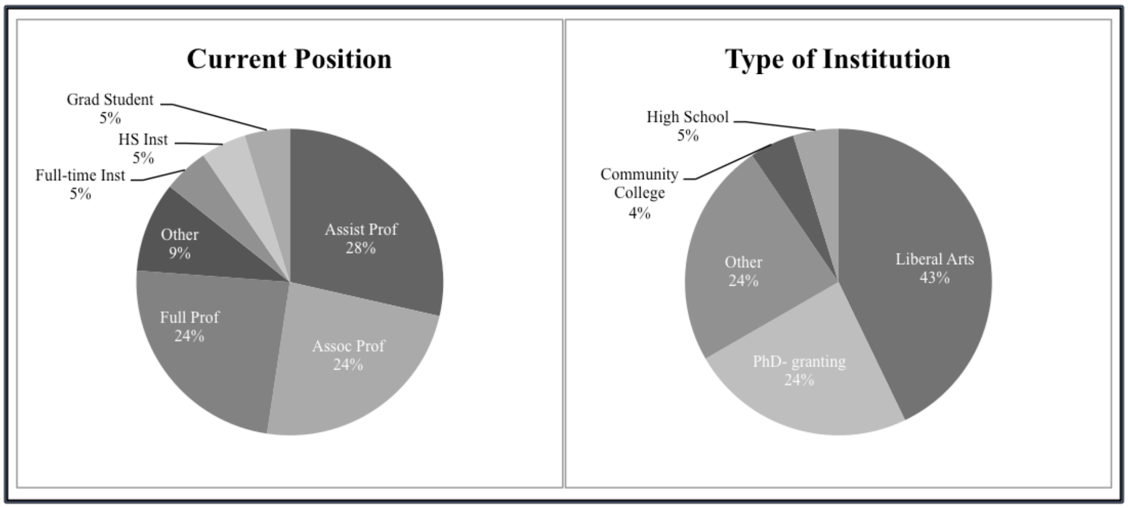

Figure 1. Position and Institution Types of Survey Respondents

In each of the two 2-hour workshop sessions, all whole-group and breakout segments were video- and/or audio-recorded for subsequent analysis. We began analyzing this recorded data by generating content logs to document the sequence of events in each segment of the workshop. Each content log was organized in a table with four columns: timestamp, description of events, focus of talk, and other comments. The 'focus of talk' column aimed to help us track whether the focus of talk was on the mathematics (M), the teacher (T), or students (S), and whether it was the facilitator or participants who were doing that talking. From these content logs, we generated summaries of each session to describe the focus and use of the time along with initial characterizations of the participants' pedagogical reasoning. We noted stark differences in the conversations of the linear algebra breakout group as compared to those in the abstract algebra group, so we decided to conduct our analysis as a comparative case study of these two groups (Yin, 2003). Content logs were then used to generate codes for the focus of participants' talk during the session and to identify conversational moments (selectively transcribed for closer analysis) when participants were engaged in pedagogical reasoning.

Findings

Our preliminary findings are two-fold: First, differences in facilitation appear to have played a role in how participants engaged in the mathematics on the first day of the workshop. Second, the nature of participants' engagement with the mathematics was related to their subsequent pedagogical reasoning. In this preliminary report, we focus primarily on the different ways in which participants in two of the breakout groups engaged in the mathematics on the first day of the workshop, and the variation in facilitation that may help explain those differences in engagement. In our presentation, we will provide further elaboration on differences in subsequent pedagogical reasoning of the two groups.

The facilitators of both the linear algebra and the abstract algebra group intended for the entire hour of the first day's breakout group to be focused on working through the mathematics in the respective task sequences. However, our content logs revealed the Abstract Algebra group spent a much larger portion of their hour-long breakout session on the first day of the workshop working through the math (86% of the time spent working through the math) than did the Linear Algebra group (30% of the time spent working through the math). Additionally, the nature of the mathematical talk of the two groups differed in that the abstract algebra group appeared to engage in the mathematics much more deeply than did the linear algebra group. We coded talk into six categories: logistics (e.g. "Does everyone have a handout?"), introductions, implementation questions (e.g. "How many times a week does your class meet?"), pedagogical moves (e.g. "I have them present their work as soon as we finish a task"), discussing mathematics (e.g. "They [students] came to different conclusions based on whether or not they considered all linear combinations"), and doing mathematics (e.g. "We want to show the additive inverse we'd expect from the big group stays in the small group."). Table 2 summarizes each breakout group's conversational focus on day 1 according to these categories.

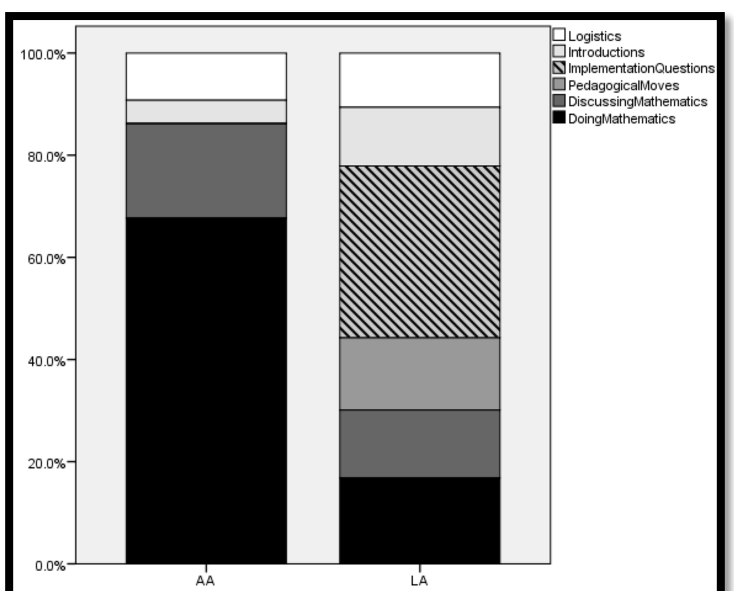

Figure 2: Conversational focus during Day 1 Breakout Groups

It was initially unclear why such differences in participants' engagement in the mathematics were observed. Analysis of the facilitation across the two breakout groups points to several factors that help explain these differences.

At the outset of the Abstract Algebra breakout session, the facilitator handed out the task statement and asked participants to turn and work together in small groups. As participants begin working, she circulated amongst them, listened, and occasionally chimed in with questions about their thought processes, methods, or mathematical assumptions. One participant later described the work of this breakout group, saying that the facilitator "modeled some instructor behaviors… pressing us on why we were thinking how we were thinking, pressing toward the subtlety without leading. We realized that because we understand abstract algebra, there are a bunch of similar ways to work with the definitions that are not obviously equivalent to a new user."

In the Linear Algebra session, the facilitator (who is one of the authors) also distributed the mathematical tasks for participants to work on, but devoted several minutes at the beginning to introductions in an effort to help create a safe, collaborative environment for sharing. However, this opportunity for participants to contextualize their institution (size and type of college, which students take linear algebra, etc.) also seemed to encourage speakers to bring up topics not directly related to the mathematics at hand (airing concerns about content coverage, logistics, student prerequisites, etc.). Additionally, there were moments in which the facilitator -- endeavoring to strike a balance between math instructor and professional development leader, and to respect the assumed content knowledge of her group members – inadvertently set norms that discouraged participants from fully engaging with the mathematics. Specifically, the facilitator began small group work by asking participants to begin by working on the second task in a sequence of related tasks, rather than starting with the first task, positioning the initial mathematical work as "easy." We posit that this created a setting with implicit professional risk: the participants were more or less strangers to one another, and several expressed feeling out of practice with the subject, so this potentially increased the pressure on those already feeling vulnerable. Later, in an attempt to refocus the group on the math, the facilitator suggested working through a task from the vantage point of a "typical student." Interestingly, instead of easing the mathematical pressure, this also created a barrier, with at least two participants later remarking that they didn't know how their students might approach the task. Finally, one of the participants had previously used the materials and was introduced as a potential resource for other instructors. Many of the digressions from the mathematics in the Linear Algebra group came in the form of specific questions directed to this participant.

Initial analysis suggests that this set-up up participants' mathematical engagement on the first day of the workshop was consequential for participants' subsequent pedagogical reasoning; in our presentation we will provide more detail on the differences in this subsequent reasoning.

Questions for Audience

- Might different content lend itself to participants engaging differently (e.g. linear algebra vs. abstract algebra)? If so, how can we account for this?
- Can we define or operationalize the kinds of tasks or activities that are productive for advancing participants' pedagogical reasoning?
- In what ways is it (or might it be) important for the facilitator to be inquiry-oriented in their stance toward participants' pedagogical reasoning (during workshop facilitation)?

Active Learning in Undergraduate Precalculus and Single-variable Calculus

Naneh Apakarian
San Diego State University

Dana Kirin
Portland State University

The study presented here examines the active learning strategies currently in place in the Precalculus through single variable calculus sequence. While many lament the lack of active learning in undergraduate mathematics, our work reveals the reality behind that feeling. Results from a national survey of mathematics departments allow us to report the proportion of courses in the mainstream sequence utilizing active learning strategies, what those strategies are, and how those strategies are being implemented.

Key words: Census Survey, Precalculus, Calculus, Active Learning, Instructional Methods

Research suggests experiences in introductory mathematics courses can significantly influence student persistence within the STEM fields (Bressoud, Mesa, & Rasmussen, 2015; PCAST, 2012; Seymour & Hewitt, 1997; Wake, 2011). In the United States, the Precalculus to Calculus 2 (P2C2) sequence often serve as key prerequisite courses for students intending to pursue degrees in STEM fields, and difficulties in these courses often prevent students from continuing on in STEM. One approach that shows great promise for improving student success in the P2C2 sequence is the use of student-centered instruction. Recent studies have highlighted the educational benefits of using active learning strategies in post-secondary mathematics classrooms, including improved STEM retention rates (Ellis, Kelton, & Rasmussen, 2014; Ellis, Rasmussen, & Duncan, 2013; Rasmussen & Kwon, 2007; Seymour, & Hewitt, 1997) and narrowing achievement gaps (Kogan & Laursen, 2014; Laursen, Hassi, Kogan, & Weston, 2014). The use of such practices was also identified as a characteristic of programs with successful Calculus I programs (for a more detailed discussion see Bressoud & Rasmussen, 2015). Despite these educational benefits, Kuh (2008) points out that these instructional practices are currently not the norm in higher education.

The study presented here reports preliminary findings from data collected as part of a larger study, *Progress through Calculus* (PtC). The main research question addressed in this report is *how, and to what extent, are active learning strategies being implemented in the P2C2 sequence?* Narrowing down on this broad question, this presentation addresses the following questions:

1. How prevalent are active learning strategies in the P2C2 sequence?
2. What particular active learning strategies are being used, and how common are they?
3. What (if any) institutional factors relate to the use of active learning strategies?

Methods

The data reported here comes from a census survey undertaken as part of a larger, multi-phase project studying departmental and institutional factors that influence student success through the P2C2 sequence. The survey was administered to the 341 departments across the country that award graduate degrees in mathematics. The survey closed with an impressive overall response rate of 68%. The survey elicited information about many aspects of each department's implementation of the P2C2 sequence as a whole, informed by the results of the CSPCC study (Bressoud, Mesa, & Rasmussen, 2015; Bressoud & Rasmussen, 2015). This presentation reports on a subset of the data wherein participants provided detailed information about the individual courses that make up the mainstream P2C2 sequence.

The details requested about these mainstream courses included questions about course delivery to ascertain the primary format for regular class meetings and recitation sections (when applicable). 201 institutions completed these details, giving us information on 904

P2C2 courses. The following section includes descriptive statistics (frequencies, proportions, etc.) gathered from these responses. Ongoing analysis is examining the relationships between the use of active learning strategies and other factors (e.g., importance of active learning, DFW rates, instructor type).

Results

To frame our findings, we begin by noting that 44% of all mathematics departments responding to this survey reported that active learning strategies are "very important" for successful P2C2 courses, but *75% of those* reported that they are not very successful at implementing those strategies. Overall, 14% of institutions report being "very successful" with active learning strategies, 60% report being "somewhat successful," with the rest marked "not successful" or "not applicable."

The first question we answer relates to the usage of active learning strategies in introductory undergraduate mathematics courses across the country. Participants were asked to identify the primary instructional format for regular class meetings of each course in their department's mainstream P2C2 sequence. The proportions that follow in this section refer to the proportion of *courses* taught in a certain way, not the proportion of institutions offering such structures. Perhaps unsurprisingly, over 60% of courses are primarily taught in a lecture format. Of particular interest to us is the discovery that approximately 16% of courses incorporate some active learning techniques, while a further 3% are taught using mainly active learning techniques. Further investigation revealed that these proportions fall off through out the P2C2 sequence. While nearly 26% of precalculus courses incorporated at least some active learning techniques, this drops to 20% in first calculus courses, and drops again to 13% in secondary calculus. These proportions did not vary significantly between MA- and PhD-granting institutions.

Data was also collected regarding the instructional format of recitation sections (or labs) when applicable. Approximately one-third of the reported courses have recitation sections, and 15% *of these* use active learning strategies (5% of all courses). Overall, we found that 22% of reported courses have some active learning in the instructional approach in regular course meetings, recitation sections, or both.

Our data also allows us to look at what "active learning strategies" mean when usage is reported. Note that the responses to this question were not exclusive, as a course might utilize several different strategies. The most prevalent technique was group work, reported in 78% of courses and 92% of recitations that included active learning. IBL, clicker surveys, and flipped classes were each reported in 15-20% of lectures, and a sizable proportion indicated that they use something other than the options provided. The story is similar in recitation sections, except for the use of clicker surveys (only appeared in 2% of "active" recitations). The patterns of usage do not change across courses in the P2C2 sequence.

Conclusion & Future Directions

Our current quantitative analysis reveals some of the patterns of active learning in the P2C2 sequence. Only 22% of P2C2 courses incorporate at least one active learning component, but we also found that 40% of institutions have an active learning component in at least one mainstream P2C2 course. This suggests that active learning strategies are not being used consistently through the P2C2 sequence, but only in select courses. However, in courses that implement active learning strategies, we see a consistent trend in *the types* of active learning strategies being implemented across the P2C2 sequence. At this time, analysis of our existing data is still ongoing. Further analysis of this data will link active learning strategies and implementation to institutional factors (e.g., understanding of importance, school size) as well as student factors (e.g., DFW rates, target audience), thus providing a more complete picture of the role active learning plays in the P2C2 sequence.

Talking about teaching: Social networks of instructors of undergraduate mathematics

Naneh Apkarian
San Diego State University

The RUME community has focused on students' understandings of and experiences with mathematics. This project sheds light on another part of the higher education system – the departmental culture surrounding undergraduate mathematics instruction. This paper reports on the interactions of members of a single mathematics department, centered on their conversations about undergraduate mathematics instruction. Social network analysis of this group sheds important light on the informal structure of the department.

Keywords: *Social networks, instructors, organizational culture, community*

It is widely known that experiences with introductory undergraduate mathematics courses are a significant factor affecting retention rates in STEM majors (Bressoud, Mesa, & Rasmussen, 2015; PCAST, 2012; Seymour & Hewitt, 1997). This has led to increased research and attention to these introductory courses. Very little of that research, however, uses a systems-level approach. In thinking about undergraduate mathematics education, we must consider the entire system at work and the cultures and communities at play at each level. Students and instructors function as individuals embedded in a variety of cultures and communities, each with their own pressures, values, beliefs, assumptions, and practices.

Focusing on the department as a unit of analysis makes particularly good sense when considering introductory mathematics courses. Many institutions offer multiple sections of courses such as Calculus I each term, taught by a range of instructors. The potential variation in experiences at a single institution is remarkable, and so case studies of individual classrooms do not capture the entire picture. This position is supported by the findings of the *Characteristics of Successful Programs in College Calculus* (CSPCC) study, wherein a coordination system was found to be one of the seven key features of successful programs (Bressoud & Rasmussen, 2015). Another reason to take a department-level approach is the potential of the department as a unit of change (e.g., Gibbs, Knapper, & Piccinin, 2008; Wieman, Perkins, & Gilbert, 2010). Work in education and organization science has shown that change is a social construct, best effected and sustained by a group rather than an individual (Corbo et. al., 2015; Daly, 2010).

Methods

Social network surveys were distributed to 61 individuals in the mathematics department at a large research university, one that was identified in the CSPCC study as being relatively more successful at implementing Calculus I. Network questions were used to ascertain the ties that exist between members of the community of calculus instructors, as well as the strength of those ties, and a variety of Likert scale and demographic questions were used to characterize the actors between whom ties do or do not exist (Coburn & Russell, 2008). Five relational networks were measured: advice about teaching (R1); sharing of instructional materials (R2); discussions about teaching (R3); friendship (R4); and influence on instruction (R5). The survey also included Likert scales designed to characterize the individuals, subgroups, and the larger community in terms of trust, innovative climate, professional learning community collaboration and involvement, as well as mathematical affect and beliefs.

Findings

Looking at the different networks, I note differing levels of inclusivity, from a high of 85% included (R3) to a low of 52% (R5). I further note the split, in terms of inclusivity, of the networks into R1, R2, and R5 vs. R3 and R4. This indicates that more actors are involved in discussions about instruction and friendship within the department than the sharing of advice, instructional materials, or influence. One possible interpretation of this is that R3 and R4 are more general relations than the others. Another is that R1, R2, and R5 all seem to involve acknowledging another as "expert" at something, while R3 and R4 may be relations between equals.

Instructors of the Precalculus through Calculus 2 (P2C2) courses are disproportionately active in the networks, especially in R1, R2, and R5. This is gauged by looking at the makeup of the main component of each relationship graph (in each case the only component) and how many of each instructor type are included in that component (Table 1). In R1, R2, and R5, P2C2 instructors account for significantly more of the graph component than their overall representation. In R3 and R4, the distribution of P2C2 and non-P2C2 is close to their overall distribution (within 3 people). The coordination of superficial aspects of P2C2 course structure (e.g., textbook, exams) seems to explain the over-representation of P2C2 instructors in the materials network (R2), but it does not directly explain their over-representation in advice (R1) and influence (R5). These network results seem to indicate that there is more to this coordination system than simply shared course elements.

Table 1: Components of relational networks, including P2C2 instructor breakdown.

Relation	Component (V, E)	Proportion of component that is P2C2 instructors	P2C2 instructors in component (n=23)	Non-P2C2 instructors in component (n=38)
R1	(38, 83)	0.500	0.826	0.500
R2	(36, 65)	0.528	0.826	0.447
R3	(52, 120)	0.385	0.870	0.842
R4	(51, 138)	0.431	0.957	0.763
R5	(32, 55)	0.500	0.696	0.421

Given the network investigations under investigation, it is natural to look for individual actors who are the "most" at something: Who asks for advice the most? Who is asked for advice the most? Who is the most influential? When looking for standout actors, we turn to their degree, the number of ties attached to their node. By asking about *in-degree, out-degree*, and *total degree*, we can begin build a rough picture of important actors. For sake of brevity, this proposal attends only to the advice network (R1) while the presentation will attend to all five. Total degree had mean 2.7 and standard deviation 4.7; in-degree had mean 1.4 and s.d. 3.7, and out-degree had mean 1.4 and s.d. 1.9. There is more variation in actors' out-degrees than in-degrees, which implies that while actors in the network seek different amounts of advice, they seek that advice from a select few. There is a clean break in the in-degree distribution separating three actors from the rest by more than two standard deviations.

Discussion

Since the data collected represents a snapshot of the department in its current state, it is impossible to establish causality between the coordination system in place and the social relations measured in this study. One explanation is that this department is made up of community-minded faculty members, the most communicative of whom are teaching the coordinated P2C2 courses. Another explanation is that the coordination system and the coordinators have developed a sense of community and shared responsibility for teaching these introductory courses, leading to an increase in communication about instruction. The discovery that the coordinators, who are formally in charge of P2C2 instruction, are also informal community leaders confirms Rasmussen and Ellis's (2015) finding that coordinators do more than simply manage the uniform elements of courses – they are central to active communities of instructors engaged in teaching mathematics.

Ways in which engaging in someone else's reasoning is productive

Naneh Apkarian

Typical goals for inquiry-oriented mathematics classrooms are for students to explain their reasoning and to make sense of others' reasoning. In this paper we offer a framework for interpreting ways in which engaging in the reasoning of someone else is productive for the person who is listening. The framework, which captures the relationship between engaging with another's reasoning, decentering, elaborating justifications, and refining/enriching conceptions, is the result of analysis of 10 individual problem-solving interviews with 10 mathematics education graduate students enrolled in a mathematics content course on chaos and fractals. The theoretical grounding for this work is that of the emergent perspective (Cobb & Yackel, 1996).

Keywords: Decentering, Argumentation, Social Norms, Fractals, Paradox.

Typical goals for inquiry-oriented mathematics classrooms are to foster particular social norms, such as students explaining their reasoning, listening to others' reasoning, and making sense of that reasoning (Yackel & Cobb, 1996). Indeed, such goals for student participation have been central to a long line of recommendations in the United States (National Council of Teachers of Mathematics, 2000; National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010). The purpose of this paper is to offer a framework for understanding the various ways in which engaging in the reasoning of someone else is productive for the person who is listening to and attempting to make sense of this reasoning. Prior research has documented ways in which teachers can initiate and sustain such norms for participation (e.g., Lampert, 1990; Stephan & Whitenack, 2003), but most research into the benefits of such engagement focuses on the *students'* thinking, not that of the one engaging in the other's reasoning (e.g., Teuscher, Moore, & Carlson, 2015). While there has been some research into mutual intellectual benefit stemming from peer-to-peer engagements (e.g., Kieran & Dreyfus, 1998), it has not been at the collegiate level. Our work contributes to this surprisingly sparse literature, extends notions identified in disparate settings, and adds nuance to existing notions of engaging and decentering.

The theoretical grounding for this work is that of the emergent perspective (Cobb & Yackel, 1996), which coordinates the individual cognitive perspective of constructivism (von Glasersfeld, 1995) and the sociocultural perspective based on symbolic interactionism (Blumer, 1969). A primary assumption from this point of view is that mathematical progress is a process of active individual construction and a process of mathematical enculturation. The interpretive framework, shown in Figure 1, lays out the central constructs in the emergent perspective. The within row relationships between respective collective and individual constructs is said to be reflexive, meaning that they are mutually constitutive, evolving together in a dynamic system. For example, (Yackel & Rasmussen, 2002) analyze individual students' evolving beliefs about their and others' role in relation to evolving classroom social norms. This work speaks to one way in which engaging in the reasoning of others (a social norm) is productive for the individual; namely doing so positively shapes beliefs.

Collective Perspective	Individual Perspective
Classroom social norms	Beliefs about own role, others' roles, and the general nature of mathematical activity
Sociomathematical norms	Mathematical beliefs and values
Classroom mathematical practices	Mathematical conceptions and activity

Figure 1. The interpretive framework

In furthering the relationships between the constructs in Figure 1, we argue for *across* row relationships. In particular, we take the stance that classroom social norms are also inextricably intertwined with individual mathematical conceptions and activity. In so doing we make an empirically grounded argument for a theoretical connection between the upper left hand cell of the interpretive framework and the bottom right hand cell.

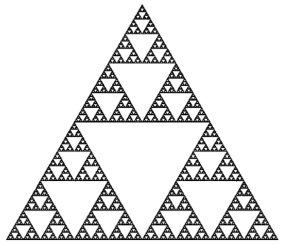
In our broader research program (Hershkowitz, Tabach, Rasmussen, & Dreyfus, 2014; Tabach, Rasmussen, Hershkowitz, & Dreyfus, 2015), we are investigating the coordination between individual and collective processes. In this report, however, we focus on analyzing individual mathematical conceptions and activity in an individual interview setting, with the subsequent goal of coordinating this analysis with an analysis of classroom video-recordings. This report lays a foundation for this subsequent analysis, but the framework for ways of engaging in someone else's reasoning is potentially significant on its own.

Methodology

The methodological approach for the larger study falls under the genre of "design-based research" (Cobb, 2000; Design-Based Research Collective, 2003). The study took place in an intact graduate level mathematics course about chaos and fractals with 11 students (10 of whom agreed to participate in individual interviews). Students were (or intended to be) secondary school teachers or community college instructors. Their masters degree program required a substantial component of mathematics, and the chaos and fractals course qualified as one of their mathematics courses. The course was taught by one of the research team members. Data collected as part of the larger study included video-recordings of each class session, individual problem solving interviews conducted at the middle and end of the semester, and copies of all student work. In this paper we report on an analysis of the 10 individual, mid-semester problem-solving interviews.

The following question from the mid semester interview is the focus of this analysis:

In class, we discussed the Sierpinski Triangle. How do you think about what happens to the perimeter and the area of the Sierpinski Triangle as the number of iterations tends to infinity?



Follow-up questions:

a. One a scale from 1 to 10 with 10 being the most confident, how confident are you about what happens to the area? Can you say more about why you said [confidence number]?
b. On a scale from 1 to 10, with 10 being the most confident, how confident are you about what happens to the perimeter? Why do you say [confidence number]?
c. A student named Fred claimed the following. Please read it out loud. What do you think about his argument? (Please explain)

Fred's Argument: The computation shows that the perimeter goes to infinity because the perimeter is given by $3\times({}^{3}/_{2})^{n}$ which increases to infinity as n tends to infinity. But, the perimeter can't *really* be infinitely long, because there is nothing left to draw a perimeter around, since the area goes to zero.

The Sierpinski Triangle is a fractal, and is the result of an infinite iterative process that begins with an equilateral triangle. Connecting the midpoints of its sides results in another equilateral triangle with sides half the length of the original's and area that is one-fourth of the original's, which is then removed. Repeating this process, *ad infinitum,* results in the Sierpinski Triangle. At each step of the process, the area of shrinks by a factor of ¾ and the perimeter grows by a factor of ${}^{3}/_{2}$. The perimeter of the Sierpinski Triangle can be described by the limit, as $n\to\infty$, of $P_0\times({}^{3}/_{2})^{n}$, and the area by the limit, as $n\to\infty$, of $A_0\times({}^{3}/_{4})^{n}$, where P_0 and A_0 refer to the perimeter and area of the starting triangle. Thus the Sierpinski Triangle has a perimeter of infinite length and an area of zero. This apparent contradiction comes from the fact that it is a fractal with Fractal dimension $\log_2(3)$, putting it between one- and two-dimensions.

The question was structured so that we would first gain insight into students' own reasoning about the area and perimeter of the Sierpinski triangle, followed by an opportunity for them to engage in the hypothetical reasoning of "Fred." The basis for Fred's reasoning was taken from a whole class discussion that took place several weeks before the interview. Thus, Fred's reasoning is authentic to the students and provides an ideal opportunity for us to subsequently coordinate individual and collective analyses.

While most studies of decentering and engagement have involved interactions between two or more people, ours involves one person interacting with the work of another, who cannot respond. While this setup potentially restricts the ability of interviewees to engage with Fred and his argument, it has certain affordances as well. One affordance is that all interviewees reacted to the *same* statement, allowing us to make direct comparisons. This setup also controls for a variety of other features, such as personal histories, that may influence how people react to each other in face-to-face settings.

The transcripts and student work produced during the interview were open coded using methods from grounded theory (Strauss & Corbin, 1998). This open coding, which was conducted collaboratively by the authors to minimize bias and ensure interpretations were grounded in the data, was informed by literature on student thinking about infinity, and in particular infinite iterative processes (Núñez, 1994; Mamolo & Zazkis, 2008), but did not rely on an a priori coding scheme.

The initial open coding of these interviews revealed differences between students' initial responses and those that followed reading Fred's argument. It also revealed a variety of ways of engaging and responding to Fred. We then supplemented our initial coding, using Toulmin's argumentation scheme (Toulmin, 1969) to analyze the pre- and post-Fred arguments presented by the students. Finally, each transcript was distilled into an argumentation log (Rasmussen & Stephan, 2008), coupled with the primary ways of reasoning being used in each argument and instances of engagement, and supplemented by statements about the mathematics that were not necessarily part of a coherent argument. Again using grounded theory, these were analyzed for shifts and relationships.

Results

Our analysis of students' responses revealed that responding to Fred's argument was a productive experience for most students. There was variation across students with regards to both the extent and nature of their engagement and growth, but we note two major categories of productivity that stemmed from an ability to engage in Fred's reasoning and decenter from their own: elaborating justifications and refining/enriching conceptions of particular mathematical ideas. Figure 2 is intended to capture the relationship between engaging with another's reasoning, decentering, elaborating justifications, and refining/enriching conceptions. Specifically, engaging with another's thinking can be foundational for (re)engaging with one's own thinking. That is, the act of decentering provided the means for elaborating justifications and refining one's thinking. The intersecting ovals in Figure 2 for these two acts signify the reciprocal relationship between justifying and refining conceptions.

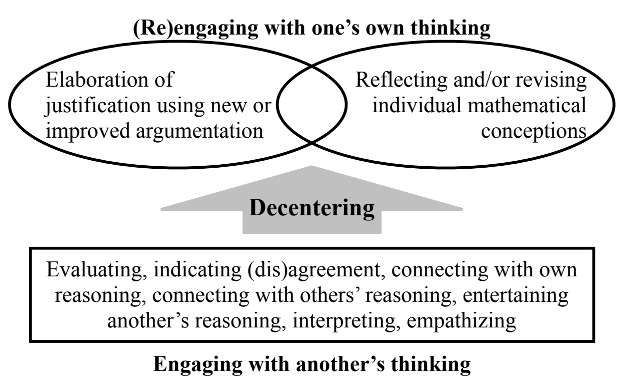


Figure 2. Productivity of engaging in another's reasoning

Since all of the interviewed students were or intended to be teachers at the secondary or postsecondary level, it is particularly interesting to look at their ability to engage with another's thinking. Doing so is foundational to teacher noticing (Jacobs, Lamb, & Philipp, 2010) in which teachers can instructionally build on student thinking. We found that all of the interviewees exhibited the ability to engage with Fred's thinking. We identified the following ways that interviewees engaged in Fred's reasoning: a) evaluating (with or without justification); b) indicating (dis)agreement (with or without justification); c) making connections to their own reasoning; d) making connections to classmates' reasoning; e) entertaining Fred's reasoning; f) interpreting Fred's reasoning; g) diagnosing Fred's reasoning; and h) empathizing with Fred. These ways of engaging provide an opportunity for the individual to decenter. By decenter, we mean putting aside one's own reasoning in an attempt to understand another's reasoning (Steffe & Thompson, 2000; Teuscher, Moore, & Carlson, 2015). Many interviewees, through decentering, engaged or re-engaged with their own thinking in a way that furthered their own thinking. This analysis lays the groundwork for coordinating individual and collective ways of participating in discourse since evaluating (with justification) and indicating (dis)agreement connect strongly to foundational classroom social norms.

In this paper we give a few brief examples of engaging and decentering. Most students gave some indication of agreement or disagreement with Fred's argument, e.g. "I agree with him that the perimeter increases to infinity […] but I disagree with his second line." This example shows a fairly superficial engagement in which the interviewee attended to Fred's reasoning but viewed it from her own point of view. Other students went further, e.g. "I disagree because we thought about it in terms of fencing […] so eventually it's all fence." The second student's explanation makes it clear that while she has not necessarily built a model of Fred's line of reasoning, she is aware of her own model and believes Fred's is different. This second student then elaborated and improved upon her original argument.

Interviewees also demonstrated a range of depth when engaging with Fred by interpreting his reasoning. Some interpreted Fred's thinking from their own point of view, but others made clear attempts to deduce Fred's reasoning from *his* point of view – in one case an interviewee requested more information about Fred's argument before settling on an interpretation. We saw evidence, across all interviews, that each act of engaging functioned as a potential stepping-stone to decentering, an opportunity that some students took up while others did not. We saw that students who engaged deeply with Fred's thinking and decentered from their own point of view appeared to (re)engage with their own thinking.

As a consequence of decentering, many of the students clarified and even advanced their own lines of mathematical reasoning as expressed by Figure 2. As Fred's argument was in response to a question they had already answered, many reacted by re-explaining or expanding their initial justification. Within mathematical thinking we observed two main subcategories: the elaboration of justification for their claims and the expansion of their thinking regarding the mathematical concepts involved in the task. By elaboration of justification, we mean that students were observed adding new or improved warrants and backings to strengthen their argument or even providing entirely alternative explanations. As an example, one student, Sandor, reacted to Fred's argument by noting that that it is *because* the area of the Sierpinski Triangle goes to zero that the perimeter goes to infinity, and explicitly connected the removal of triangles at each recursive step to adding the perimeter of these triangles to the total perimeter. Prior to engaging with Fred's statement, he had treated the two results as essentially separate features of the process – the connection between the two had gone unnoticed or at least unexplained.

With regards to the underlying mathematical concepts, we observed students exploring the nature of infinity, perimeter, and the Sierpinski Triangle itself in greater depth than they had in their initial arguments. Some students appeared to become aware of a distinction between potential infinity (the unending process) and actual infinity (the final resultant state) in their attempts to clarify their reasoning. Many students took the opportunity to define, or re-define, the perimeter of an object. Students also reflected on the fractal nature of the Sierpinski Triangle, noting that it exists "between" dimensions and therefore does not act in the way that a "normal" one- or two-dimensional object might, and that therefore traditional thinking about a perimeter enclosing area is not necessarily valid in this context.

While we identify decentering and mathematical thinking as distinct, we note that they are not disjoint. All of these examples of expanded thinking and reasoning occurred to some extent as a reaction to the thinking of someone else. We posit that decentering functioned as a catalyst for this process. Seeing Fred's argument, interviewees demonstrated a variety of strategies for engaging with student reasoning, which were taken up with varying depth. Deeper engagement took the form of decentering, which predicated (re)engagement with and growth of their own reasoning. That is to say, the greater the extent to which students engaged with Fred and decentered, the more productive the experience was with regards to their own thinking.

The Case of Curtis

To clarify the constructs and interpretations outlined above, we present the case of a single student, with pseudonym Curtis. We choose this student as an example because of the brevity and clarity of this portion of his interview, as well as the range of constructs identified in his experience with Fred. Figure 3 shows Toulmin analyses of Curtis's pre- and post-Fred arguments, as well as his comment about infinite processes.

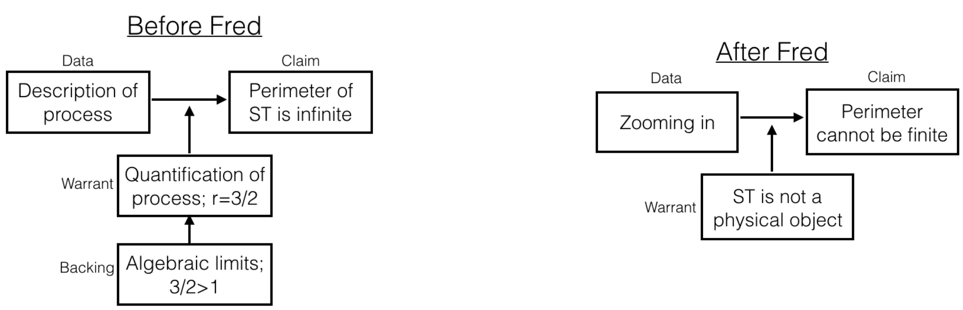

Figure 3. Toulmin analysis of Curtis' arguments.

Toulmin analysis of Curtis' pre- and post-Fred argumentation revealed shifts and changes. A small shift occurred in Curtis' claim: initially he showed that the perimeter is infinite, afterward he showed it could not be finite. This new claim is drawn from different data and is supported by a different warrant. Where initially Curtis used formal/symbolic reasoning, his second argument draws on heuristics and a sense that the Sierpinski Triangle is not a real object. He also brings up the fact that infinite processes do not have a 'final step' after which they reach their final state, something that was not mentioned prior to Fred.

Retracing the emergence of new topics for Curtis, we found that they were directly linked to his engagement with Fred's reasoning, and in particular resulted from his ability to decenter and look at Fred's reasoning in ways not related to his own. Curtis comments that Fred's "logic doesn't work," addressing more than just his faulty claim. The new warrant that Curtis provides, that the Sierpinski Triangle is not a physical object but rather "kind of just a concept," directly addresses an unspoken assumption on Fred's part. It seems that Curtis has identified and reacted to an implicit backing in Fred's argument – that the Sierpinski Triangle is a geometric object that obeys two-dimensional rules. Curtis' diagnosis of a misconception underlying Fred's reasoning implies that he has considered Fred's argument from a different viewpoint, effectively trying to put himself in Fred's shoes and understand fully his reasoning.

In addition to presenting a new argument, Curtis presents it in a new style. While his original argument was based in formal limits and notation, his new argument adopts some of Fred's informal, heuristic, and geometric language. Again, this supports the idea that Curtis is working from Fred's point of view, rather than his own.

Finally, Curtis' added commentary about infinite processes comes from his interpretation of Fred's argument. He says that Fred's argument is equivalent to there being a final step, a point where something is taken away and the area becomes zero, and notes that this is not how infinite processes work. This seems to address Fred's data, that the object becomes something with no area.

Altogether, we see that Curtis addresses all the pieces of Fred's argument (not just the claim) by thinking through Fred's reasoning (not just comparing it to his own). This includes an implicit backing that Fred does not explicitly state. He does so using Fred's style of reasoning, and (re)engages with his own reasoning to present a second argument and an observation about infinite processes. Throughout his response to Fred, Curtis addresses Fred's reasoning and explains why it does not work, rather than simply asserting that his own original ideas are correct.

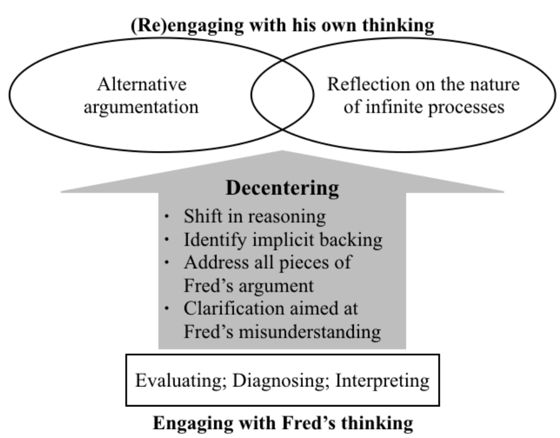

Figure 4. Curtis' productivity from engaging with Fred's reasoning.

Conclusion

In conclusion, we return to classroom social norms and the ultimate role we envision for our framework. We argue that the ways of engaging we observed in these interviews are closely related to particular classroom social norms. The relevant social norms related to engaging in others' reasoning include listening to others' reasoning, attempting to make sense of this reasoning, and indicating agreement or disagreement, with reasons. Moreover, acting in accordance with these norms led, through decentering, to enriched and refined mathematical conceptions and activity. The case of Curtis illustrates that decentering is an individual cognitive mechanism triggered by engaging with another's reasoning.

Prior work posits a reflexive relationship between engaging in others' reasoning (i.e., social norms) and individual beliefs. In Figure 1, this relationship coordinates the cells in the top row of the interpretive framework. As far as we are aware, the analysis in this paper is the first to coordinate social norms and individual mathematical conceptions and activity. That is, we provide evidence for a relationship between social norms (upper left hand cell of the interpretive framework in Figure 1) and individual conceptions (bottom right hand cell). This importance of this work lies in coordinating different analytic tools that separately address collective and individual phenomenon. Thus, our framework not only contributes to a nuanced understanding of engaging and decentering with another's reasoning, but also leads to links between individual mathematical conceptions and social activity.

Students' understanding of mathematics in the context of chemical kinetics

Kinsey Bain — Purdue University
Alena Moon — Purdue University
Marcy Towns — Purdue University

Abstract: This work explores general chemistry students' use of mathematical reasoning to solve quantitative chemical kinetics problems. Personal constructs, a variation of constructivism, provides the theoretical underpinning for this work, asserting that students engage in a continuous process of constructing and modifying their mental models according to new experiences. The study aimed to answer the following research question: How do non-major students in a second-semester general chemistry course and a physical chemistry course use mathematics to solve kinetics problems involving rate laws? To answer this question, semi-structured interviews using a think-aloud protocol were conducted. A blended processing framework, which targets how problem solvers draw from different knowledge domains, was used to interpret students' problem solving. Preliminary findings describe instances in which students blend their knowledge to solve kinetics problems.

Keywords: Rates, Problem Solving, Blended Processing, Chemistry, Kinetics

Understanding fundamental concepts in chemistry is intrinsically tied to understanding mathematical symbolism and operations, as well as translating between equations and physical realities. Because of this reality, studies in science education have begun to focus on students' understanding of and use of mathematics in scientific contexts (e.g. Becker & Towns, 2012). Findings from such studies allow researchers and practitioners to find ways to enhance students' abilities to interpret and use mathematical expressions in conjunction with conceptual understanding, rather than blindly applying routine mathematical procedures.

Research on quantitative problem solving investigates students' abilities to solve the problem correctly (e.g. Wilcox, Caballero, Rehn, & Pollock, 2013), to understand and set up the problem (e.g. Bodner & McMillen, 1986), or to execute problem-solving steps (e.g. Reif & Heller, 1982). However, such studies rarely examine how individuals *use* equations (Kuo, Hull, Gupta, & Elby, 2013). Because of the great importance of mathematics in chemistry, it is of the utmost importance to understand *how* equations are used and understood by chemistry students. Kuo et al. (2013) propose that equations could be used in two ways, where the second is more sophisticated and expert-like: 1) as computational tools to obtain an answer or 2) as holding meaning when blended with conceptual understanding.

This study explores undergraduate chemistry students' quantitative problem solving in the context of chemical kinetics because it is an anchoring concept of the undergraduate chemistry curriculum that requires the use of mathematics to understand and solve problems (Holme, Luxford, & Murphy, 2015; Holme & Murphy, 2012; Murphy, Holme, Zenisky, Caruthers, & Knaus, 2012). It has the power to provide insight into the nature of chemical reactions and processes, because it ties observable phenomenon with theoretical aspects of chemistry that are modeled mathematically (Çakmakci, Leach, & Donnelly, 2006). In addition, studies in this content area are understudied when compared to other topics in chemistry education research (CER) (AUTHOR, 2016, submitted).

The aim of this study is to identify how undergraduate chemistry students understand and use equations to solve kinetics problems. The guiding research question for this work is: How do non-major students in second-semester general chemistry and a non-majors physical chemistry course understand and use mathematics to solve kinetics problems involving rate laws? This study will provide insight into the mathematical processing stage of quantitative problem solving, providing instructors with an understanding of how students studying kinetics understand and use both the concepts and mathematics involved.

The theoretical framework for this study is personal constructs, a variation of constructivism, a framework that presents individuals as making sense of their experiences by inventing knowledge constructions and continually modifying them as they encounter more experiences (Bodner, 1986; Bodner, Klobuchar, & Gleelan, 2001). Specifically, Kelly's (1955) theory of personal constructs, a combination of personal and social constructivism, argues that while individuals differ in their knowledge constructions, one individual's constructs can be similar to another's, due to social interaction. A cognitive framework called blended processing is used to help describe and analyze problem solving. Blended processing describes a cognitive process that explores and models human information integration (Coulson & Oakley, 2000; Fauconnier & Turner, 1996, 1998, 2002). It provides a way to describe and understand individuals' mental spaces (or knowledge constructions) and their interactions (Bing & Redish, 2007; Hu & Rebello, 2013). In the context of science education research, blended processing can describe the "opportunistic *blending* of formal mathematical and conceptual reasoning *during* the mathematical processing stage" (Fauconnier & Turner, 2002; Hull, Kuo, Gupta, & Elby, 2013; Kuo et al., 2013; Sherin, 2001).

The primary data source for this study is individual semi-structured interviews with undergraduate chemistry students, which are conducted using a think-aloud protocol (Becker & Towns, 2012). This interview technique has students perform a task while explaining their thought process out loud. During these interviews participants solve kinetics problems involving rate laws, tables of data, and graphs. The written work is recorded physically on Livescribe™ paper and digitally by a Livescribe™ smartpen that captures both audio and writing in real time. The protocol is adapted from Kuo et al. (2013) to use a chemical kinetics context. It contains equations that the participants are asked to explain and problems they would be asked to solve in a general chemistry or upper-level undergraduate physical chemistry course.

The participant sample was selected using a homogenous sampling technique (Patton, 2002). Student participation is voluntary. Fall 2015 data collection yielded 21 individual interviews with second-semester general chemistry students. Spring 2016 data collection is ongoing with both second-semester general chemistry students and physical chemistry students. For completing the interview, students are compensated with a $10 iTunes gift card.

Audio data is transcribed verbatim following the interviews. To condense our data in a way that is conducive to answering our research question, we organized interviews into problem solving maps. To make the maps, we identified problem solving "steps" in large tables, where all data from the interview corresponding to each step were categorized with a brief descriptor, such as "highlights purpose of the equation." Keeping in mind a conceptual framework of blended processing, an open coding approach was used to analyze the problem solving maps. Frequently, codes were assigned to excerpts of data as they were organized into steps in the map, which meant that a problem-solving step received one code. However, there were also instances where multiple codes were assigned to all the data in one step or different codes were assigned to different parts of the data in one step. Preliminary thematic findings will be presented and discussed. Evidence of blended processing will be explored, in conjunction with evidence of other modes of reasoning.

This study holds the promise of developing a better understanding of how non-major chemistry students understand chemical kinetics, but more importantly how they use and understand mathematics in chemistry contexts.

Using learning trajectories to structure teacher preparation in statistics

Abstract

As a result of the increased focus on data literacy and data science across the world, there has been a large demand for teacher preparation in statistics. However, exactly how this preparation should be structured remains an open question. The purpose of this paper is to report on the NSF-funded Project-XXX professional development program. Project-XXX provided professional development to enhance teachers' statistical knowledge for teaching. The project constructed two hypothetical learning trajectories for teacher learning and subsequently used the hypothetical learning trajectories to structure the professional development curriculum. This main goal of this paper is to illustrate how the utilization of the learning trajectory structure to design professional development curriculum allowed participating teachers to develop several aspects of Statistics Knowledge for Teaching (Groth, 2013).

Introduction

Large-scale research provides some indication of the key characteristics of effective teacher training (Doerr, Goldsmith, & Lewis, 2010; Garet, Porter, Desimone, Birman, & Yoon, 2001; Heck, Banilower, Weiss, & Rosenberg, 2008; Gersten et al., 2014). These include a focus on content knowledge, opportunities for active learning, and coherence with other learning activities (Garet et al., 2001).

The purpose of this article is to report on how using teacher learning trajectories to design teacher training offers a structure to develop teacher content knowledge in deep and meaningful ways. This study is based on the implementation of Project-XXX, a project funded by the National Science Foundation to develop professional development curriculum materials to enhance teachers' content knowledge of two fundamental statistics topics – sampling variability and regression. Project-XXX first developed hypothetical learning trajectories for teacher learning for these two topics and then designed a professional development curriculum around these learning trajectories. In exploring the results of the implementation of this professional development curriculum, we recognized the important role that the learning trajectories played in creating opportunities for teacher participants to achieve key developmental understandings in relation to knowledge of the content.

We aim to answer the following research question: *How did the use of learning trajectories to design professional development curriculum support the development of teachers' statistics knowledge for teaching* The findings suggest that learning trajectories offer a promising structure for aiding teacher professional development curriculum design.

Learning Trajectories

Given a specific topic, a learning trajectory (or learning progression) for that topic can be thought of as a framework that serves as a map for how to achieve different cognitive learning levels or learning outcomes. Learning trajectories (LTs) represent recent advances in instructional and curriculum design (Duschl, Schweingruber, & Shouse, 2007; Mohan, Chen, & Anderson, 2009; Stevens, Delgado, & Krajcik, 2010) that promote deep and integrated understanding of target topics by providing a model for the successive and gradual thinking about a topic one must go through to achieve depth of understanding. However, while learning trajectories essentially organize learners' thinking and learning, how a learning trajectory is built and the scope for which it is used differs in the literature.

Some authors build learning trajectories as a descriptive tool formed from extensive descriptive research and observations of students' learning in various settings. In this sense, learning trajectories are a way to synthesize how learners acquire increasingly advanced ways of thinking independent of instruction of a particular topic. For example, learning trajectories can be viewed as incrementally more sophisticated ways to think about a concept that emerge naturally while one moves toward expert-level understanding (Stevens, Shin, & Krajcik, 2009).

Another way learning trajectories can be built is through the consultation of expert opinions of how learners acquire advanced ways of thinking given a particular instructional treatment. For example, Confrey and Maloney (2010) describe LTs as "a researcher-conjectured, empirically-supported description of the ordered network of constructs a student encounters through instruction (i.e. activities, tasks, tools, forms, of interaction and methods of evaluation), in order to move from informal ideas, through successive refinements of representation, articulation, and reflection, towards increasingly complex concepts over time" (Confrey, 2008; Confrey et al., 2008, 2009).

Project-XXX focuses on developing learning trajectories for teachers' thinking and learning. *The Project-XXX learning trajectories are defined as a curricular map for sampling variability and regression for teachers.* The trajectories are based on the analysis of statistical content and consultation of previous literature on the teaching and learning of sampling variability and regression along with a team of expert opinions of sensible sequences of this content. The trajectories therefore describe how teachers can acquire advanced ways of thinking about sampling variability and regression given a particular instructional path.

Theoretical Framework

We employed LTs as a map for *teacher* learning. *In this sense, the LTs were used to create a teacher curriculum, through a series of instructional tasks and assessments, for teacher learning of sampling variability and regression.* The LTs in this study therefore served to guide, develop, and order a sequence of instructional tasks for teacher training. In applying the LTs to teacher learning, we intersect LTs with frameworks of teacher knowledge. In particular, we draw upon the Mathematical Knowledge for Teaching (MKT) framework and the Statistical Knowledge for Teaching (SKT) framework (Groth, 2013).

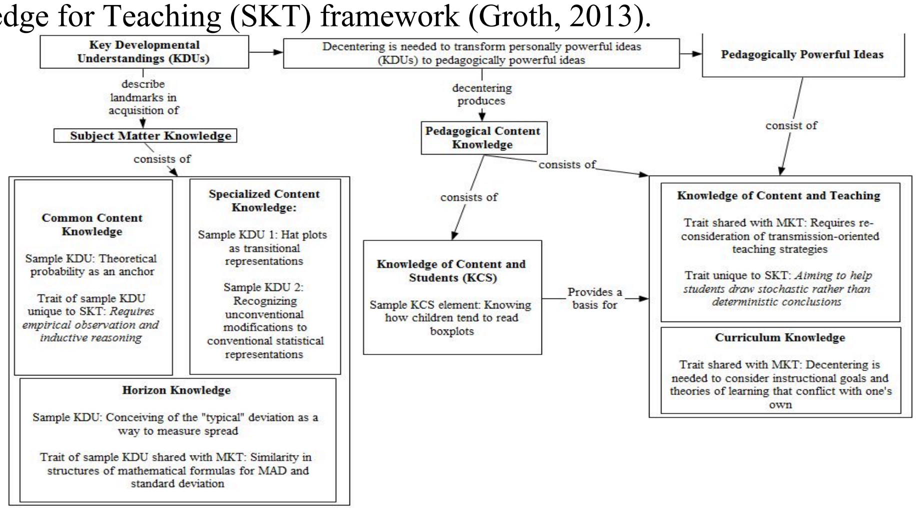

Figure 1 SKT Framework (Groth, 2013, pp. 143)

Groth (2013) identified Key Developmental Understandings (KDUs) as landmarks in the teachers' development of subject matter knowledge. Building from the work of Simon (2006), Groth describes KDUs as significant conceptual shifts. According to Groth, these landmarks or conceptual shifts can occur in each of the three types of subject matter knowledge in his framework (common content knowledge, specialized content knowledge, and horizon content knowledge). Groth's SKT framework also incorporates ideas outlined by Silverman and Thompson (2008) regarding the development of pedagogical content knowledge. In particular, Silverman and Thompson assert that teachers' development of KDUs with regard to subject matter knowledge are a necessary, but perhaps insufficient, first step with regard to improving student learning.

The primary purpose of the Project-XXX professional development was to develop teachers' SKT. Prior to the design of the professional development course, as part of the project, teacher LTs were constructed for the topics of sampling variability and regression. These LTs served as guides for the structure of the professional development. Figure 2 represents the relationship between teacher learning trajectories, professional development, and SKT. This study focuses on understanding how this process might work.

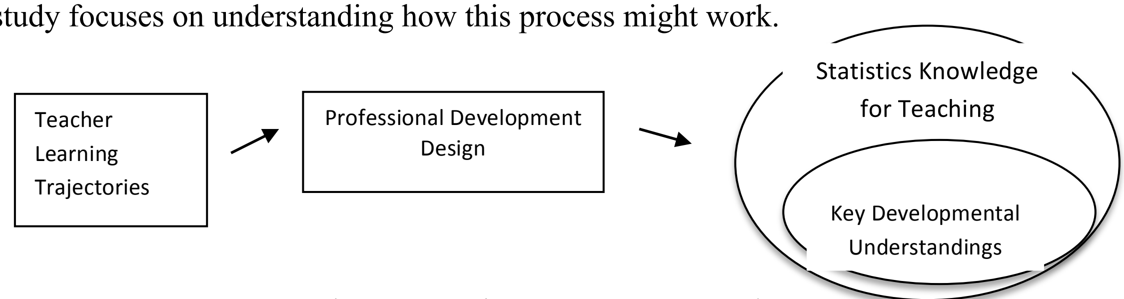

Figure 2. Project-XXX Conceptual Framework

Methods

Participants

Nine secondary teachers completed the entire pilot course. Seven of the 9 teachers taught in the local public school district. Two of the teachers taught in a private school within the city. Their average number of years teaching statistics was 2.4.

Data Sources

End-of-Loop Assessment Tasks. Assessment tasks were completed by the teachers at critical points of the LT in order to measure understanding with respect to the content included in the LT. The scoring of each part was modeled after the AP Statistics scoring of: E (Essentially Correct); P (Partially Correct); or I (Incorrect). The assessment tasks were scored each week by two scorers who were part of the research team but not present during the professional development session. The scorers graded the papers separately and then discussed their scores to come to a consensus on the final scores.

End-of-LT Assessment. At the completion of the content of each LT, teachers were assigned as homework an assessment intended to bring together the content of the entire trajectory.

Video of Class Sessions. Each class session of the professional development was videotaped. Outlines of the videos were created and portions of the videos were transcribed. The videos provide a means to confirm and elaborate on the observed patterns of teacher learning documented from the teachers' written work.

Analysis

A two-phase process was used to investigate how the use of LTs supported the development of Statistical Knowledge for Teaching (SKT), with a particular focus on Key Developmental Understandings (KDUs). The first phase took place during the analysis of teachers' written work on the End-of-Loop Assessment Tasks and the end-of the LT projects. This analysis provided insight into which ideas were pivotal to teacher understanding thus permitting the research team to identify a preliminary list of KDUs.

In the second phase of the data analysis, these prospective KDUs were then examined through the analysis of classroom interactions. During this phase, the videos were examined in order to determine how teachers' Statistical Knowledge for Teaching developed as they progressed through the LTs. Results of this analysis will be presented in the conference talk.

Results

We present illustrative examples of the KDUs that we identified along with supporting evidence consisting of samples of teacher work or transcript segments. While analyzing the teacher written work, several points were identified as being pivotal to teachers' development of SKT. Such ideas were those that repeatedly surfaced in multiple teachers' written work throughout the PD as well as in-class discussions.

Example 1 Common Content Knowledge KDU: Sample Size and the Sampling Distribution

One of the most persistent ideas that surfaced in teachers' work and discussion involved the relationship between sample size and the shape and spread of the sampling distribution. We have identified this as a KDU reflecting Common Content Knowledge in Groth's framework insofar as this is not a concept specific to the domain of teaching.

Teachers repeatedly made statements alluding to the fact that when repeated samples were taken and a sample mean was computed, then the shape of the sampling distribution should become more bell-shaped and the variability of the sampling distribution should decrease. For example, an assessment task for sampling variability asked teachers to compare three different approximate sampling distributions taken with samples of n=5, 15, and 30 according to their shape, variability, and center. There is evidence at this point that the nine teachers developed an understanding of the effect of the sample size on the spread, even if they were not yet clearly articulating the relationship to shape. Three samples of teacher responses are provided:

Assessment task question: Compare the three distributions that you constructed. What can you say about the shape of the distribution as the sample size, *n*, increases? What can you say about the mean? What can you say about the standard deviation?

Teacher Example 1: As *n* increases, the data gets more "compact" around the population mean $27,000 – thus the variation decreases. The mean income was closer to the population mean when n=15 than when n=30, but still both close to $27,000. The standard deviation decreases as *n* increases.
Teacher Example 2: As the sample size increase, the distributions are becoming less spread out. There is less variability in the distributions as the sample size increases.
Teacher Example 3: The shape of the distribution is more unimodal and symmetric, becoming more approximately normal. There is less variation as the sample size n increases. The mean got smaller and then bigger as the sample size increased. However, the mean stayed in the same interval between 25,000 and 30,000. The standard deviation decreased as the sample size n increased. I would expect that trend to continue, but the standard deviation was decreasing at a slower rate as n increased.

The videos of the class sessions provide further support for the assertion that this was a KDU for teachers that the loop design of the LTs fostered. After investigating these ideas over a period of time, teachers expressed different "aha" moments around the effect of the sample size. For example, the activity for Loop 3 engaged the teachers in sampling from four populations with vastly different distributions (bimodal distribution, skewed distribution, roughly normal distribution, and scattered distribution). The teachers took samples of size n=5, n=10, and n=25 and generated approximate sampling distributions for each sample size. They compared the sampling distributions of different sizes and noted the similarities in the effect of the sample size on the sampling distribution.

> Instructor: So, tell us what you've got there from Jamal [the bimodal distribution] and what happened with the samples of different sizes?
>
> Teacher 6: As you can see, as you increase the sample size, the variability gets smaller and smaller, if you look you are going from 20 to about 110, versus the spread going from 20 to about 80 where for size 10 you are going about 52 to 66, your variability is decreasing.

As the discussion continued, several teachers also compared the sampling distributions to the corresponding population distributions, noting the way in which the distributions with the larger sample sizes behaved in a similar manner, regardless of the distribution of the population. In particular, even when the population had a non-symmetric or bimodal shape, as the sample size increased, the variability of the sampling distribution decreased. During this comparison of the different distributions, one of the teachers, focused on the behavior of sampling distributions of the bimodal population distribution, began to talk through the reasons behind what she had observed.

> Teacher 5: No matter what the population looked like, there was a mean. And our data, or our samplings, were samplings of the average. So, they all should have been near the average of the population. No matter what [the population] looked like.

Another teacher builds on this idea and offers an argument for why the variation of the sampling distribution should logically decrease with an increase in the sample size:

> Teacher 7: I guess they can't do this because they are obviously…cards, but if we had done N=60, a.k.a. all the cards, it would have just been a straight line at 60… So that like N = 60 literally is just 60, 60, 60, 60 [the mean of the sample] over and over again, just a straight line of 60, *but that would have been a good thing to compare to n = 4, n=10, n = 30*. [Note: The example to which she was referring had a population mean of 60 and a population size of 60.]

In this segment, the teachers appear to not only recognize the effect of the sample size on the spread of the sampling distribution (as with their written work, their descriptions of the shape are not as explicit at this point). They also appear to be creating corresponding mental images of why this makes sense, no matter what the shape of the population is.

The significance of this idea as a KDU is reflected in their own comments a few minutes after the observations from Teacher 5 and 7 described above.

> Teacher 3: You know…I'm not sure that I ever understood that…I'm serious.
>
> Teacher 5: The light did come on, in terms of understanding what was happening in this activity.

Example 2 Specialized Content Knowledge KDU: Line of Best Fit Counterexamples

Specialized content knowledge, defined in the SKT framework as knowledge of content needed in the practice of teaching, may include teachers' ability to comment on student work and strategize ways they can address student errors. One way to illustrate to students their errors would be to provide students with examples for which their solution will not work. The ability to develop such counterexamples is knowledge specific to teaching.

In the regression LT, the teachers were asked to examine a scatterplot of drop heights versus bounce heights of a golf ball and place a piece of spaghetti on the scatterplot in such a way that they believed represented a line of best fit. Teachers also had to explain what their criterion was for the placement of the line and why they chose to place it there. This same activity had been given to 8th grade students. A second component to the teacher activity was then for the teachers to comment on the 8th grade students' work and, if the work showed a misunderstanding, then provide a counterexample scatterplot that would illustrate to the student that their placement criterion would not be successful in general.

During part one of the activity, all of the teachers created criteria that matched that of the previously collected student data. For example, one teacher asked "do you assume it [the spaghetti] goes through (0,0)?" She noted that in the context of the problem, dropping balls, if you dropped the ball from 0 height, you would get a 0 bounce height. She thus concluded that her line of best fit must go through the origin. This same reasoning was also seen in the student work. Another teacher stated that she placed her line in such a way that "there are 4 dots above and 4 dots below and so it is in the middle." Again, similar reasoning was uncovered in the student work with a student stating that they wanted to "split" the points.

When teachers were given the student results to analyze, they were asked to evaluate whether the criteria the students used to place their line was one that would work for *any* data set. If not, then the teachers were to give an example scatterplot for which their student criteria would not work. This proved difficult for the teachers. For example, one student had the origin criteria similar to one of the teachers. Looking at the student work, she stated: "I think that is a good idea." However, teacher 8 responded by saying "in this case, it [going through the origin] is ok but not all the time." At this point, a conversation emerged as to whether the criterion the student applies must work for any set of linear data or just the golf ball data in front of them. After a short deliberation about what defining a criterion means and how it should be applied, it was accepted that a criterion must work for any set of data. Then, the teachers created the counterexample of a data set that had a negative association and thus would require a line to have a negative slope so it would not enable the line to go through the origin. Although the teachers were able to develop counterexamples to help guide student misunderstandings in the context of the line of best fit, the work was non-trivial.

Discussion & Conclusion

As noted by Simon (2006), for someone to develop a Key Developmental Understanding, one must have repeated exposure to the concept. Additionally according to Simon, students without a KDU "do not tend to acquire it through explanation or demonstration" (p. 362); instead a KDU must emerge through discovery. In this way, a person would be able to shift their understanding and gain a Key Understanding. We gathered evidence to show that the Project-XXX LTs offered a platform for teachers to develop KDUs by scaffolding more complex ideas and repeatedly looping for each topic. Due to limitations in space, only two examples were presented above. We assert that the design of the Project-XXX activities to progress teachers through the LT facilitated the development of Statistical Knowledge for Teaching and the emergence of KDUs. In addition, the LT also allowed for the conceptual unpacking necessary to develop teachers' knowledge.

The LT's mapping created clearly-defined conceptual boundaries that allowed us to recognize when inadequate connections were begin made to horizon content knowledge. Thus, although this is a small study with nine teachers, we see great promise in the use of LT's in the design of teacher preparation curriculum to support the growth of teachers' knowledge. The SKT construct asserts that teacher statistical knowledge for teaching consists of both content knowledge and pedagogical knowledge. We saw evidence in this small scale study that building professional development using LTs shows promise in helping teachers advance both their content knowledge and their pedagogical knowledge. In addition to the development of subject matter knowledge, we also saw evidence of the translation of this subject matter knowledge into pedagogically powerful ideas.

The goal of this paper was to analyze the affordances of LTs in the design of professional development. In particular, we sought to understand how the use of LTs might support the development of Statistics Knowledge for Teaching, with a particular focus on the key developmental understandings that emerged. Doerr et al. (2010) have identified this type of small-scale study as making important contributions to our understanding of professional development. In particular, through the description and analysis of the "critical elements" (Borko et al., 2008) of the program, it is possible to better understand the teacher learning process and the potential of the program for sustained success.

We view the findings in this paper contributing to the advancement of knowledge and literature base in three ways. First, this study provides small-scale evidence that learning trajectories can not only be used to map student curriculum and learning, but also can be used as maps for teacher curriculum and learning. Prior to this study, learning trajectories have been used in the professional development only as tools to discuss student learning. However, this study illustrates several advantages that learning trajectories can offer to actually build, organize, and structure teacher learning. The LTs in this study were used to guide the nature and order of the sequence of content.

A second contribution of this study is the connection of learning trajectories to existing teacher learning constructs such as Statistical Knowledge for Teaching, Key Developmental Understandings, and Pedagogically Powerful Ideas. This study provides evidence that learning trajectories offer a means to observe and develop such constructs with teachers.

An additional contribution of this study is the presentation of two teacher learning trajectory maps for the challenging statistical topics of sampling variability and regression. These trajectories and accompanying materials can be utilized by others to teach teachers these topics.

The analysis of the use of the hypothetical LTs as a "critical element" of the program suggests that LTs can offer similar structures for teacher learning that mirror those previously documented for student learning. In particular, the LTs offered a framework for identifying and achieving KDUs and making instructional decisions based on the KDUs. The LTs gave the research team a way to see how KDUs were directly related to the development of SKT. Furthermore, the LTs provided a means for teachers to achieve KDUs due to their repeated exposure while moving through the loop structure of an LT. By construction, the LTs provided scaffolding for KDU development. The repeated exposure illustrated when cognitive shifts were occurring in teachers' thinking. In addition, this repetition allowed teachers to transform KDUs into pedagogically powerful ideas.

While Project-XXX has a specific focus on teachers' statistics knowledge, we suggest that the implications for mathematics teacher training are broader than this teacher population. In particular, by focusing on a "critical element" of Project-XXX– the use of LTs for teacher knowledge – we submit that the model has potential for other content within mathematics teacher professional development. One of the goals of Project-XXX was to focus on statistical content. While sampling variability and regression represent two important statistical content topics, there are various other topics about which teachers are likely to have had limited opportunities to develop knowledge for teaching (e.g., transformational geometry). The use of LTs for teacher learning offers a potentially powerful strategy for developing teachers' knowledge of these concepts, as well as others within the larger mathematics curriculum.

A case study of developing self-efficacy in writing proof frameworks

Ahmed Benkhalti, New Mexico State University
Annie Selden, New Mexico State University
John Selden, New Mexico State University

This case study documents the progression of one non-traditional individual's proof-writing through a semester. We analyzed the videotapes of this individual's one-on-one sessions working through our course notes for an inquiry-based transition-to-proof course. Our theoretical perspective informed our work with this individual and included the view that proof construction is a sequence of (mental, as well as physical) actions. It also included the use of proof frameworks as a means of initiating a written proof. This individual's early reluctance to use proof frameworks, after an initial introduction to them, was documented, as well as her later acceptance of, and proficiency with, them. By the end of the first semester, she had developed considerable facility with both the formal-rhetorical and problem-centered parts of proofs and a sense of self-efficacy.

Key words: Transition-to-proof, Proof Construction, Proof Frameworks, Self-efficacy

This case study concentrates on how one non-traditional mature individual, in one-on-one sessions, progressed from an initial reluctance to use the technique of proof frameworks (Selden, Benkhalti, & Selden, 2014; Selden & Selden, 1995) to a gradual acceptance of, and eventual proficiency with, both writing proof frameworks and completing many entire proofs. This case study further illuminates the well-known, and documented, tendency of students to write proofs from the top-down, and consequently, to be unable to develop complete proofs. (See the case of Willy, who focused too soon on the hypothesis, in Selden, McKee, & Selden, 2010, pp. 209-211). We also consider how this approach to proof construction helped this individual gain a sense of self-efficacy (Bandura, 1994, 1995) with regard to proving.

Theoretical Perspective

In our analysis and in our teaching, we consider proof construction to be a sequence of mental and physical actions, some of which do not appear in the final written proof text. Such a sequence of actions is related to, and extends, what has been called a "possible construction path" of a proof, illustrated in Selden and Selden (2009a). For example, suppose that in a partly completed proof, there is an "or" in the hypothesis of a statement yet to be proved: "If A or B, then C." Here, the situation is having to prove this statement. The interpretation is realizing the need to prove C by cases. The action is constructing two independent sub-proofs; one in which one supposes A and proves C, the other in which one supposes B and proves C.

When several similar situations are followed by similar actions, an *automated link* may be learned between such situations and actions. Subsequently, a situation can be followed by an action, without the need for any conscious processing between the two (Selden, McKee, & Selden, 2010). When students are first learning proof construction, many actions, such as the construction of *proof frameworks* (Selden, Benkhalti, & Selden, 2014; Selden & Selden, 1995), can become automated. A *proof framework* is determined just by the logical structure of the theorem statement and associated definitions. The most common form of a theorem is: "If P, then Q", where P is the hypothesis and Q is the conclusion. In order to construct a proof framework for it, one takes the hypothesis of the theorem, "P", and writes, "Suppose P" to begin the proof. Immediately afterwards, one takes the conclusion of the theorem, "Q", skips towards the bottom of the page, and writes "Therefore Q", leaving enough space for the rest of the proof to emerge in between. This produces the *first level* of the proof framework. At this point, one should focus on the conclusion and "unpack" its meaning. It may happen that the unpacked meaning of Q has the same logical form as the original theorem, that is, a statement with a hypothesis and a conclusion. In that case, one can repeat the above process, providing a *second level* proof framework in the blank space between the first and last lines of the emerging proof. (For some examples, see Selden, Benkhalti, & Selden, 2014).

Prior Research

While studies on students' learning to write proofs have been made before, they have not so specifically focused on proof frameworks. Hazzan (1999) has written about how students cope with the transition to upper level proof-based mathematics, specifically when they take their first undergraduate abstract algebra course. Dahlberg and Housman (1997) were interested in how a student develops his/her concept image when learning a new mathematical concept. They found that students who engaged in example generation and reflection during the study of definitions were able to attain a more comprehensive understanding. Housman and Porter (2003) found a correspondence between students who used transformational proof schemes and those who successfully generated examples when asked to do so. Selden, McKee, and Selden (2010) reported instances of students' tendencies to write proofs from the top down and their reluctance to unpack and use the conclusion to structure their proofs. This study extends that work.

Methodology: Conduct of the Study

We met regularly for individual 75-minute sessions with a mature working professional, Alice, who wanted to learn how to construct proofs. Alice followed the same course notes previously written for an inquiry-based course used with beginning mathematics graduate students who wanted extra practice in writing proofs. The sessions were almost entirely devoted to having Alice attempt to construct proofs in front of us, often thinking aloud, and to giving her feedback and advice on her work. The notes had been designed to provide graduate students with as many different kinds of proving experiences as possible and included the kinds of proofs often found in typical proof-based courses. They covered some sets, functions, real analysis, and algebra, in that order.

Alice had a good undergraduate background in mathematics from some time ago and also had prior teaching experience. She only worked on proofs during the actual times we met. While she usually came twice a week to see us and work on constructing proofs, sometimes when her paid work got a bit overwhelming, she would take a week off. Thus, unlike the graduate students who took the course as a one-semester 3-credit class, Alice worked with us on our course notes for two semesters at her own pace and did not want credit.

We met in a small seminar room with blackboards on three sides, and Alice constructed original proofs at the blackboard, eventually using the middle blackboard almost exclusively for her evolving proofs. After several meetings, she began to use the left board for definitions and the right board for scratch work. She did not seem shy or overly concerned with working at the board in front of us, and from the start, we developed a very collegial working relationship. She seemed to enjoy our interactions as she worked through the course notes. Thus, we gained greater than normal insight into her mode of working. We videotaped every session and took field notes on what Alice wrote on the three boards, along with her interactions with us. For this particular study, we reviewed the first semester videos and field notes several times, looking for signs of progression in Alice's approach to constructing proofs.

The Progression

Our First Meeting with Alice

We introduced Alice to the idea of proof frameworks and explained in detail how and why we use them. We also introduced her to the idea of unpacking the conclusion and mentioned that proofs are not written from the top down by mathematicians. With guidance, she was able to prove "If $A \subseteq B$, then $A \cap C \subseteq B \cap C$." In addition, she worked three exercises on writing proof frameworks--one on elementary number theory and two on set equality. Near the end of this meeting, Alice produced a proof framework for the next theorem in the notes. We felt that she not only understood our reasoning for using proof frameworks, but also how to construct them.

Our Second Meeting with Alice—Her Reluctance to Use Proof Frameworks Surfaces

At the beginning of the second meeting, Alice went to the middle board and produced the same proof framework, as she had done five days earlier at our first meeting (Figure 1).

Theorem: Let A, B, and C be sets. If $A \subseteq B$, then $C - B \subseteq C - A$. Proof: Let A, B, and C be sets. Suppose $A \subseteq B$. Suppose $x \in C - B$. So $x \in C$ and x is not an element of B.	Thus $x \in C$ and x is not in A. Therefore x is in $C - A$. Therefore, $C - B \subseteq C - A$.

Figure 1. The proof framework that Alice produced on the middle blackboard.

Then Alice stopped and after a long silence of 65 seconds, much to our surprise, said, "I have a question for you. I find it very difficult to see the framework. Let me show you how I do it, because somehow I get confused with the framework." We asked her what it was about the framework that was confusing, but she seemingly could not put it into words. So we encouraged her to write the proof the way she preferred. Thus, on the left board, Alice began to write the proof in her own way in top down fashion (Figure 2). She then paused for 15 seconds, and said, "We need to have one more," and wrote into her proof attempt, **"and $x \in A$"** immediately below **"$x \in C - B$"**, indicating with a caret that **"and $x \in A$"** was also part of her supposition (Figure 3). Then, after a 35-second pause, she added to her proof attempt, "**Since $x \in A$ and A is a subset B. Then $x \in B$.**" Shortly thereafter, Alice quietly said, "Oh, a contradiction". This was followed by, "Yeah, 'cause x doesn't belong to B. Yeah, problem here."

Theorem: Let A, B, and C be sets. If $A \subseteq B$, then $C - B \subseteq C - A$. Proof. Let A, B, C be sets. Suppose A is a subset of B. We need to prove that $C - B$ is a subset of $C - A$. Suppose $x \in C - B$. We need to prove that $x \in C - A$.

Figure 2. Alice's attempt at constructing a proof in her own way.

Then, after a ten second pause, Alice said, "The problem is right here, isn't it?" pointing and underlining "***B***" and the statement "**and $x \in A$**." We asked, "And what do you think that problem is?" Alice replied, "I assumed that [pointing to **"and $x \in A$"**], but I do not know. I only know this [pointing to **"A is a subset of B"**]. We replied, "So that's a good point you've made."

Theorem: Let A, B, and C be sets. If $A \subseteq B$, then $C - B \subseteq C - A$. Proof. Let A, B, C be sets. Suppose A is a subset of $\underline{\boldsymbol{B}}$. We need to prove that $C - B$ is a subset of $C - A$. Suppose $\boldsymbol{x \in C - B}$. We need to prove that $x \in C - A$. **<u>and $x \in A$</u>.**

Figure 3. Alice's adjustments to her proof attempt, done in her own way.

After that, for a few minutes, we talked about the structure of proofs, and why we use proof frameworks. Then we asked Alice to elaborate on why **"and $x \in A$"** is a problem. She said, "I didn't write it right. I should have said here [pointing to the blank space to the left of **"and $x \in A$"**] I'm going to make an assumption like **'Suppose x belongs to the A'**, and then since x belongs to the A and I know that A is a subset of B, **then the x will belong to the B**." She continued, "I also know that x belongs in the $C - B$, because I said it earlier. Then x belongs to the C but **x does not belong to the B**." To which one of us replied, "And then you said something. I thought I heard you say the word **'contradiction'**." Alice explained, "Yeah, I got a contradiction because then I'm saying here [pointing to the board] the x belongs to the B, and the x doesn't belong to the B." We agreed, and she offered, "That assumption [pointing to **"and $x \in A$"**] was bad." We then reiterated why proof frameworks are structured the way they are, and suggested that we could take Alice's original framework (Figure 1) and what Alice had written on the left board (Figure 3), and change the order to write a proof. We proceeded to help Alice do this.

Subsequent Meetings with Alice

As the meetings went on, we observed that Alice became very methodical in her approach to proving, and also somewhat more accustomed to writing proof frameworks. We hypothesize this was because of her technical work experience and perhaps because of her natural tendencies. By the 12th meeting, Alice had developed the following pattern of working: She would write the statement of the theorem to be proved on the middle board, then look up in the course notes the definitions of terms that occurred in the theorem statement, write them exactly as stated on the left board, and use the right board for scratch work. Indeed, during the 12th meeting, when she got to the theorem, "Let X, Y, and Z be sets. Let f: $X \rightarrow Y$ and g: $Y \rightarrow Z$ be 1-1 functions. Then $f \circ g$ is 1-1," she wrote the first and second level frameworks ostensibly on her own, and with some guidance from us, completed the proof and read it over for herself aloud.

By the 19th meeting at the end of the first semester, Alice was more fluent with writing proof frameworks than on the 12th meeting, and she had adopted the technique of writing definitions on the left board and changing the variable names to agree with those used in the theorem statement – all without prompting from us. This is remarkable as our experience has been that many students do not change variable names in definitions even when we suggest doing so, and this can often lead to difficulties. Alice continued meeting with us and working on the course notes at her own pace during the second semester. We plan to continue our analysis of those videos for Alice's continued progression.

Summary of Results

Alice came to us apparently with a reasonable undergraduate mathematics background, some of which she had forgotten. At the first meeting we explained the use of proof frameworks and our rationale for using them, and she practiced producing several of them. However, at the second meeting she told us that she found this way of working confusing. When she attempted her own alternative method of proving, she got into difficulty, and as a result, was more willing to try using proof frameworks again. Over the course of our subsequent meetings that semester, Alice became fluent with writing both first and second level frameworks, and adopted a methodical way of working. As time went on, she was able to complete proofs with less guidance from us. Indeed, she often mainly required some help with the problem-centered parts of proofs. In the following semester, she continued meeting with us and working on the course notes. We feel that, by the end of the second semester, she had developed a sense of self-efficacy (Bandura, 1994, 1995) regarding her proving ability and expect to document that further.

Implications

The initial tendency of many university students to write proofs in a top-down fashion tends to fade after sufficient exposure to writing proof frameworks. One might ask where this tendency comes from. According to Nachlieli and Herbst (2009), it is the norm among U.S. high school geometry teachers to require students, when doing two-column proofs, to follow every statement immediately by a reason. This implies top-down proof construction. However, as noted previously, automating the actions required to write the formal-rhetorical part of a proof can allow students to "get started" writing and exposes the "real problem" to be solved in order to complete the proof (Selden & Selden, 2009b). For this, persistence and self-efficacy are needed.

Discussion Questions

1. What more should we look for when we analyze the second semester videos?

2. In our experience, mathematicians just know how to structure proofs (e.g., including how proofs can begin and end). Apparently, they have tacitly learned this, as well as the importance of "knowing where they are going" (e.g., unpacking the conclusion). How and when do mathematics majors learn this, when not introduced to doing so explicitly via an inquiry-based course like ours?

RUME- and Non-RUME-track students' motivations of enrolling in a RUME graduate course

Ashley Berger, Rebecca Grider, Juliana Bucher, Mollie Mills-Weis, Fatma Bozkurt, Milos Savic
University of Oklahoma

The purpose of this ongoing study is to investigate students' motivations in taking a graduate-level RUME course. Seven individual semi-structured interviews were conducted with graduate students enrolled in a RUME course at a large Midwestern university that has a RUME Ph.D. option in the mathematics department. Our analysis of those interviews utilized two theoretical frameworks: Self-Determination Theory (Ryan & Deci, 2000) and Hannula's (2006) needs and goals structure. Preliminary analysis of the interviews indicates that non-RUME-track students are extrinsically, need-motivated, while RUME-track students are intrinsically, goal-motivated when taking a RUME course. The researchers conjecture that knowing what influences non-RUME-track students may aid in closing the gap between the mathematical and RUME communities.

Introduction

There is a limited amount of research with regard to motivation in mathematics education (Wæge, 2009). Particularly, in our search, there appears to be little research regarding motivation of future mathematics educators at the tertiary level (e.g., Herzig, 2002). Hannula (2004) defined motivation to be "a potential to direct behaviour that is built into the system that controls emotion. This potential may be manifested in cognition, emotion and/or behaviour." According to Wæge (2009), motivation can be influenced by teachers: "students' motivation for learning mathematics, although it is considered relatively stable, can be influenced by changes in the teaching approach" (p. 90).

Pedagogy courses are sometimes offered within mathematics departments to help shape and educate graduate students who will go on to teach at the college level. These courses are sometimes referred to as Introduction to RUME courses. The purpose of this ongoing study is to investigate students' motivations in taking a graduate-level RUME course. In particular, our research goals for the current study are (a) to classify students' motivations for enrolling in and participating in the course, and (b) to investigate what the students took away from the course with respect to their academic goals, their career goals, their future course selections, and/or their current teaching practices. We are especially interested in the similarities and differences between RUME- and non-RUME-track students with respect to these questions.

Theoretical Perspective

Self-Determination Theory (SDT) is a general motivation theory that focuses on psychological needs (Ryan & Deci, 2000). They distinguish between psychological needs by looking at intrinsic and extrinsic motivation. Intrinsic motivation is defined as "doing an activity for the inherent satisfaction of the activity itself" while extrinsic motivation is "the performance of an activity in order to attain some separable outcome" (Ryan & Deci, 2000, p. 71). From their studies, Ryan & Deci developed the Self-Determination Continuum (see Figure 1).

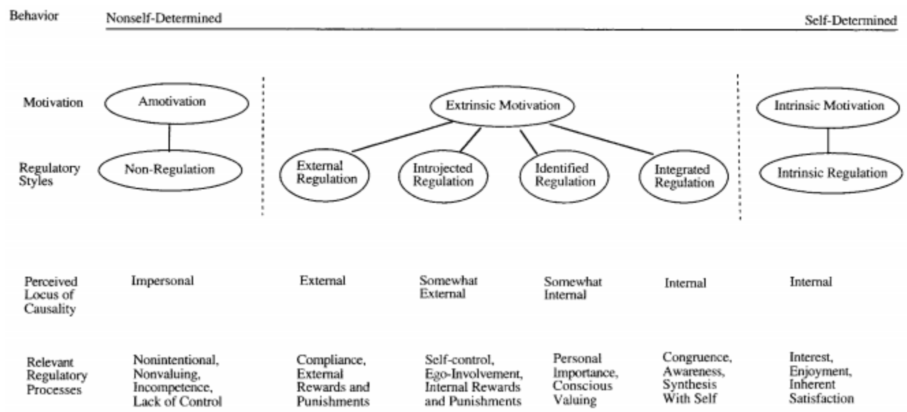

Figure 1; The Self-Determination Continuum (Ryan & Deci, 2000, p. 72)

Hannula (2006) says that "as a potential, motivation cannot be directly observed. It is observable only as it manifests itself in affect, cognition, and behaviour" (p. 175). He gives the examples of motivation being observable through beliefs, values, and emotional reactions. Needs (e.g., "autonomy, competency, and social belonging" (Hannula, 2006, p. 167)) which may transfer to goals, are used to structure this potential. Hannula's (2006) needs and goals structure, combined with Ryan & Deci's (2000) intrinsic and extrinsic framework, together will inform our analysis of the data.

Methodology

Seven individual semi-structured interviews up to 30 minutes in length were conducted. The individuals were students from a large Midwestern university who were enrolled in an Introductory to Math Pedagogy Research course. Four participants were interested in a RUME-track Ph.D. in mathematics. The class met for fifty-minute class periods three days a week. A research team member who was not enrolled in or teaching the course recruited the participants and conducted the interviews. In these interviews, students were asked about their motivations for taking the course, how those motivations have changed over time, how mathematics and RUME are related, and what they expect to leave the course with.

Preliminary Results

"I will admit that one primary reason is for the RUME teaching certificate that you get when you get your Ph.D. However, I am interested in the way that students learn math." –Student G (Non-RUME-track)

"My real passion is in teaching and in not so much teaching but in researching ways to create better teachers." – Student C (RUME-track)

Student G is expressing intrinsic motivation with the potential being rooted in needs while Student C is expressing extrinsic motivation with the potential being rooted in goals. A preliminary conjecture is that the non-RUME-track students' motivations are extrinsic, while the RUME-tracked students are more intrinsic. The potential motivators between the RUME-track students might tend toward goals, while the non-RUME-track students might tend toward competence, i.e. needs. Through this study, the researchers hope to gain a better understanding of why students take RUME courses and what they get out of them. Specifically, knowing the influences of non-RUME-track students can aid in closing the gap between the mathematical and RUME communities. Future research should include why non-RUME track students *do not* take RUME or pedagogy courses when given the opportunity.

How Calculus students at successful programs talk about their instructors

Annie Bergman
Portland State University

Dana Kirin
Portland State University

Ben Wallek
Portland State University

The CSPCC (Characteristics of Successful Programs in College Calculus) project was a 5-year study focused on Calculus I instruction at colleges and universities across the United States with overarching goals of identifying the factors that contribute to successful programs. In this poster, we draw from student focus group interview data collected from schools that were identified by the CSPCC project as being successful. The analyses we will present in this poster will characterize the ways in which calculus students talk about their instructors in an attempt to understand how their perceptions shape their experience.

Key words: Calculus, Student Perception, Thematic Analysis, Instructors

Over the past decade, numerous reports point to the need for national efforts to increase the number of students pursuing and professionals with degrees in science, technology, engineering, and mathematics (STEM) fields (see for example NSB, 2007; PCAST, 2012; Thomasian, 2011). According to the PCAST report (2012) increasing the retention rate of the students who enter college intending to major in a STEM field has the potential to significantly decrease the gap between the number of STEM degrees produced and the projected number of STEM degrees needed to sustain the United States position in the global market. While there are many reasons students leave STEM fields, there is a growing body of research that suggests that intending STEM students are switching out of STEM fields due to experiences in their introductory mathematics courses (Ellis, Kelton, & Rasmussen, 2014; PCAST, 2012; Rasmussen & Ellis, 2013), including experiencing poor instruction (Bressoud, Mesa, & Rasmussen, 2015; Seymour & Hewitt, 1997). In the United States each year over 300,000 students enroll in tertiary Calculus, many of which are just beginning their post-secondary education (Blair, Kirkman, Maxwell, 2013; Bressoud, Carlson, Mesa, & Rasmussen, 2013). To this end, we seek to better understand student experiences in successful Calculus courses by answering the question, *how do students in successful Calculus programs talk about their instructors?*

Methods

The CSPCC (Characteristics of Successful Programs in College Calculus) project was a 5-year study focused on Calculus I instruction at colleges and universities across the United States with overarching goals of identifying the factors that contribute to successful programs. The study consisted of a national survey conducted in fall 2010, followed by explanatory case study visits at seventeen institutions that were identified as successful because of student persistence (continuing to the next course in the calculus sequence) and reported increases in students' interest, confidence, and enjoyment of mathematics as a result of taking Calculus 1.

During site visits the research team conducted semi-structured student focus group interviews with current Calculus students in which they were given an opportunity to discuss various course components, their instructor, and overall course experience. We began data analysis by reading the interviews in their entirety and then choosing a subset of interview questions we felt were most relevant to our research goal. This subset of questions included:

- What types of things happen in class that help you learn calculus content?
- What would you say is your instructor's attitude towards calculus?
    - Does your teacher seem to care about your learning?
    - Does your teacher think students are capable of understanding calculus?

  - Do you think that this is typical of teachers in this math department?
- What do you think makes this program special?

Ongoing thematic analysis (Braun & Clarke, 2006) is being conducted on student responses from this subset of questions to identify overarching ways in which students at these institutions talk about their instructors. In the following section we highlight some initial themes that have emerged from our analysis.

Initial Findings

Currently our findings include three distinct perceptions of calculus instructors and their roles/characteristics in the classroom: (1) Students report instructors overwhelming *helpfulness* as an attempt to directly aid in students academic success; (2) a generally *friendly* demeanor; and (3) the instructor promoted an encouraging *atmosphere* in the classroom where students can interact with mathematics. To illustrate these findings we present experts from student interviews in Table 1.

Table 1

Emerging Themes Regarding How Students Talk About Instructors

Preliminary Theme	Institutional Level	Excerpt
Helpfulness	Bachelors	She's willing to help you as much as she possibly can if you're willing to try.
	Masters	She actually loves math so she wants to do everything possible for us to love math. She tries absolutely as hard as she can.
Friendliness	Bachelors	She's never condescending.
	Doctoral	I went to his office hours and he's really friendly and it makes it a lot easier to actually enjoy doing the math.
Great atmosphere	Bachelors	… Ms. M is interested in us doing well so it's a great atmosphere. That really helps… I mean you definitely have down there that the teacher definitely helps to make the experience, right?
	Bachelors	He creates a very comfortable environment and he (has) a really cool way of putting concepts together and making it connect with everything.

Conclusion

Overall students in successful Calculus programs speak highly of their experiences in the classroom and with the instructor. While analysis is still ongoing, one particularly interesting finding is the difference in the manner in which students at various institutional levels speak about their instructors. For instance, at bachelors granting institutions students tend to speak about their instructors with a very familiar tone while students at doctoral granting institutions give a real sense of distinct between them and their instructors, both physically and personally. Through ongoing analysis we hope to further develop current themes, illuminate more themes, and continue to investigate differences across institutional levels.

Student problem solving in the context of volumes of revolution

Anand M. Bernard
Brigham Young University

Steven R. Jones
Brigham Young University

The literature on problem solving indicates that focusing on strategies for specific types of problems may be more beneficial than seeking to determine grand, general problem solving strategies that work across large domains. Given this guideline, we seek to understand and map out different strategies students' used in the specific context of volumes of revolution problems from calculus. Our study demonstrates the complex nature of solving volumes of revolution problems based on the multitude of diverse paths the students in our study took to achieve the desired "epistemic form" of an integral expression for a given volume problem. While the large-grained, overarching strategy for these students did not differ much, the complexity came in how the student carried out each step in their overall strategy.

Key words: problem solving, calculus, volumes of revolution, epistemic games

Introduction

Helping students become proficient in problem solving, or the ability to complete a task where a solution is not immediately known, is an important goal in mathematics education (Lester, 2013; National Research Council, 2001; Schoenfeld, 1992). In the last several decades, researchers have studied problem solving and students' problem solving abilities (Lesh & Zawojewski, 2007; Schoenfeld, 1992), and one critical finding has been that it is difficult to determine general problem solving strategies that are useful for any situation. Researchers argue that coming up with a list of strategies for problem solving is difficult because lists are either too small and cannot account for all situations, or too broad such that students are left without a sufficient guide for which strategies to use (Lesh & Zawojewski, 2007). While it is difficult to find strategies to solve problems generally, some researchers have suggested that it may be more beneficial instead to develop strategies for particular types of problems (Lesh & Zawojewski, 2007; Schoenfeld, 1992).

Calculus problems involving volumes of revolution may provide just such a context, since they are not so broad that it becomes impractical to develop general problem solving strategies, yet are complex in that there is no single set procedure to find a solution and students cannot simply memorize one template to apply to all problems. Students need to choose between using the disk, washer, and shell methods and must choose whether to integrate with respect to *dx* or *dy*. Students must also be able to recall and apply knowledge from a range of different mathematical topics (e.g. integration techniques, geometry, and solving equations). Also, we have found no literature on student understanding of volumes of revolution, meaning that it is an area in need of exploration. Thus, in this paper we examine the strategies students use to solve volumes of revolution problems. In particular, this paper is meant to address the following questions: (1) What strategies did students use when solving volumes of revolution problems? (2) What particular features of the problems guided or focused the students in their problem solving strategies?

Epistemic Forms and Games

In investigating problem solving strategies for volumes of revolution, we employ the lens of epistemic games (Collins & Ferguson, 1993). Epistemic games provide a useful language for describing how students go from a *starting condition*, which in our case is the initial volume of revolution problem, to a desired outcome called an *epistemic form*. An epistemic form consists of "an external structure or representations and the cognitive tools to… interpret that structure" (Redish, 2004, p. 30). Collins and Ferguson provided examples of possible epistemic forms like lists, charts, and diagrams, and Redish added to the list things like an abacus or a graph. In our study, the specific "external structure" that makes up the epistemic form is an integral expression that is set up to match the volume of the particular solid given in a problem.

In order to advance from the starting condition to the epistemic form, one must make *moves*, which in our case consists of actions (mental or physical) that a student performs to achieve the desired form. The overall activity of taking the starting condition, making moves, and arriving at an epistemic form is called an *epistemic game* (Collins & Ferguson, 1993). Recently researchers in physics education have used epistemic games as a means to analyze how students problem solve in physics tasks (Black & Wittmann, 2007; Tuminaro & Redish, 2007), and we extend this to investigate students' problem solving strategies in mathematics contexts as well. Depending on the grain size one uses in analyzing the moves that constitute an epistemic game, the description one provides of a student's epistemic game can vary (Black & Wittmann, 2007). In this study, we examine both larger-grained and smaller-grained games, and we define a *global game* as one that describes the general moves a student makes and a *local game* as one that is played out within each of the moves of a global game.

Methods

For this study, eight students from a second semester calculus course were invited to participate in a one-hour interview regarding volumes of revolution problems. The students came from a course in which the instructor had attended to a conceptual development of the disk and shell methods and had also given examples of some cases where each method would not work, given the techniques available to the class. In order to get a range of participants, students were chosen based on their responses to four quiz problems given in class. Three students (Gabi, Doug, Trevor) got all four quiz problems correct, two students (Sarah, Frank) got three correct, two students (Bryan, Claire) got two correct, and one student (John) got only one correct. In the interview, the students were asked to set up integrals for four standard, textbook-style volumes of revolution problems, where a region bounded by certain curves is rotated around either the *x*- or *y-axis* (such as in Stewart, 2012, p. 430-445). The problems indicated in words to take the region bounded by the following curves and rotate it around the specified axis, and to determine the volume of the generated solid: (1) $y=\sqrt{1-x}$, $y=2x$, $y=0$ around *x*-axis; (2) $y=\sqrt{1-x}$, $y=2x$, $y=0$ around *y*-axis; (3) $f(x)=4x-\frac{1}{2}x^4$, $y=0$ around *y*-axis; (4) $f(x)=4x-\frac{1}{2}x^4$, $y=0$ around *x*-axis. Graphs of the functions in each problem were also provided to the students. The students were asked to discuss their thinking aloud and the interviewer asked clarifying questions while the student worked.

The videotaped interviews were first watched to record the steps the individual students took in setting up the integrals. These steps were used to define a set of "moves" for the global epistemic games the students played. Once these moves had been described, the videos were watched again in their entirety to code each student's work according to these moves. These gave rise to patterns in the types of global games the students played. Next, each global move was analyzed to determine the specific local game each student played within each move. The local games were then compared and contrasted across students.

Results

In the following subsections we discuss the global games we observed and then present our findings on the local games played within each global move. We acknowledge here that slight differences occurred among some students, but the following is an attempt to synthesize the main patterns found in the data.

Global games

Six of the eight students played quite similar global games, with two variations (compare Figures 1a and 1b). The main difference seemed to be whether the students began setting up the integral before finding the bounds for the integral, or vice versa. Each move within these global games are explained in the following subsections as we examine each move more closely. Two students played different global games, that we do not portray in Figure 1. When solving shells problems, Gabi played the game in Figure 1a, but when solving disk/washer problems, she skipped the "visualizing slice" and "finding volume of slice" moves, since she seemed to have the related formulas memorized and could use them effectively. The other student, Bryan, rarely got past the visualzing volume move and had difficulty in making further progress.

(a)
(b)

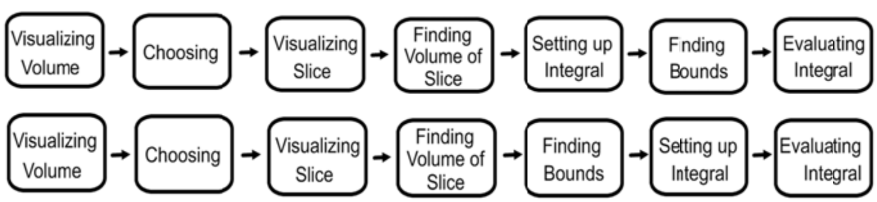

Figure 1. Global games played by (a) Claire, Frank, Gabi, John, Sarah, and (b) Doug, Trevor

Local games

While the majority of students had very similar global games, variations of students' problem solving strategies were more evident in the local games played within each move, especially as seen in the *choosing* game. In the following subsections, we explore each move in more detail.

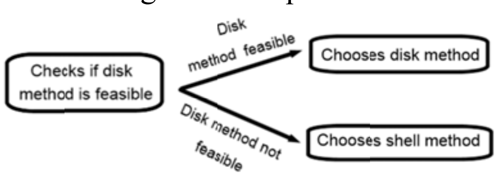
Visualizing volume

The visualizing move involved an attempt to visualize the three-dimensional object whose volume was being calculated. There seemed to be two types of visualizing local games played by the students. All of the students started this local game by visualizing the area that would be revolved around one of the axes. For most students, this involved determining the curves that bounded the region and shading the region between the curves. All but two students then proceeded to visualize the revolution of this region in some way. The majority of the students drew a reflection of the area on the other side of the axis of rotation and gave descriptions of what the solid would look like. It is interesting to note, however, that the two students (Frank and Trevor) made no attempt to visualize the region's actual revolution. These two students also had more difficulty in setting up the integral expressions than some of the other students. This suggests that visualizing the rotated solid may be a factor that influences students' ability to solve these types of problems.

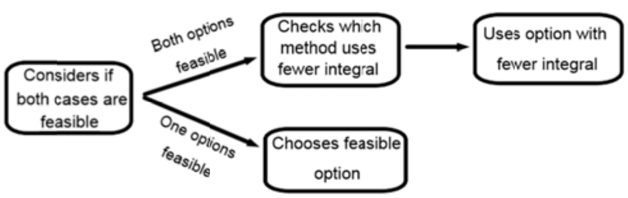
(a) 
(b) 
Figure 2. Visualizing game for (a) Bryan, Claire, Doug, Gabi, John, Sarah, and (b) Frank, Trevor

Choosing

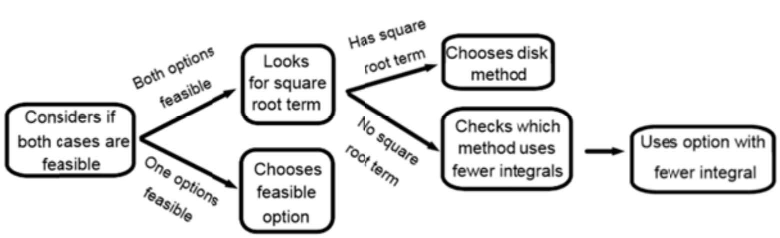
The greatest variety among the students occurred in the *choosing* move, which involved determining whether to use disks, washers, or shells methods. While many of the students shared similar reasonings for choosing to use one method or another, each student seemed to play their own unique local game during this move. The most common move in the choosing local game was checking the feasibility of the disk/washer or shell methods, or in other words checking whether the resulting integral could *not* be evaluated given the techniques available to the students. Six of the eight students made the move "check feasibility" during the choosing local game, with four of the students' making it their first move (see Figure 3). In fact, Trevor based his entire decision solely on whether the disk/washer method was feasible or not (see Figure 3a). Claire also started off checking feasibility, but if both methods were feasible she would also check the number of integrals each method used (i.e. whether the region had to be split up due to intersection points or other features). In Doug's game, if both methods were feasible, he would look check to see if there was a square root term, and if so, he said he would always choose disks/washers, since squaring the function would eliminate the square root. If there was not he would choose the method that requires the fewest integrals (see figure 3c). Sarah had the most complicated choosing game (see figure 3d). If both methods were feasible she would randomly choose a method and keep going with that method until she ran into a problem. Like Doug, the number of integrals and square root terms seemed to be important in her choosing local game.



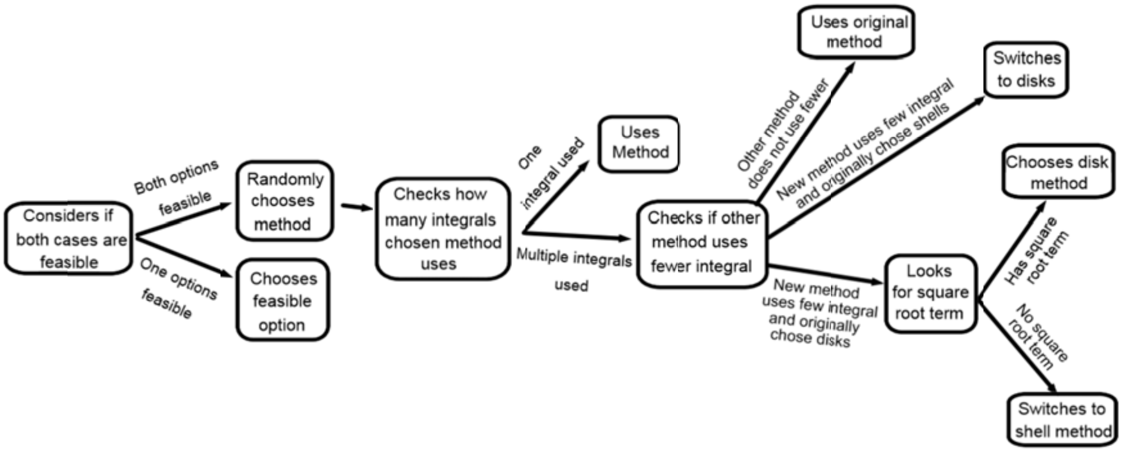
(a)



(b)

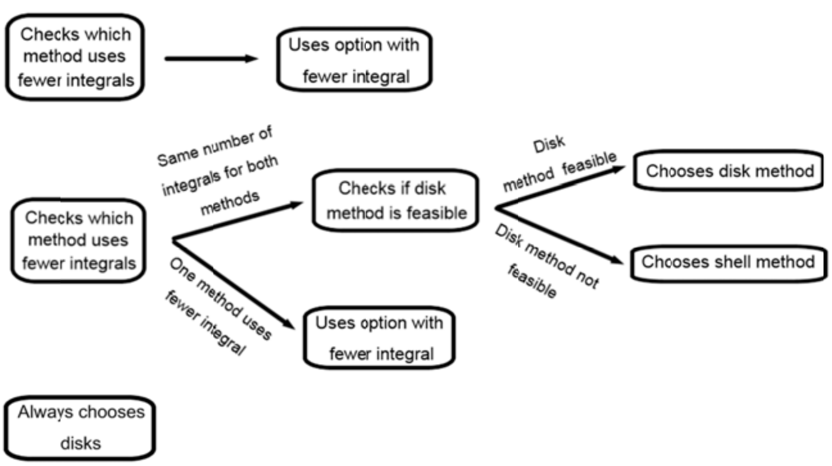


(c)



(d)
Figure 3. Choosing local game for (a) Trevor, (b) Claire, (c) Doug, and (d) Sarah

As mentioned in the previous paragraph, the number of integrals required (i.e. whether the region had to be split up) was a defining factor for many students in deciding whether to use the disk/washer or shell method. Five of the eight students made the move "check number of integrals," with two of them making it their first move within this local game (see Figure 4). In fact, determining "number of integrals" was the *only* move made by Gabi in this local game. If disks/washers or shells resulted in the same number of integrals, Frank would always default to the disk/washer method (see figure 4b), using the shell method only if the disk/washer method was not feasible. Another student who preferred disks/washers to shells was Bryan. In fact, when asked what method he would likely use in solving the problems, he indicated he would *always* choose disks or washers (see Figure 4c) because he was more comfortable working with them.



(a)
(b)
(c)
Figure 4. Choosing local game for (a) Gabi, (b) Frank, and (c) Bryan

John had a rather unique choosing local game (see Figure 5). His initial strategy depended mainly on whether the solid of revolution had a "hole" through the middle of it or not. If the solid did have a "hole" in the middle he would always try to use the shell method first. If not, then he would always try using the disk method first.

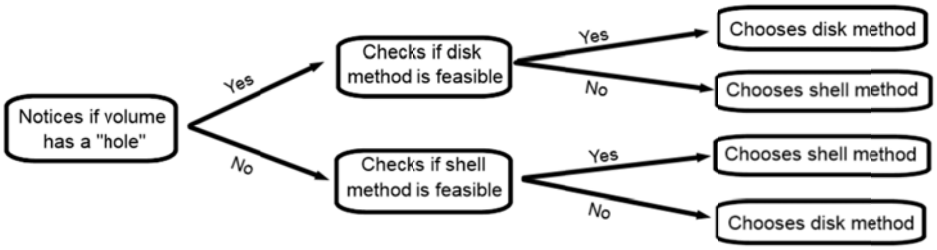


Figure 5. Choosing local game for John

Visualizing and finding the volume of one slice (disk/washer)

In the "finding the volume of one slice" game for disks/washers, which consisted of determining the integrand and differential to use for the integral, several students seemed to take the same general approach, though some students skipped some of the steps that others explicitly took. Sarah and Doug explicitly found all of the parameters needed for obtaining the volume of the disk, including the radius, the area of the disk's face, and the thickness/differential. They then put all this information together in a volume formula for one disk. Trevor also focused on finding different parameters involved in find the volume of the disk, but never explicitly attended to finding the thickness/differential of the disk, only adding the differential in later when he began to write the formula. Four of the students did not explicitly attempt to find any of the parameters, but would begin directly applying a memorized formula for the volume of disks or washer. These are summarized in Figure 6.

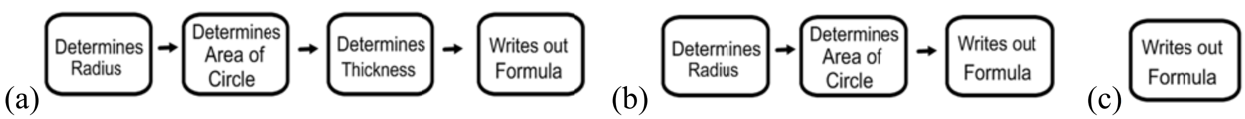

Figure 6. Finding volume of one slice local game for (a) Doug, Sarah, (b) Trevor, and (c) Claire, Frank, Gabi, John

Visualizing and finding the volume of one slice (shells)

The students all followed essentially the same basic local game when determining the integrand and differential for the shell method (see Figure 7). They would draw a generic shell and then draw a rectangular prism that represented a shell being cut and flattened, as had been shown in class during the conceptual development of the shell method. Students would then find the radius, circumference, height, and thickness/differential (although the ordering of these differed from student to student) and put these together to write down the integrand and differential. The fact that students always seemed to explicitly find the different parameters associated with shells, while being able to skip steps or use the formulas for disks, leads us to conclude that students were generally more familiar or comfortable with the disk method.

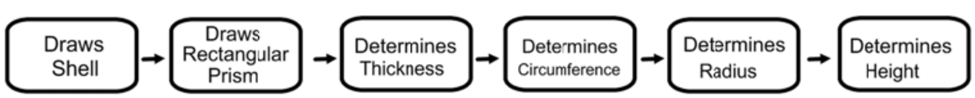

Figure 7. Finding volume of one shell local game played by most students

Setting up the integral and finding bounds

The setting up the integral and the finding bounds local games, which we discuss together due to space limitations, consisted of writing out the actual integral expression for the volume of revolution problem, with some moderate variation existing in how the students played this local game (see Figure 8). Four students first found all the information they needed to set up the integrand, began to write the integral expression, and then would return to the problem to find limits of integration. Sarah, however, began setting up an integral *before* determining any of the parameters she would needed and would then fill in the integral exprsesion as she found more information. Doug and Trevor on the other hand waited until *all* necessary information had been found before they began working on writing out the integral expression.

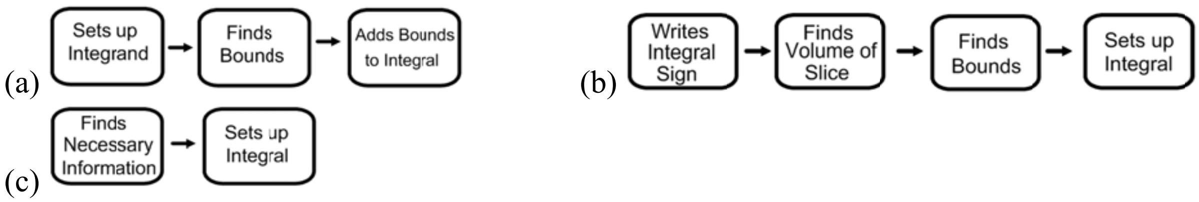

Figure 8. Setting up the integral local game played by (a) Claire, Gabi, Frank, John, (b) Sarah, and (c) Doug, Trevor

Discussion

In this study, we have analyzed and mapped out different epistemic games that students played in the volumes of revolution problems. We identified both global games for the entire problem solving process, as well as the local games that made up the individual moves of the global games. In this way, we have attended to both the larger-grained and smaller-grained strategies enacted by the students in this study as they solved volumes of revolution problems. The most striking outcome of this analysis is how it complexifies, to us, the nature of solving volumes of revolution problems. What could easily be viewed as a problem solving context with only six particular outcomes (one each for associating the disk, washer, and shell methods to a choice of *dx* versus *dy* integration), has been shown to have a much richer variety. The students in this study employed a range of moves to create the desired epistemic form of a completed integral expression. Especially in the *choosing* local game, we were surprised by the amount of diversity and complexity in how the students made moves toward the epistemic form.

Interestingly, however, this range did not seem to occur at the global level, though we acknowledge that this may be due to the common classroom experience for the eight students. Our study found that six of the the students played global games with essentially the same moves and with essentially the same move ordering. The only real difference was whether students would find all necessary information to set up the integral first, or whether they would begin to set up the integral and then go back to the problem to find missing information. We note that this type of overall global game resembles the *pictoral anaylsis* epistemic game described by Tuminaro and Reddish (2007) in physics problem solving contexts. As such, it is possible that learning to solve volumes of revolution problems could have potential effects on some aspects of students' physics problem solving.

We also conclude that solving volumes of revolution problems may be at the right level of complexity according to the problem solving literature, which suggests that contexts that are neither too broad nor too narrow may provide the best setting for developing problem solving strategies (Lesh & Zawojewski, 2007). The volumes of revolution problem context was clearly shown in this paper to be anything but trivial, but is also confined to a more narrow domain, so that strategies *can be* (and were!) developed by students. No student had a memorized template for all volume problems, meaning that they all engaged in problem solving at some level.

In regards to being able to solve volumes of revolution problems specifically, our data suggests that some moves may be especially useful, including visualizing the volumes of revolution, being equally comfortable with all available methods, checking to see which methods are feasible, determining which method uses fewer integrals, and examining which methods involve simpler algebra. Consequently it may be useful for calculus instructors to spend time developing some of these local games. For instance, an instructor may wish to have their students draw out solids of revolution so that they can become comfortable visualizing the desired object, or to have students examine the number of integrals required to work out a problem with respect to *dx* versus *dy*. While this list certainly does not contain all useful strategies in solving volumes of revolution problems, we believe that understanding which moves are useful can help students develop flexible problem solving strategies regarding volumes of revolution.

Equity in Developmental Mathematics Students' Achievement at a Large Midwestern University

Kenneth Bradfield
Michigan State University

With so many students entering college underprepared for the mainstream sequence of mathematics courses, mathematics departments continue to offer developmental or remedial courses with innovative methods of delivery. In order to support students in their college education, researchers continue to investigate the effectiveness of undergraduate remediation programs with mixed results. This paper provides quantitative data from an NSF-funded project from a large Midwestern university over three years of a developmental mathematics course. Pre- and post-measures show that both urban and African-American students benefited the most from supplemental instruction in contrast to the online-only format. Based on these results, I offer recommendations for undergraduate mathematics departments to support equitable opportunities for marginalized students ensuring a successful developmental mathematics program.

Keywords: Developmental mathematics; Equity and diversity

Mathematics departments across the country offer developmental courses or remediation to support the entering students they deem unprepared to meet the entry standards of their introductory courses. Researchers estimate more than a third of all incoming freshman sign up for a developmental course upon entering college often resulting in an over-abundance of students enrolling in developmental courses (Bettinger et al., 2013; Scott-Clayton, Crosta, & Belfield, 2014). With the cost of these programs nationwide for institutions of higher learning in the billions of dollars (Bettinger, Boatman, & Long, 2013), mathematics departments search for innovative solutions to ensure they can afford to support the education of as many students as possible.

The variety of delivery methods that mathematics departments use to provide content and instruction often lack in research-based teaching methods or resources creating an inequitable environment in terms of educational opportunity in developmental programs. TAs or faculty with little to no training in teaching strategies typically instruct these courses coupled with the over-representation of minorities in developmental courses can potentially cause students more harm in the first years of college (Attewell et al., 2006; Larnell, 2013). Designed as gateways to future mathematical success for all students, Bonham and Boylan (2011) acknowledged that "developmental mathematics as a barrier to educational opportunity represents a serious concern for the students as well as higher education policy makers" (p.2).

Considering these concerns, our NSF project[1] team reviewed three years of quantitative data collected from the developmental mathematics program at a large Midwestern university to compare the effects of various instructional methods between groups of students with similar backgrounds. Results in this paper compare how urban, low-income, and African-American students (who made up approximately one-eighth of the entire population of students enrolled in the online math course over the three year period) faired in an online-based tutoring program

[1] This project was supported, in part, by the National Science Foundation awarded to Kristen Bieda (PI), Beth Herbel-Eisenmann, Raven McCrory, and Pavel Sikorskii (Co-PIs) under the grant DUE-1245402.

with or without additional face-to-face instruction faired compared to each other. The success of the urban and African-American students with additional face-to-face instruction compared to their peers provides a window into how researchers can evaluate and mathematics departments make changes to their developmental program to ensure more equitable opportunities for all students. I will first provide some background literature to further situate this study.

Literature Review

Current issues surrounding developmental mathematics consist of how mathematics departments select students and deliver content to ensure students' successful completion of their degree requirements and how researchers evaluate the effectiveness of programs providing reliability and generalizeability. Scott-Clayton, Crosta, and Belfield (2014) found that placement methods, typically involving the use of an exam, fail to correctly identify the students who need remediation. Other community college programs have experimented with incorporating high school transcript data (Jackson & Kurlaender, 2013); however, Bettinger et al. (2013) acknowledged that tests and high school performance still ignore the unseen qualities of students that influence their success in their first year of college, e.g. study habits and perseverance. Researchers continue to search for the right combination of indicators for placement and eventual success in developmental mathematics course (Scott-Clayton et al., 2014).

Mathematics departments are often limited by their resources and materials to offer their students research-based mathematics resources and instruction. Bonham and Boylan (2011) argued that successful programs incorporate technology and innovative materials for the classroom, extracurricular resources for students, and professional development for instructors. Since not all institutions can provide these opportunities for their students, innovative solutions arise that include online resources or tutoring programs paid by student tuition money. Researchers continue to search for opportunities for mathematics departments to provide resources and instruction to support the students who need them most.

In addition to the selection of students and the delivery methods, scholars have discussed methods to evaluate developmental mathematics programs to ensure reliability and provide higher education policy makers justification to enact institutional changes. Bettinger et al. (2013) noted that the amount of variation due to geography, student backgrounds, and other factors that currently go unseen that cannot be measured quantitatively or provided on a high school transcript and called on more studies to explore this variability. In providing data from particular geographic areas and groups of students, researchers can begin to explore similarities and differences to facilitate discussion around a complex solution to the complex problem of inequitable opportunities in developmental mathematics education.

Considering these discussions, the NSF-funded project investigated quantitative data from a census of all students in three years of the developmental mathematics course at a large Midwestern university to answer the following question:

- What effects does a supplementary face-to-face instruction in a developmental mathematics course have on different subpopulations of students' performance and future participation in mathematics?

Methods

I present quantitative data over three years of an NSF-funded project comparing the various methods of delivery of a developmental mathematics course at a large Midwestern university. Approximately 800 students each year enrolled in the online version of the developmental mathematics course, as determined predominately by placement exam score. The program ALEKS is the curriculum for the online course. Freshman identified by advisors as at-risk for failing first-year courses enroll in groups of around 15-20 students in a supplementary face-to-face section that meets twice a week with each class lasting two hours. Each class is taught by mathematics graduate students with the exception of one section taught by senior pre-service mathematics teachers as part of an NSF-funded project in concert with the teacher education department. While the sections led by mathematics graduate instructors engaged in material directly supporting the students' work on the ALEKS program, the seminal section with pre-service mathematics teachers engaged in a curriculum and instructional methods grounded in mathematics education research.

The project investigated the effect of taking any of the supplementary face-to-face sections on students' success in the online developmental course and on their performance in subsequent math courses. In this paper, I present comparisons of the percent difference between the means of quantitative pre-measures (ACT mathematics score, university placement exam, ALEKS pre-score) and post-measures (ALEKS post-score, final exam, final grade) to determine differences in outcomes between African-American, urban, and low-income[2] students who enrolled in the online-only version of the course and those who enrolled in the supplementary face-to-face sections. These particular students were selected based on the large percentage of students self-reported as African American and low-income hailing from the large urban area nearest to the university (75% and 90% respectively) and the teacher education department's interest in potential future summer enrichment programs for students from this area. I also provide similar comparisons between the enrollment and grades in the pursuant credit-bearing mathematics course for the students in the first year of the data set.

Results

The data for each of the three years demonstrates that African-American, urban, and low-income students who took the supplementary face-to-face course made significant gains in the online course compared to their peers who were not enrolled in the face-to-face enrichment course.

Table 1 includes the percent difference between the face-to-face and online only students within the subpopulations of students from the large urban area, low income, and African-American separately. Overall the data demonstrates that the face-to-face students started slightly behind and finished significantly ahead in both the urban and African-American groups and started significantly behind and finished slightly ahead in the low-income group. Considering this data also represents census data for a university over three years, this data shows the supplementary face-to-face instruction associates with a significant gain in post-measures across each of these subpopulations.

[2] Ethnicity was self-reported while the urban and low-income information was provided by researchers' map of the state near the urban area in question in conjunction with income information by zip code provided by the University of Michigan's Institute for Social Research: http://home.isr.umich.edu/.

Table 2 Percent Enrolling and Passing Next Math Course in 2012

		N	N enroll	% Enroll	N pass	% Pass
Urban	Face to face	47	35	***74.5%*****	18	***38.3%****
	Online	55	26	47.2%	14	25.5%
Low income	Face to face	75	52	***69.3%*****	26	34.7%
	Online	122	69	56.6%	41	33.6%
African American	Face to face	84	64	***76.2%*****	31	***36.9%*****
	Online	113	63	55.8%	29	25.7%
All students	Face to face	171	130	***76.0%*****	68	39.8%
	Online	619	394	63.7%	221	35.7%

Note: $* p < 0.05$, $** p < 0.01$

Table 2 shows the percent of students who enrolled and passed the proceeding mathematics course offered by the mathematics department within each of the subpopulations. Overall the data demonstrates that a significantly higher percentage of students enrolled in the next math course across not only all subpopulations but also the entire population of students. In addition, significantly higher percentage of students in the urban and African American subpopulations passed the course (receiving GPA>2.0).

A common theme of both of these tables indicates that the supplementary face-to-face section benefits not only students' performance in the online course for these subpopulations, but also potentially contributes to success in the next math course.

Discussion and Future Directions

These results provide an example of Bettinger et al.'s (2013) call for researchers to compare groups of students with similar backgrounds demonstrating how characteristics through information provided by the registrar can provide an avenue for a positive change in providing students opportunities in developmental programs. Factors to consider for determining students placement that include test scores and high school transcript information (Jackson & Kurlaender, 2013) can potentially include demographic information as well.

Providing students with face-to-face instruction increased the performance of the urban and African-American subgroups in this student population. Universities that offer online-based opportunities could experience strong gains in performance by providing supplementary face-to-face instruction sections to underprivileged students. This is not to say that engaging students in these opportunities is a panacea as students come from diverse backgrounds with a variety of different ways of learning and knowing. Even with the variety of student backgrounds, the data demonstrates sub-populations of student based on demographics that benefited the most from the resources offered by their institution. Although providing students with these sections could improve gains in performance, other mathematics departments should tread carefully and provide instruction that improves students' mathematical proficiency and not knowledge of correct procedures alone (Larnell, 2013; Kilpatrick, Swafford, & Findell, 2001).

As "success" in a mathematics course goes beyond just performance on course exam, future studies could dig deeper into how the students experienced the developmental mathematics program as well as track students' success longitudinally. Although the selection of students attending this institution was not a random sample of the nation, the scale of this case provides a window into a single university over three years to anticipate similar results for other large, public universities. Other mathematics departments could then take their own nuanced steps based on their results to ensure more equitable opportunities for their students' education and ameliorate the inequities in the first year of undergraduate mathematics. Further questions continue to remain to continue the goal of spurring the growth of developmental mathematics programs across the country to meet the needs of all students entering their respective universities:

- What makes face-to-face supplemental courses more successful for students than online-only courses?
- Which universities have similar demographics as the one referenced in this report?
- How can we motivate mathematics departments to make changes supported by evidence to invest in students' developmental mathematics programs?

Exploring student understanding of the negative sign in introductory physics contexts

Suzanne White Brahmia, Rutgers University
Andrew Boudreaux, Western Washington University

Recent studies in physics education research demonstrate that although physics students are generally successful executing mathematical procedures, they struggle with the use of mathematical concepts for sense making. In this poster we investigate student reasoning about negative numbers in contexts commonly encountered in calculus-based introductory physics. We describe a large-scale study (N > 900) involving two introductory physics courses: calculus-based mechanics and calculus-based electricity and magnetism (E&M). We present data from six assessment items (3 in mechanics and 3 in E&M) that probe student understanding of negative numbers in physics contexts. Our results reveal that even mathematically well-prepared students struggle with the way that we symbolize in physics, and that the varied uses of the negative sign in physics can present an obstacle to understanding that persists throughout the introductory sequence.

Introduction

Signed numbers carry rich information about physics contexts. A confounding feature in physics is that the operations of addition and subtraction (represented by the symbols "+" and "–") can easily be confused with the descriptors, positive and negative, that can characterize the opposite natures of some physical quantities (position, charge, velocity, etc.)

Developing flexibility with negative numbers is a known challenge in math education. Vlassis[(1)] used written diagnostic questions and interviews to investigate the understanding of negative numbers by Belgian students taking algebra. She found that in order to fully understand the concept of a negative number, students had to develop a flexibility with the various ways in which negative numbers are used in context. The most challenging context is common to physics – quantifying opposites.

Sherin[(2)] refers to quantifying opposites in physics as the symbolic form "competing terms cluster," which includes the notion of zero to represent balance, and positive and negative quantities as competing terms in an expression. This cluster is built on a stable set of coordinated resources that includes a conceptual understanding of signed numbers and zero. He observes that flexibility with this symbolic form is a feature of expert problem solving in introductory physics.

Bajracharya, Wemyss, and Thompson[(3)] investigated student understanding of integration in the context of *P-V* diagrams in introductory physics. Their results suggest an incomplete understanding of the criteria that determine the sign of a definite integral. Students struggle with the concept of a negative area, and with the concept of positive and negative directions of integration. Even for students in calculus-based physics, negative quantities pose challenges.

Experimental Design

We administered a set of three questions at the end of the fall 2015 semester in the calculus-based introductory courses in Mechanics, and in E&M; a portion of each class was given a MC version of the questions while the rest were given an open ended version and asked to explain their reasoning. Each set probes the use of a signed quantity: 1) to represent a component of a vector quantity in 1-D, 2) to quantify opposites, and 3) to represent a difference of a position dependent quantity measured at two different locations (see Fig. 1).

Discussion

Our results show that engineering students really struggle to make sense of the physics use of the negative sign in almost every context except the one that is familiar from math class.

Surprisingly after a semester of calculus-based physics, one-third of the engineering students fail to recognize the context in which they learned about negative numbers - the position on a number line (see Fig 1, Mech 3)

Figure 1: Assessment items, "Mech" was administered in the Mechanics course and "EM" was administered in the E&M course.

Mech 1: An object moves along the x-axis, and the acceleration is measured to be $a_x = -8$ m/s^2. Consider the following statements about the "–" sign in "$a_x = -8$ m/s^2". Pick the statement that best describes the information this negative sign conveys about the situation.

a. The object moves in the negative direction
b. The object is slowing down
c. The object accelerates in the $-x$-direction
d. Both a and b
e. Both b and c

Mech 2: A hand exerts a force on a block as the block moves along a frictionless, horizontal surface. For a particular interval of the motion, the hand does W = – 2.7 J of work.
Consider the following statements about the "–" sign in the statement W = –2.7 J. The negative sign means:

I. the work done by the hand is in the negative direction
II. the force exerted by the hand is in the negative direction
III. the work done by the hand decreases the mechanical energy associated with the block

Which statements are true?

a. I only
b. II only
c. III only
d. I and II only
e. II and III only

Mech 3: A cart is moving along the x-axis. At a specific instant of time the cart is at a position x = –7 m. Consider the following statements about the "–" sign in "x = –7 m". Pick the statement that best describes the information this negative sign conveys about the situation.

a. The cart moves in the negative direction
b. The cart is to the negative direction from the origin
c. The cart is slowing down
d. Both a and b
e. Both a and c

EM 1: At a location along the x-axis, the electric field is measured to be $E_x = -10$ N/C. Consider the following statements about the "–" sign in "$E_x = -10$ N/C". Pick the statement that best describes the information this negative sign conveys about the situation.

a. The test charge is negative
b. The field is being created by negative charge
c. The field points in the $-x$-direction
d. Both a and b
e. Both b and c

EM 2: Valeria combs her hair in the winter and there is a transfer of charge such that $DQ_{comb} = -5$ mC. Consider the following statements about the "–" sign in the mathematical statement $DQ_{comb} = -5$ mC. The negative sign means:
I. negative charge was added to the comb. II. charge was taken away from the comb.
III. all of the electric charge in the comb is negative
Which statements could be true?

a. I only
b. II only
c. III only
d. I and III only
e. II and III only

EM 2: In physics lab, a student uses a voltmeter to measure the voltage across the terminals of a battery. The voltmeter reads –5V.
Consider the following statements about the "–" sign in the voltmeter reading "– 5V". Pick the statement that best describes the information this negative sign conveys about the situation.

a. the voltage is in the opposite direction as the current
b. there are 5V of negative charge in the battery
c. the voltage is in the negative direction
d. the voltage at one terminal is 5V less than the voltage at the other terminal
e. this battery has negative voltage

Table 1: Response rates, Mechanics(n=310) and E&M (n=402). Correct response rate is in bold type

Choice	*Mech 1*	*Mech 2*	*Mech 3*		*EM 1*	*EM 2*	*EM 3*
a	8%	17%	6%		16%	**33%**	32%
b	26%	17%	**67%**		21%	28%	14%
c	**26%**	**23%**	6%		**36%**	18%	18%
d	6%	29%	19%		12%	15%	**33%**
e	34%	14%	2%		14%	5%	3%

Mary, Mary, is not quite so contrary: Unless she's wearing Hilbert's shoes

Researchers (Leron, 1985; Harel & Sowder, 1998) have argued that students' lack a preference for indirect proofs and have argued that the lack of preference is due to a preference for constructive arguments. Recent empirical research (author, 2015), however, which employed a comparative selection task involving a direct proof and an indirect proof of the contraposition form, found no evidence of a lack of preference for indirect proof. Recognizing that indirect proofs of the contradiction form may differ from those that employ the contraposition, this study documents students' proof preferences and selection rationales when engaging in a comparative selection task involving a direct proof and an indirect proof of the contradiction form.

Key words: Indirect proof, Proof preferences, Proof by contradiction

It has been argued by many that indirect proofs, that is, proof by contraposition and proof by contradiction, are particularly difficult for students (Tall, 1979; Robert & Schwarzenberger, 1991) and that students' difficulties are related to a lack of preference for these forms of proof (Leron, 1985; Harel & Sowder, 1998). Several reasons for students' difficulties and lack of preference have been proposed. Tall (1979) conducted an empirical study of 37 students' levels of confusion in relation to proofs by contradiction of the irrationality of the $\sqrt{2}$ using an instrument that included the standard proof and two alternative proofs. He found that students experienced significantly lower levels of confusion with one of the alternative forms; namely, that which employed generic structures (i.e., proof structures that were not specific to the numbers used). Tall argued that use of generic proofs will aid students' understanding of indirect proofs. In a reflective account of multiple teaching experiments, Leron (1985) noted that not only are students perplexed by proofs by contradiction but that such proofs stand in contrast to much of students' mathematical activity, for they call on students to not only build up a "false world" but to destroy this world. Hence, according to Leron, students' difficulties are related to the coupling of non-constructive reasoning and a detachment from one's "real" mathematical world. Using the standard proof of the infinitude of primes, Leron reported that constructive approaches, which explore and analyze mathematical objects in their own right prior to their use as tools for obtaining contradictions, may enhance students' understanding of proofs by contradiction. Harel and Sowder (1998) have also argued that students are not convinced by proof by contradiction and lack a preference for this form of proof. Drawing of data from 6 teaching experiments they argue that students' dislike of indirect proofs represents a particular manifestation of the constructive proof scheme: a scheme in which "students' doubts are removed by actual construction of objects – as opposed to mere justification of the existence of objects" (p. 272). Lastly, Antonini and Mariotti (2008) studied students' views and production of indirect proofs. Drawing on the theory of *Cognitive Unity* and a specific characterization of *Mathematical Theorems* (Mariotti, Bartolini Bussi, Boero, Ferri & Garuti 1997), this research has sought to explore: (a) linkages between students' informal, indirect geometric arguments in technological environments and their production of proofs by contradiction; and, (b) the nature of students' difficulties with indirect proofs. Specifically, within their work a distinction is made between mathematical theories (e.g., Euclidean geometry; Riemannian geometry; Number theory) and metatheories (e.g., Standard logic, Constructive logic). Drawing on interviews with university students, Antonini and Mariotti demonstrated that students' difficulties with indirect proof may be tied to students' lack of acceptance of metatheorical properties (e.g., $P \rightarrow Q \equiv \sim Q \rightarrow \sim P$). For instance, when presented with a proof by contraposition of the statement, "If n^2 is even then n is even," students readily accepted the contrapositive proof as a proof of the statement, "If n is odd then n^2 is odd" but struggled to accept the proof as a proof of the original statement. Speaking to this issue, a student remarked, "… The problem is that in this way we proved that n is odd implies n^2 is odd, and I accept this; but I do not feel satisfied with the other one" (p. 407). Antonini and Mariotti's work is novel, for their work is the only research that proposes students' lack of acceptance of indirect proofs may be due to metatheoretical issues.

Four aspects of research on students' difficulties and lack of preference for indirect proof are noteworthy. First, research on students' difficulties with indirect proof is unique in that it is the only area of research within the broad spectrum of research on students' difficulties with proof in which researchers have linked students' difficulties to a lack of preference for that form of proof. Second, while researchers (Tall, 1979, Healy & Hoyles 2000, Knuth, 2002) have routinely engaged students in comparative selection tasks to determine which form of proof students' find most convincing, researchers have not examined students' preferences (or lack of preference) for indirect proofs using comparative selection tasks involving a direct and an indirect proof. Indeed, there is a scarcity of empirical evidence to support current claims regarding students' lack of preference. Third, while Antonini and Mariotti (2008) have provided evidence of students' lack of acceptance of metatheoretical statements there is the question of whether it is a lack of acceptance or a lack of recognition of these statements that is prevalent and at the root of students' difficulties. Fourth, current accounts of students' dislike of indirect proofs and preference for constructive and generic proofs have ignored the fact that these reactions may be the result of the mathematics community's practices related to introducing novices to indirect proofs and the discourse that occurs around such proofs. For instance, in *How to Solve It*, a famous problem solving text by Polya (1957), the section on *reductio ad absurdum* and indirect proof[1] concludes with a section titled "Objections," in which Polya states:

> We should be familiar both with 'reductio ad absurdum' and with indirect proof. When, however, we have succeeded in deriving a result by either of these methods, we should not fail to look back at the solution and ask: Can you derive the result differently (p. 169).

Arguably, Polya's remarks do not provide the reader with a strong endorsement of either method. Moreover, such sentiments are not difficult to obtain as illustrated by the textbook excerpts shown in Figure 1.

[Concluding remarks, section on proof by contradiction] Many mathematicians feel that if a result can be verified by a direct proof, then this is the proof technique that should be used, as it is normally easier to understand. Text: *Mathematical Proofs: A Transition to Advanced Mathematics* (Chartrand et al., pg. 132)
A proof by contradiction is often easier, since more is assumed true; you are able to assume both the hypothesis and the negation of the conclusion. On the other hand, a proof by contradiction is likely to be less elegant than a proof by contrapositive. In any case, for elegance and clarity, it is better to choose a direct proof over an indirect proof whenever possible. Text: *Introduction to Advanced Mathematics* (Barnier & Feldman, 2000, p. 43).
There are times when it is not easy to see how to prove a mathematical statement, say ψ. When this happens one should try the strategy called proof by contradiction. This strategy is perhaps the strangest method of proof. Text: *A Logical Introduction to Proof* (Cunningham, 2012, p. 93).

Figure 1. Proof by Contradiction Text Excerpts

[1] Polya refers to proof by contraposition as indirect proof and proof by contradiction by its Latin name, *reductio ad absurdum*.

[2] Hardy referred to reductio ad absurdum (proof by contradiction) as a mathematician's "finest

These excerpts are not meant as backing for the claim that the mathematics community as a whole has exhibited a lack of preference. Indeed, the writings of Hardy (1940/2005), Euclid, Archimedes, and many contemporary mathematicians, as well as the famous proofs by contradiction of Hilbert (*cf*. Hilbert, 1890), stand in contrast to the remarks shown above.[2] Instead, the excerpts illustrate how a lack of preference might be due to various enculturative acts rather than an attribute of students. Yet, much of the research on indirect proof has ignored students' rationales for either preferring or exhibiting a lack of preference for such proofs. To be certain, there is a need for research that not only documents students' comparative preferences but also students' selection rationales; that is, their reasons for choosing a particular proof form.

In (author, 2015), a study was reported in which 53 mathematics majors were surveyed using a comparative selection task (see Figure 2) involving a direct and a (contraposition-form) indirect proof of the following theorem: *Suppose a set A has the property, for any subset B, A* $\subseteq$ *B, then A* = $\varnothing$*.* The proofs were presented side-by-side and students were asked, "Which proof, in your opinion, is the most convincing? In other words, which proof better persuades you of the truth of the theorem" and "Please explain your selection." The two proofs in the selection task were designed so as to control for various proof features; namely, the proofs were similar in length, and designed with the intent to be equal in their level of familiarity and complexity. For instance, complexity was equated by the prevalence of the proofs' content in the same textbook chapters in multiple texts. These controls were employed because pilot work had shown that when either complexity or familiarity were not equated, each were individually predictive of students' selections regardless of the proof type (i.e., direct or indirect).

Theorem 3: Suppose a set A has the property, for any subset B, A $\subseteq$ B. Then, A = $\varnothing$.	
Proof A:	**Proof B:**
Suppose A $\neq \varnothing$. Then there exists an *a*, such that $a \in$ A. Hence, A$\not\subseteq \varnothing$. Thus, there exists a subset B for which A$\not\subseteq$ B.	Assume A has the stated property. Recall, that $\varnothing$ is a subset of every set. Thus, $\varnothing \subseteq$ A. By the given property, A $\subseteq \varnothing$. Thus, A = $\varnothing$.

Figure 2. Comparative Selection Task

Surprisingly, the survey results indicated that the *indirect:direct* selection ratio for the Theorem 3 proof comparative selection task was 27:26. Thus, no evidence of a lack of preference was found. This finding lies in contrast to the findings of prior research and raises several questions: (1) to what extent is a lack of preference prevalent; and, (2) if prevalent, what are the characteristics of contexts in which a lack of preference is manifested? Furthermore, analyses of the students' selection rationales demonstrated that students' primary rationales were *certainty* and *complexity*. *Certainty* refers to the degree to which a student is certain of his/her understanding of the given proof and *complexity* refers to students' identification of one proof as being more complex than the other. What is of particular interest is that students' rationales did not identify a "more complex" proof nor were students more certain of one proof than the other. Instead students' responses demonstrated that complexity and certainty were subjective; that is,

[2] Hardy referred to reductio ad absurdum (proof by contradiction) as a mathematician's "finest weapon."

dependent on the individual and his or her understanding of the content employed. Drawing on Balacheff's cK¢ theory, (author) argued that preferences are mediated by students' conceptions.

While providing grounds for questioning the extent to which a lack of preference is prevalent among undergraduate students, reasons to continue investigating students' preferences remain. To begin, proof by contradiction and proof by contraposition differ at the metatheoretical level, with contraposition proofs requiring a direct proof of the contrapositive statement and use of the logical equivalence, $(P \rightarrow Q) \equiv (\sim Q \rightarrow \sim P)$, while proofs by contradiction require learners to not only negate a conditional statement (which is arguably more difficult than negating a premise and a conclusion separately) but also to produce an unspecified contradiction and to correctly interpret the ramifications of that contradiction (e.g, as the negation of a negated statement rather than as an error). In the previous study, the Theorem 3 selection task engaged students in a *direct:indirect* proof selection involving a *direct proof:proof by contraposition* comparison. Hence, there is reason to question if the lack of definitive preference, as evidenced by the students' selection ratio, is predictive of students' preferences in comparisons involving a proof by contradiction; especially, given the differences cited above. With this said, there are cultures in which the two forms of proof (contraposition and contradiction) are not distinguished at a nominal level, *e.g.*, in Italian (*cf.* Antonini & Mariotti, 2008). Moreover, pilot data showed students' may categorize a proof by contraposition as a proof by contradiction. Consequently, it may be that students' lack of definitive preference when engaging in *direct proof:proofs by contraposition* comparisons is predictive of students' preferences during *direct proof:proof by contradiction* comparisons. Certainly, more research is needed. The aim of this study is to address this need by pursuing the following research questions:

1. Do undergraduate mathematics students exhibit a lack of preference for indirect proof, when engaging in comparative tasks involving both a direct proof and proof by contradiction?
2. Which rationales do students provide for their selection of the most convincing proof, when engaging in comparative tasks involving both a direct proof and proof by contradiction?

The Study

The research reported in this paper is part of a larger research program generally focused on undergraduate mathematics students': (a) development of hypothetico-deductive reasoning (Piaget, 1968/1964); and (b) emerging *conceptions* of indirect proof, where conception is used in the sense of Balacheff's cK¢ model (2010; 2013). To investigate students' preferences, as these relate to selecting the most convincing proof, 85 mathematics students were recruited and given a paper survey containing Theorem 3 and two proofs of the statement, which were a direct and an indirect proof of the contradiction form (see Figure 3). The form was similar to that used in the previous study, with two exceptions; namely, the indirect proof form and a slight adjustment to the wording of the direct proof so as to produce proofs with equated lengths, (as determined by word counts of 40 and 41 words). As was the case in the prior study, complexity and familiarity were viewed as equated due to the content occurring in the same chapter in multiple introduction to proof texts.

The surveys were administered in either an abstract algebra or analysis course. Students completed the surveys under the supervision of the researcher and returned the surveys directly to the researcher. Proof order was randomized to avoid a priming effect. Analyses of the data involved the determination of selection ratios and the coding of students' rationales using a constant comparative methodology (Creswell, 1994). Multiple codes were employed when multiple rationales were provided by the students.

Theorem 3: Suppose a set A has the property, for any subset B, $A \subseteq B$. Then, $A = \varnothing$.	
Proof A	Proof B
Assume A has the stated property. Recall, that $\varnothing$ is a subset of every set. Thus, $\varnothing \subseteq A$. By the given property, since $\varnothing$ is a subset of A, $A \subseteq \varnothing$. It follows from that, $A = \varnothing$.	Assume A has the stated property and $A \neq \varnothing$. If $A \neq \varnothing$ then $A \not\subseteq \varnothing$. By the given property, $A \subseteq \varnothing$. Since, it cannot happen that $A \not\subseteq \varnothing$. and $A \subseteq \varnothing$, it follows that, $A = \varnothing$.

Figure 3. Theorem 3 Contradiction-Form Comparative Selection Task

Results

Data from the Theorem 3 comparative selection task indicate that students found the direct proof more convincing than the proof by contradiction with a *direct:indirect* selection ratio of 56:29. Thus, the students' preferences differ considerably from those observed in the *direct:indirect* comparative tasks involving a proof by contraposition (*direct:indirect* selection ratio of 26:27). Analyses of students' selection rationales also indicate differences in students' comparative assessments. Specifically, while the vast majority of students' rationales focused on *certainty* and *complexity* when engaging in the contraposition comparison, the selection rationales for the contradiction comparison were more varied. Indeed, six rationales were present in students' written remarks, which are reported with students' selection ratios in Table 1.

Selection Rationale	Selection Ratio (Contra-d: Direct)	*n*	Percent of Students
Simplicity / Ease	7:21	28	32.9%
Error (in Alternative)	4:14	18	21.2%
Directness / Straightforward	4:23	20	31.8%
Matched My Thinking	9:8	17	20.0%
Familiarity	1:12	15	15.3%
Stronger Argument	6:4	12	11.8%

Table 1. Students' Selection Rationales

Due to space limitations, examples of students' rationales will be restricted to: *simplicity*, *error*, and *matched my thinking*. Though *directness* was common, it is not included as it is self-evident in meaning. Below (Figure 4) are two examples of students' rationales coded as *simplicity*.

[Example 1.] The second is a proof by contradiction. I tend to find these proofs easier to follow. Proof A is not hard to follow as well but I think, in general, proof by contradiction is easier. (Selection: Indirect)
[Example 2.] Proof A is simpler. Proof B forces the reader to think about it more deeply. (Selection: Direct)

Figure 4. Simplicity Rationales

As can be seen by these remarks, students viewed both proofs as simple. However, as indicated by the *direct:indirect* selection ratio of 21:7, the simplicity rationale was more prevalent among students who selected the direct proof. The code *error* was used to denote student rationales that indicated a proof contained an error or that there was a statement that the student was uncertain about. Below (Figure 5.) are two examples of student rationales coded as *error*.

[Example 3.] Proof A stated the property that we need to prove and we cannot do that. (Selection: Direct)
[Example 4.] Proof A states that condition as an assumption which immediately made me question the validity of the proof. Proof B follows a standard version of a proof and make more sense than A. (Selection: Direct)

Figure 5.

As indicated by these students' rationales, there was a tendency among some students to view the contradiction argument as flawed. Indeed, the data indicate that 14 students (16.5%) selected the direct proof and provided this rationale. This finding suggests that rather than lacking a preference for indirect proof, students may have difficulty comprehending and/or validating indirect proofs of the contradiction-form.

The code *matched my thinking* was used for rationales that focused on students' statements of an alignment between their own approaches to proving and that taken in the selected proof. Four examples, which illustrate students' remarks, are provided in Figure 6.

[Example 5.] While thinking about how I would prove this theorem, Proof B seemed to match what I would have said. (Selection: Direct)
[Example 6.] Personally, I like working with direct proofs rather than contradictions. In Proof B the logic makes sense. (Selection: Direct)
[Example 7.] It was contradiction and I like to use contradiction to solve proofs. (Selection: Contradiction)
[Example 8.] When something seems obvious or believe it's true, it's easier for me to assume not and follow that way. (Selection: Contradiction)

Figure 6.

These responses, accompanied by a *direct:indirect* selection ratio of 8:9, suggest that the 20% of students who attended to their own approaches to the theorem (i.e, their habits of reasoning) did not demonstrate a preference for the direct proof by rather lacked a dominant preference. While the sample size for this rationale (and the others) is small, one must question if a preference would be evident in a larger data set. Nevertheless, it is particularly interesting that those who attended to their own approaches did not demonstrate a direct proof preference. Lastly, a note regarding the familiarity code is warranted. This code was used to indicate rationales focused on students' who cited familiarity with containment arguments (*e.g*., $A \subseteq B$, $B \subseteq A$, thus $A = B$) and their recognition that the direct proof employed a known proof technique.

Discussion

Findings from the survey suggest, as indicated by prior research (Leron, 1985; Harel & Sowder, 1998), that students may lack a preference for indirect proofs of the contradiction-form. Moreover, when these findings are considered in relation to the contraposition-form results, were no preference is evident, it appears that the two forms of proof are not the same in the eyes of undergraduate mathematics students. With this said, there are reasons that claims related to a lack of preference should be stated with caution. First, while the *indirect contraposition-form:direct proof* comparative selection task did not elicit the *error* rationale, this rationale was proposed by 16.5% of students in relation to the contradiction proof during the *indirect contradiction-form:direct proof* comparative selection task. Thus, it may be the case that students are more prone to comprehension difficulties with contradiction proofs rather than lack a preference for this form of proof. Second, while Tall (1979), Knuth, (2002), and Healy & Hoyles (2000) all reported results in which students' proof selections were impacted by familiarity, it was only the latter experiment, where a *contradiction-form:direct proof* comparison selection task was used, that students employed a *familiarity* rationale and stated that the direct proof employed a known technique. Familiarity is interesting in that while cognitive psychologist have argued that familiarity can create an immediate "feeling of rightness" it may also be the case that familiar proof forms are selected because students know those proof forms are accepted by the mathematics community or believe that the alternative is less favorable – a belief that could arise from reading texts like those in Figure 1. Thus, it is unclear if students' task-specific inclusion of the *familiarity* rationale is due to students' seeking "feelings of rightness," a type of deference to the community's argumentation norms, or something else. Certainly, more research is needed.

Furthermore, since familiarity strongly influences preferences and claims of preference have been predicated on assumptions of comprehension, it is worth examining those students who neither viewed the contradiction-form proof as flawed (*error* rationale) nor cited *familiarity*. Among the 85 students surveyed, 12 reported familiarity with containment arguments as their primary rationale and 1 reported familiarity with the contradiction proof. Additionally, while 14 reported an error in the contradiction argument, only 4 students viewed the direct proof as flawed. Removing these two categories of students from the population reduces the *direct:indirect* selection ratio[3] of 56:29 to a selection ratio of 31:24. Thus, the proportion of students selecting the direct proof (0.56) is not statistically significantly different from a 0.5 proportion ($z = 0.067$, $p < 0.05$). To be certain, among those who did not demonstrate a lack of comprehension and who did not defer to a "known technique," there is little evidence of a preference for the direct proof. Thus, while far from providing a definitive conclusion, this research raises multiple questions regarding students' preferences for or against proof by contradiction – perhaps with the exception of those who, like Hilbert, developed contradiction as a habit of reasoning.

When nothing leads to everything: Novices and experts working at the level of a logical theory

Stacy A. Brown
California Polytechnic Statement University, Pomona

Building on Antonini and Mariotti's (2008) theorization of mathematical theorem and research on students' meta-theoretical difficulties with indirect proof, this study examines mathematics majors' and mathematicians': (1) responses and approaches to the validation tasks related to the assertion $S^* \rightarrow S$, when given a primary statement, S, of the form $\forall n, P(n) \Rightarrow Q(n))$ and a secondary statement, S, of the form used in proofs by contradiction; namely, $\nexists n, P(n) \wedge \sim Q(n))$; and, (2) selection of a statement to prove given the choices S* and S. Findings indicate that novice proof writers' responses differ from advanced students' and mathematicians' both in their approaches and selections, with novices tending to become entangled in natural language antonyms and engage in the chunking of, rather than parsing of, quantified statements.*

Key words: Indirect proof, Proof by contradiction, Meta-theoretical Difficulties

How does one know that a mathematical theorem is true? Mariotti (2006) has proposed that to *know* truth in a mathematical sense requires not only a mathematical theory but also a logical theory:

> In their practice, mathematicians prove what they call 'true' statements, but 'truth' is always meant in relation to a specific theory. From a theoretical perspective, the truth of a valid statement is drawn from accepting both the hypothetical truth of the stated axioms and the fact that the stated rules of inference 'transform truth into truth' (p. 184).

These remarks align with definitions of proof, which focus on the elements of proofs and their use of logic; such as that proposed by Akin (2010), "Proofs are sequences of statements which can, in theory, be reduced to: (1) axioms, definitions, and previously proved results; or (2) statements obtained from earlier statements by the (formal – logical) rules of inference. To be certain, this definition points to the fact that without a mathematical theory from which to draw axioms, definitions, and previously proved results and without a logical theory to guide inferences, one cannot produce mathematical proofs. Indeed, we would obtain quite distinct results working in Riemannian rather than Euclidean geometry; especially if we were to use intuitionistic logic, such as that used by Brouwer, rather than the standard logic of mathematics. Working to clarify the systems that make 'truth' possible in mathematics Mariotti, Bartolini Bussi, Boero, Ferri & Garuti (1997) have argued that what characterizes a *mathematical theorem* is the triplet (statement, proof, reference theory), where reference theory is used to describe "a system of shared principles and deduction rules" (p.8).

Building on this characterization of mathematical theorem, Antonini and Mariotti (2008) examined a form of proof researchers (Robert, & Schwarzenberger, 1991) describe as highly problematic for students; namely, indirect proof. Drawing on data from interviews with tertiary students, Antonini and Mariotti demonstrated that while students may gain conviction from indirect proofs, this conviction is tied to the specific statements proved, as opposed to their logically equivalent statements. For instance, given a proof of $\sim Q \rightarrow \sim P$, students may gain conviction but fail to do so in relation to the statement $P \rightarrow Q$. Drawing on these findings, Antonini and Mariotti argue that when examined through the lens of that which characterizes mathematical theorems, indirect proofs are unique for they call on learners to employ theorems not only within the mathematical theory but also within the logical theory. Consequently, Antonini and Mariotti proposed a refinement of the (statement, proof, reference theory) triplet for indirect proofs, arguing that indirect proofs involve "the pairing of the sub-theorem (S*, C, T) and the meta-theorem (MS, MP, MT)" (p. 405). Meta-statement (MS) refers to statements such as "$S \rightarrow S^*$" where S refers to a primary statement (e.g., $P \rightarrow Q$) and S* refers to a secondary statement, such as the contrapositive of S (i.e., $\sim Q \rightarrow \sim P$). Meta-proof (MP) refers to the proof of $S \rightarrow S^*$ within the meta-theory (MT), i.e., the logical theory. Drawing on this model, Antonini and Mariotti argue students' difficulties with indirect proofs are metatheoretical; that is, due to a lack of acceptance of the meta-theorems employed.

Antonini and Mariotti's (2008) account of students' difficulties with indirect proof is unique among accounts of students' difficulties. Indeed, while researchers have argued that part of students' difficulties with indirect proof arise from difficulties negating statements (Wu Yu, Lin & Lee 2003; Antonini 2001, 2003; Thompson 1996), it is also the case that few have attended to the role of logic in such proofs. In Tall's (1979) study of students' levels of confusion related to indirect proofs of the irrationality of $\sqrt{2}$, students' confusion was attributed to the lack of generic structures in standard contradiction proofs rather than to difficulties at the level of the logical theory. One reason for this may be that the particular statement Tall (1979) examine was not a compound statement. Hence, the difficulties associated with negating conditional statements were not relevant. Drawing on reflective accounts of multiple teaching experiments, Leron (1985) explored students' responses to standard proofs of the infinitude of primes – that is to a mathematical theorem which did not take the form of a compound statement – and found that students' experience difficulties with the destructive, as opposed to constructive, nature of the indirect proof, as well as the "negative stretches" that accompany working in a "false world." Hence, working within the logical theory was not a primary source of difficulties. Through analyses of data from multiple teaching experiments, Harel and Sowder (1998) examined students' reactions to contradiction proofs and found that students lack a preference for this particular form of proof. They argued, like Leron (1985), that students' prefer constructive approaches and that such preferences are indicative of a constructive proof scheme. Beyond the rationales of Tall (1979), Leron (1985), and Harel and Sowder (1998), are Reid and Dobbin's (1998) emotioning rationale and Thompson's (1996) argument that indirect proof instruction tends to lack connections to students' informal reasoning. Indeed, multiple rationales have been proposed, though few take into account the specific meta-theorical nature of indirect proofs. This has been the case even though Goetting (1995) noted in relation to proof by contraposition, students were "wary of the validity of the 'backwards' arguments" (p. 124) and Leron (1985) noted in the case of proofs by contradiction, "we must be satisfied that the contradiction has indeed established the truth of the theorem (having falsified its negation), but psychologically, many questions remain" (p. 323) – remarks suggestive of attention to metatheoretical issues.

Arguably, Antonini and Mariotti's (2008) metatheoretical rationale represents a potentially critical advance in research on indirect proof in that it offers a route by which to explore aspects of indirect proof that are both unique and essential to that form of proof. With this said, little is known about tertiary students' metatheoretical reasoning. That this is the case may be due to the fact that there are a plethora of studies that focus on the development of proof through the refinement of students' informal arguments and that argues against the direct transition to formal proof and, consequently, do not advocate approaches involving training in logic (Jahnke, 2010; Maher & Martino, 1996). Moreover, many "Introduction to Proof" texts include instruction on logic but focus on building students' understandings through natural language activities rather than through instruction on logic as a theory (*cf.* Chartrand et al., 2013). Thus, one could conclude that there is little interest in metatheoretical issues for they run counter to current perspectives on productive approaches to proof and pedagogical practices in commonly used texts. On the other hand, the lack of research on metatheoretical reasoning is surprising since, as evident in Akin's definition, our basic definitions of proof rely on the existence of a logical theory. Furthermore, there is a profusion of research from cognitive psychology demonstrating that humans' ways of reasoning do not fully align with the forms of reasoning used in standard logic (*cf.* Oaksford & Chater, 2010). Specifically, general tendencies for interpreting conditional statements ($P \rightarrow Q$), do not align with those used in mathematics, with the exception of direct reasoning processes; e.g., accepting $P \rightarrow Q$ when P and Q are true. Thus, there are grounds for questioning pedagogical approaches premised on the idea that the logical theorems employed in mathematics will be readily employed by students. To be certain, there is reason to argue that further research is needed on students' approaches to and extent of success with metatheoretical work, especially in relation to those forms of proof for which such work is essential; namely, indirect proofs.

The Study

The purpose of this study is to address the need for research on students' approaches to and extent of success with metatheoretical work, by exploring three research questions:

1. To what extent are mathematics majors and mathematicians successful, when answering questions regarding the validity of $S^* \rightarrow S$; that is, when asked if a secondary statement S^* is sufficient to prove a primary statement S?
2. What are the similarities and differences observed among these populations when approaching questions regarding the validity of $S^* \rightarrow S$?
3. Which formulation, the statement or the secondary statement, do mathematics majors and mathematicians prefer, when asked to select a statement to prove?

These questions are of interest for they provide various avenues with which to explore the issue of students' potential difficulties working at the level of a logical theory. Indeed, if experts (mathematicians) are able to successfully verify metatheoretical statements, while novices struggle, then the findings will provide further evidence of Antonini and Mariotti's (2008) claim; whereas, if neither experience difficulties then an alternative to the metatheoretical hypothesis may be needed. Furthermore, if experts and novices avoid selection of secondary statements, then such data will provide further evidence of the preference hypotheses generated by Leron (1985) and Harel and Sowder (1998). In contrast, if no preference is evident then there will be cause to question the preference hypothesis.

Methods

To investigate mathematics students' and mathematicians' metatheoretical reasoning, three stages of data collection occurred. In the first stage, electronic surveys were sent to undergraduate mathematics majors who were within one year of completion of an introduction to proof course. The students were provided with Theorem 5 and Statement A (see Figure 1.) and asked to indicate if the following statement was true or false, "You can prove Theorem 5 by proving Statement A." Following this prompt, students were queried "If you were asked to prove Theorem 5 which would you pursue first?" and given the choices Theorem 5 and Statement A.

Theorem 5. For all positive integers n, if $n$mod(3) ≡ 2 then n is not a perfect square.
Statement A. There exists no positive integer n such that $n$mod(3) ≡ 2 and n is a perfect square.

Figure 1. Theorem 5 Task

In stage 2, clinical interviews were conducted with 21 mathematics majors, who met the criteria described above. In stage 3, clinical interviews were conducted with 6 mathematicians. In all of the clinical interviews, the manner in which the Theorem 5 task was posed matched that of the electronic survey. Interview responses were analyzed to gather categorical data for the validation and selection questions, as well as data regarding participants' approaches to the validation question. Using a constant-comparative methodology, descriptive codes were generated and used to further characterize participants' video-recorded responses.

Theorem 5 Task Design

The Theorem 5 validation task was designed with the assumption that at the conclusion of a proof by contradiction the prover would need to recognize that having shown Statement A, he or she can conclude that Theorem 5 was proven. This assumption is predicated on the following sequence of proving actions. First, to prove Theorem 5 using a proof by contradiction, one begins by assuming the negation of a statement of the form $\forall n \in \mathbf{Z}^+$, $P(n) \Rightarrow Q(n)$. Thus, by assuming $\sim(\forall n \in \mathbf{Z}^+, P(n) \Rightarrow Q(n))$, which is logically equivalent to $\exists n \in \mathbf{Z}^+$, $P(n) \wedge \sim Q(n)$. Second, the prover must arrive at a contradiction to an axiom, definition, previously proved theorem or an existing assumption (*i.e.*, something within the mathematical theory) and conclude from this contradiction that the statement $\exists n \in \mathbf{N}$, $P(n) \wedge \sim Q(n)$ is false; *i.e.*, $\sim(\exists n \in \mathbf{N}, P(n) \wedge \sim Q(n))$. While formally, one might say "It is not the case that there exists a positive integer such that …", informally one might argue, "no such n exists" or the more common, though grammatically more awkward, "there exists no positive integer n such that …". Lastly, one must recognize that the proven statement is sufficient to prove the original statement – in Antonini and Mariotti's terms, that S* proves S. Hence, the Theorem 5 validation task was designed with the last phase of this sequence in mind; that is, to explore mathematics majors' and mathematicians' perceptions of validity related to a standard phrasing of the result of a proof by contradiction. Furthermore, as was the case in Antonini and Mariotti's work, the task focused on the inferences to be drawn rather than the, perhaps technically more appropriate, determinations of equivalence.

Findings

In regard to the electronic survey, 35 mathematics majors who were advanced in terms of course work; that is, who had completed not only an introduction to proof course but also real analysis and abstract algebra courses, responded to the survey. The categorical responses are shown in Table 1 and indicate that: (a) the majority of advanced students were successful at recognizing the validity of the metatheoretical statement S* → S; and, (b) demonstrated only a slight preference for the primary (Theorem 5) over the secondary statement (Statement A), which was not significantly different from a near even split ($\chi^2 = 0.458$; $p = 0.499$, χ^2 *Good of Fit test*).

Prompt 1: *You can prove Theorem 5 by proving Statement A.*		
Response	**N**	**%**
True	29	83
False	6	17

Prompt 2: *If you were asked to prove Theorem 5, which would you pursue first?*		
Responses	**N**	**%**
Theorem 5	20	57
Statement A	15	45

Table 1. Advanced Mathematics Students' Survey Responses

While the surveys were predominantly taken by advanced students, the majority of interview volunteers were novice proof writers; *i.e.*, they had recently completed an introduction to proof course, had not completed both real analysis and abstract algebra courses but rather were enrolled in at most one of these courses at the time of the interviews. Thus, the interviews were conducted with a different population in terms of prior coursework. Findings from the interviews indicate that the novices' validation responses fell into four categories: *don't know*, *no*, *yes-no-yes*, and *yes*. For clarification, *don't know* was used for students who after deliberating indicated they were unable to determine if the statement "You can prove Theorem 5 by proving Statement A" was true or false. *Yes-no-yes* refers to responses in which the student initially articulated an intuitive response, sought to validate their intuition, decided "*no*" and then through further analyses decided (often with uncertainty) that their response was, "Yes, it's true." As seen in Table 2, where the novice proof writers' responses are shown by category, the most frequent response was *no* at 42.8%, with the majority of these students (67%) arguing that Statement A was the negation of Theorem 5. However, if the *yes* (28.6%) and *yes-no-yes* (23.8%) response categories are collapsed, then roughly half of the students were able to correctly respond to the validation statement. It is interesting to note that a secondary analysis of the sample's verbal responses, which coded students' responses for multiple instances of expressed hesitancy, equivocation, or doubt, found that 16 of the 21 students (76%) repeatedly articulated uncertainty. Lastly, interview participants overwhelming selected Theorem 5 for their "statement to prove."

Prompt 1: *You can prove Theorem 5 by proving Statement A.*		
Response	**N**	**%**
True (Yes)	6	28.6%
True (Yes-no-yes)	5	23.8%
False (No)	9	42.8%
Uncertain (Don't Know)	1	4.8%
Prompt 2: *If you were asked to prove Theorem 5, which would you pursue first?*		
Responses	**N**	**%**
Theorem 5	16	76.2
Statement A	2	9.5%
No Response	3	14.3%

Table 2. Novice Proof Writers' Theorem 5 Task Responses

Not surprisingly, the 6 mathematicians who were interviewed were, without exception, successful at the Theorem 5 validation task. Moreover, like the advanced students, their selection of a statement to prove was more balanced than that of the novices, with some expressing the selection "*either*." Data for the mathematician sample is provided in Table 3.

Furthermore, like the novices, 4 of the mathematician's (75%) expressed hesitancy or equivocations even though they did not shift their response to Prompt 1. However, unlike the novices, who doubted their responses, the mathematicians' expressions of uncertainty tended to be geared towards their own reasoning at the time of the interview; e.g., one remarked "I'm doubting myself right now for some reason" and another mentioned that it was "too early" in the morning for such questions.

Prompt 1: *You can prove Theorem 5 by proving Statement A.*		
Response	**N**	**%**
True	6	100
False	0	0
Prompt 2: *If you were asked to prove Theorem 5, which would you pursue first?*		
Responses	**N**	**%**
Theorem 5	2	33.3
Statement A	2	33.3
Either	2	33.3

Table 3. Mathematician's Theorem 5 Task Responses

Beyond the observed similarity of expressed hesitancy, the novices and mathematician responses were quite dissimilar. Indeed, while 5 of the 6 mathematicians approached the question of proving Theorem 5 by proving Statement A semantically, none of the novices were observed using a semantic approach. Instead, the novice proof writers tended to move away from the linguistic statements and work at a symbolic level, with many moving to truth tables to prove various equivalences. While it might seem that working at a symbolic level leads to a higher error rate, it appears that this is not the case. The same percentage of students who worked symbolically immediately responded *yes*, as did those who argued *no;* approximately 67% of each cohort. With this said, it is interesting to note that all (100%) of those who responded "*yes-no-yes*" worked symbolically. Since several students expressed a lack of comfort with the content as a rationale for moving to symbols, it may be that the mathematicians' greater content expertise played a role in their approaches to the Theorem 5 validation task. This finding raises questions about the skills novices need to evaluate statements with unfamiliar content.

A second important distinction between the novice proof writers' and mathematicians' approaches concerns how the two cohorts went about understanding Statement A. Specifically, the majority of novices (14 of 21; 67%) tended to engage in *chunking*; that is, they tended to break Statement A into two chunks, with the first containing the quantifying phrase, "there exists no positive integer," and the second chunk containing the open sentence, "$n$mod(3) ≡ 2 and n is a perfect square." Hence, when responding to Prompt 1, they sought relationships between the quantifying chunks of Statement A and Theorem 5 and then the open sentences, rather than holistically comparing the quantified statements, as illustrated in the transcript excerpt below.

Linda: This (Statement A) is the negation of this (Theorem 5) because this one says *for all* and this one says *there exists no* and this one is *if P then Q* and this one is *P and not Q*.

Figure 2. Chunking Transcript Excerpt

In contrast, the mathematicians and 4 of the successful students (3 who replied yes and 1 who responded *yes-no-yes*) engaged in *parsing*; that is, consideration of the various components of the quantified compound statements <u>and</u> their logical relations to each other. In other words, quantifiers were considered in relation to the open sentences they quantified rather than as separate sentence components. This approach is illustrated in the interview excerpt in Figure 3, where the student considers the negation of the quantifier in relation to the modified statement.

Nicolas: Because when you say "there exists no," that's a "for all" but then … but then you have to negate … (places fingers on P and ~ Q statements) … you, you have to negate Q.

Figure 3. Parsing Transcript Excerpt

Similarly, several mathematicians spoke aloud while responding to the Theorem 5 task, with many providing comments akin to the following mathematician's remark, "there exists no … so there is nothing that satisfies this (points to "$n\text{mod}(3) \equiv 2$ and n is a perfect square")."

Lastly, those who were observed *chunking* Statement A; that is, isolating the quantifying phrase "there exists no …" where also frequently observed becoming entangled in the natural language meanings and linguistic antonyms of "for all" and "there exists no." For instance, Patrick argued, as did others, that "for all" means "everything," "there exists no" means "nothing," and that "the opposite of nothing is everything." Thus, for some students, natural language functioned as an obstacle to validating the claim $S^* \rightarrow S$.

Discussion

The findings of the electronic survey of advanced mathematics students and the clinical interviews with novice proof writers and mathematicians indicate that while advanced students and mathematicians are quite successful validating the claim "You can prove Theorem 5 by proving Statement A," these determinations are quite difficult for novice proof writers who may engage in potentially unproductive chunking practices and employ inappropriate linkages between mathematical statements and natural language. While it is easy to argue that the majority of novices were simply weak in the content area of quantifiers and did not interpret them appropriately, for they neither engaged in valid parsing practices nor did they interpret the terms in a logically appropriate manner, there is reason to caution against this reaction. Many "introduction to proof" texts use natural language when introducing students to quantifiers and their negations. Moreover, in a review of these texts, it was found that none addressed the ambiguities that arise from natural language in relation to quantification (*cf.* Epp, 2003). Indeed, as was evident from a survey of dictionaries, and is illustrated in Figure 4, neither is there a transitive property for antonyms nor is there a lack of ambiguity to natural language when it comes to quantifying terms such as *for all* (everything), *exists no* (nothing) and *exists* (something; some), when expressed and negated using natural language antonyms.

Figure 4. Natural Language Examples of Quantified Terms

Finally, the novices "statement to prove" selections, which indicated a strong preference for Theorem 5, stand in contrast to those of advanced students and mathematicians, with neither group demonstrating a preference. Given that many novices had difficulty parsing Statement A this result is not surprising. With this said it appears that, at least for novices, the metatheoretical issues described by Antonini and Mariotti (2008) may play a role in students' interpretations and sense of certainty in the context of the results of a proofs by contradiction. In particular, given that in response to Prompt 1, 42.8% of novices replied *false* and only 28.6% replied *true*, there is reason to believe that – as Antonini and Mariotti have argued – students experience difficulties at the metatheoretical level in relation to the theorem $S^* \rightarrow S$, with the current work indicating that a potential source of these difficulties may be validating the relationships between S* and S.

Students' explicit, unwarranted assumptions in "proofs" of false conjectures

Kelly M. Bubp
Ohio University

Although evaluating, refining, proving, and refuting conjectures are important aspects of doing mathematics, many students have limited experiences with these activities. In this study, undergraduate students completed prove-or-disprove tasks during task-based interviews. This paper explores the explicit, unwarranted assumptions made by six students on tasks involving false statements. In each case, the student explicitly assumed an exact condition necessary for the statement in the task to be true although it was not a given hypothesis. The need for an ungiven assumption did not prompt any of these students to think the statement may be false. Through prompting from the interviewer, two students overcame their assumption and correctly solved the task and two students partially overcame it by constructing a solution of cases. However, two other students were unable to overcome their assumptions. Students making explicit, unwarranted assumptions seems to be related to their limited experience with conjectures.

Key words: Conjectures, Unwarranted Assumptions, Mathematical Proof, Task-Based Interviews

The proving process is a complex combination of creativity and rigor that encompasses a multitude of activities including analyzing and identifying patterns and relationships, generating conjectures and generalizations, and evaluating, refining, proving, and refuting mathematical conjectures (Committee on the Undergraduate Program in Mathematics (CUPM), 2004; de Villiers, 2010; Durand-Guerrier, Boero, Douek, Epp, & Tanguay, 2012). However, many students have limited experience with the activities in the proving process that involve uncertainty and decision-making, such as exploring conjectures (Alibert & Thomas, 1991; de Villiers, 2010; Durand-Guerrier et al., 2012). This limited experience may inhibit students' development of "an attitude of reasonable skepticism" with respect to mathematics (Alibert & Thomas, 1991; de Villiers, 2010; Durand-Guerrier et al., 2012, p. 357).

Prior research has shown that high school and undergraduate students make unwarranted assumptions in proofs (Dvora, 2012; Selden and Selden, 1987; Weiss, 2009). In these cases, the students seem to be either unaware they had made an unwarranted assumption or the assumption was based on their perception of a geometric figure and was unrecognized as unwarranted. But what leads students to knowingly make unwarranted assumptions in a non-geometric proof context? Especially when the truth value of the statement is unknown? What makes a student explicitly assume an ungiven assumption rather than consider a statement may be false? These are the questions I investigate in this paper, but my actual research questions are: Why do students explicitly make unwarranted assumptions on prove-or-disprove tasks? What types of explicit, unwarranted assumptions do students make? Under what conditions do students overcome their explicit, unwarranted assumptions?

Literature Review

"One of the most important steps in [mathematical] research is to conjecture what is the truth and then attempt to verify it by hunting down a proof" (Burger, 2007, p. xii). Suppose a mathematician believes a certain conjecture is true, but while attempting to prove it, the mathematician needs an assumption that is not a hypothesis? There seem to be three reasonable courses of action commonly practiced by mathematicians: (a) consider that the conjecture may be false and search for a counterexample, (b) add the assumption to the hypotheses and prove a weaker conjecture, or (c) assume the needed assumption and justify it later (Burger, 2007; Selden & Selden, 1987; Weiss, Herbst, & Chen, 2009). Although (a) and (c) should lead to a decision on the truth value of the conjecture, in (b), the conjecture has been weakened and there is no verification of the truth value of the original conjecture.

In order for students to experience mathematics the way mathematicians do, they need to be engaged in exploring, proving, and refuting conjectures. CUPM (2004) suggests that students majoring in the mathematical sciences "learn a variety of ways to determine the truth or falsity of conjectures…to examine special cases, to look for counterexamples," and to analyze "the effects of modifying hypotheses" (p. 45). In his article on teaching proving, Dean (1996) suggests that when students are exploring a conjecture, "if little progress is being made, the student might add an additional hypothesis and see if this leads anywhere" (p. 53). In Burger's textbook, *Extending the frontiers of mathematics: Inquiries into proof and argumentation* (2007), directions for each problem statement in the text are 'Prove and extend *or* disprove and salvage' (p. xii). Burger (2007) offers many suggestions for extending a proven conjecture or salvaging a refuted conjecture, including weakening or adding to the hypotheses, respectively. Lastly, some high school teachers believe allowing students to make an assumption with the caveat that they must return and justify it later is a valuable instructional strategy (Weiss et al., 2009).

Despite the recommendations of CUPM (2004), many students have limited experiences exploring and refuting conjectures (Alibert & Thomas, 1991; de Villiers, 2010; Durand-Guerrier et al., 2012). In particular, "students are rarely, if ever, presented with false mathematical statements and asked to determine whether or not they are true" (Durand-Guerrier et al., 2012, p.357), and high school "students are rarely held accountable for finding the conditions under which a claim could be true (Herbst & Brach, 2006)" (Nachlieli, Herbst & Gonzalez, 2009, p. 432).

High school and undergraduate students' limited experiences may partially account for the difficulties they have studying conjectures. Students struggle with (a) knowing how to begin an exploration, (b) formulating ideas and opinions about the truth of a conjecture, and (c) connecting ideas and opinions to proofs or counterexamples (Alibert, 1988). Durand-Guerrier and Arsac (2005) suggest that students' difficulties determining the truth value of conjectures may stem from their narrow collection of possible counterexamples and limited mathematical knowledge as novices. In geometric contexts, high school students often make unwarranted assumptions based on geometric figures or diagrams even though they are taught not to do so (Weiss, 2009).

Other difficulties students have may be related to the inappropriate use of the strategies used by mathematicians and suggested by educators for exploring conjectures. Some high school and undergraduate students unknowingly make unwarranted assumptions that reduce a general conjecture to a special case (Selden & Selden, 1987; Weiss, 2009). Although mathematicians examine special cases when exploring conjectures, they do so knowingly and realize the general conjecture still needs to be considered (de Villiers, 2010). Weiss et al. (2009) reported on high school teachers' reactions to a video episode of a teacher allowing a student to make an unwarranted assumption in a proof under the condition that the student returned to justify the assumption later. Some teachers expressed concern that students would distort this practice (common of mathematicians) by developing a habit of making unwarranted assumptions and failing to return to them (Weiss et al., 2009).

Method of Inquiry

The data in this paper come from a larger study that (a) examined the reasoning students use to evaluate conjectures, (b) identified systematic errors students make during the proving process, and (c) investigated cognitive unity between students' evaluation of conjectures and construction of associated proofs and counterexamples.

Participants

The participants were twelve undergraduate students from a public university in Ohio who had passed at least one proof-based mathematics course with a grade of B or better. Ten students were in their fourth year of undergraduate study, and eleven students were mathematics or secondary mathematics education majors.

Procedures

I conducted two task-based interviews with each participant which were audio-recorded and transcribed. Participants were asked to think aloud during the completion of four tasks and to clarify or expand on their thinking as necessary. Each task was provided one at a time on a separate sheet of paper. Participants were provided with a list of definitions of terms in the tasks, but no other materials were allowed. Participants used a LiveScribe Pen and paper that recorded synchronously audio and writing. After each task, I asked follow-up questions on the participants' work on the task. Upon completing all tasks, I asked each participant general questions about their approaches to and understanding of proof and disproof.

Tasks

Each task required the participants to evaluate a conjecture and prove or disprove the conjecture accordingly. The tasks involve basic properties of functions and were chosen to be accessible to the participants. In line with Alcock and Weber (2010), each task referred to general objects and their properties and should have been approachable with either semantic or syntactic reasoning. The following three tasks will be discussed in this paper:

Injective Function Task: Let $f: A \to B$ be a function and suppose that $a_0 \in A$ and $b_0 \in B$ satisfy $f(a_0) = b_0$. Prove or disprove: If $f(a) = b$ and $a \neq a_0$, then $b \neq b_0$.

Monotonicity Task: Prove or disprove: If $f: \mathbb{R} \to \mathbb{R}$ and $g: \mathbb{R} \to \mathbb{R}$ are decreasing on an interval *I*, then the composite function $f \circ g$ is increasing on *I*.

Global Maximum Task: Prove or disprove: If f is an increasing function, then there is no real number c that is a global maximum for f.

Each statement in these tasks is false. Any noninjective function is a counterexample for the Injective Function Task. A counterexample for the Monotonicity Task requires a function g with outputs that are not elements of the chosen interval *I*. Finally, any increasing function defined on a closed interval serves as a counterexample for the Global Maximum Task.

Analysis

I identified all errors made by participants in the proving process. Instances in which participants made assumptions that were not given hypotheses in the task were classified as *unwarranted assumptions*. An unwarranted assumption was further categorized as *explicit* if the participant expressed awareness of making it.

Results

Six of the twelve students in this study made an explicit, unwarranted assumption. Each of these students did so on exactly one task. In each case, the assumption the student made was exactly what was needed to make the statement in the task true, but was not a given hypothesis. Additionally, in the face of the needed assumption, no student considered the possibility that the statement may be false without prompting from the interviewer. In this section, I describe these students' explicit, unwarranted assumptions and the extent to which they overcame them. First, I discuss Edward and Jalynn, each of who overcame their explicit, unwarranted assumptions and correctly solved the associated tasks. Next, I present Evan and Inigo, who partially overcame their explicit, unwarranted assumptions by constructing task solutions involving cases. Lastly, I discuss Aurelia and Jay who failed to overcome their explicit, unwarranted assumptions and incorrectly solved the associated tasks.

Edward and Jalynn

Edward and Jalynn each made an explicit, unwarranted assumption while attempting to prove the statements in the Monotonicity and Injective Function Tasks, respectively. With prompting from the interviewer, they eventually realized that their assumptions were problematic and correctly decided the statements were false.

Edward

Edward decided that the statement in the Monotonicity Task was true and constructed a proof for it. Within his proof, Edward made the explicit, unwarranted assumption that the range of the function g was in the interval *I*. Upon completing his proof, he noted, "I'll say it's increasing on *I*. Although I didn't do a good job at all of proving where *I* is or working with where *I* is." I asked him how concerned he was about that, and he said:

> If they are both decreasing on an interval *I*, that doesn't necessarily mean the intervals overlap…Because we would need the range of g to be in *I*…we would need the domain of f to be the same decreasing interval as the range of *g,* and we'd need the domain of *g* to be decreasing. So, and I didn't prove that connection. I should have.

I inquired, "Does that invalidate your proof?" He responded, "Yes. I would not necessarily believe this proof because I didn't match up the range to the domain."

I pressed further regarding this assumption in his proof, and he indicated that it was a necessary but unwarranted assumption: "If I make that assumption,…it does work…But without making that assumption, I don't think it holds….I don't think that's an assumption I can legitimately make." Upon making sense of why the assumption was necessary for the statement to be true, Edward finally decided that the statement was false. He concluded:

> Without this [the assumption], f…could be increasing or decreasing on *I*. I mean, depending on where the range of *g* is mapped onto the domain of f and what, whether it's increasing or decreasing at that interval…'cause the interval…doesn't necessarily line up at f and g. That makes this statement false.

Thus, through interviewer prompting and analysis of the necessity of his assumption, Edward realized that he could not justify his assumption and the statement was false.

Jalynn

Jalynn knew that the Injective Function Task was related to the concept of one-to-one, but was confused by the notation $f\colon A \to B$, wondering whether it only indicated the domain and range of the function or if it also implied that the function was onto or one-to-one. After she began her proof, she realized she needed the assumption that the function f was one-to-one and said, "I can assume that it's one-to-one….There would just be a condition for it then." With this explicit, unwarranted assumption, Jalynn constructed a proof for the statement.

After she completed her proof, I asked Jalynn if she thought that the assumption that f was one-to-one was a necessary condition for her proof. She said that she was unsure because she was still confused about whether the notation indicated that the function was one-to-one. So, I asked her what she thought if we just assumed that the notation only indicated the domain and range of the function, and she replied "[that] probably would change it, but, I'm just trying to think of an example." She wrote $f(x) = x^2$, and showed that $f(3) = f(-3) = 9$. She indicated that this function was not one-to-one and that f being one-to-one was a necessary condition for this statement to be true.

Finally, I asked Jalynn to clarify whether she thought the statement was true or false, and she replied "it's true if it's one-to-one and it's false if. Overall it would be false in any case, just like how here [referring to her counterexample $f(x) = x^2$]…I guess it just asks for the general case." Like Edward, through prompting to consider the necessity of her explicit, unwarranted assumption, Jalynn analyzed it in the context of an example and realized she needed to consider the general case in which the statement was false.

Inigo and Evan

Inigo and Evan each made an explicit, unwarranted assumption while proving the statements in the Injective Function and Global Maximum Tasks, respectively. They were able to partially overcome these assumptions by constructing cases–one with and one without the assumption–for their solutions to the tasks. However, neither student realized that only one of the cases applied to the given task.

Inigo

Inigo assumed the statement in the Injective Function Task was true. While constructing his proof, in order to claim $f(a) = f(a_0)$ implies $a = a_0$, Inigo said he needed to assume f was one-to-one. He did so, making an explicit, unwarranted assumption, and completed his proof. He then said, "I know there's a flaw in some logic there because of this [underlining his assumption that f is one-to-one], but I'm finished." Inigo was content to stop with an invalid proof, but I was not willing to let it stand. I asked him if he could tell me why he thought it was wrong, and he said "I am assuming that this is one-to-one. And it's not necessarily one-to-one….And I know you can't actually make that assumption here". Inigo then realized that $f(x) = x^2$ served as a counterexample and said "So when it's one-to-one, that holds [indicating his proof]; and then when it's not, there [underlining his counterexample]….I broke this into cases." Thus, through prompting, Inigo only partially overcame his explicit, unwarranted assumption, deciding that a complete solution to the task included two cases. He did not realize that only the case without the assumption applied to the statement in the given task.

Evan

On the Global Maximum Task, Evan thought mistakenly that the given statement said the function *did* have a global maximum rather than saying it did *not* have a global maximum. Thus, Evan decided the statement was false and constructed a proof by contradiction to disprove the statement (proving the function did not have a global maximum). However, this proof included the implicit, unwarranted assumption that the domain of the function f was $\mathbb{R}$.

Because Evan had misread the statement, I confirmed with him that he thought the statement was false and asked him to reread the statement to ensure he was saying what he wanted to say. Upon looking back at his disproof, he realized he made the assumption that the domain of f was $\mathbb{R}$ and said he would "add a disclaimer" to his proof. He included his assumption in his disproof which made it an explicit, unwarranted assumption. Additionally, Evan wrote a second case in which the domain was a closed interval and proved the statement was true in that case. Like Inigo, Evan concluded he had two cases, but did not realize only one actually solved the given task.

Aurelia and Jay

Aurelia and Jay each made an explicit, unwarranted assumption while proving the Global Maximum and Injective Function Tasks, respectively. Both students failed to overcome these assumptions and incorrectly solved the tasks.

Aurelia

Aurelia struggled to determine the truth value of the Global Maximum Task. Upon first reading the statement, Aurelia said "So, I'm assuming that means if f is increasing throughout the whole entire function? So, this is obviously not true if you have…[a] function that stops at a certain point." However, she questioned whether a function could have a restricted domain. She drew a graph of $f(x) = x^2$ restricted to $[0,2]$ and asked herself "is that considered a function?" She was uncertain whether it was a function, but decided to assume that it was not a function because she thought I was "not trying to trick [her]". Thus, she made the explicit, unwarranted assumption that a function cannot have a restricted domain. This allowed her to assume that the function in the task was defined on $\mathbb{R}$, and she used this assumption to incorrectly "prove" the false statement.

Jay

Jay assumed the statement in the Injective Function Task was true and constructed a proof in which he made the explicit, unwarranted assumption that the function f was one-to-one. After he completed his proof, I asked him what the key step was in his proof, and he said "Well, just, for me, the idea since $a \neq a_0$, then, I, sort of, made a jump and assumed that $f(a)$ then is not equal to $f(a_0)$." I inquired about making this "jump", and he replied "That'll only be true if the function was one-to-one, but from just the given information, I don't know exactly if it is one-to-one." I continued attempting to draw information out of him about his use of one-to-one despite being uncertain whether f was one-to-one, but I was unable to get him to reconsider his assumption. He repeated that his proof would work if he knew the function was one-to-one, but he never indicated decisively whether he knew this. Despite my pressing, Jay was unable to overcome his explicit, unwarranted assumption and was satisfied with his "proof" for this false statement.

Discussion

Consistent with prior research with high school and undergraduate students, the students in this study seemed to lack key strategies for thinking about and identifying false statements. Some students made explicit, unwarranted assumptions rather than consider a given conjecture was false. In each case, the student completed a "proof" of a false statement that relied on and included the explicit, unwarranted assumption. Multiple students in this study, including Edward and Inigo, said they are rarely asked to consider statements in which the truth value is unknown. Inigo noted, "All throughout math classes, we're bombarded with what's true and not with what's false." It seems possible that limited exposure to conjectures may have inhibited these students' development of a healthy skepticism toward mathematics, as has been suggested in the literature (Alibert & Thomas, 1991; de Villiers, 2010; Durand-Guerrier et al., 2012). This may have led the students to do whatever it took to prove the statements rather than consider their potential falsity. This suggests students need more opportunities to engage in evaluating, refining, and refuting conjectures.

Another possible explanation for the students' behavior, as indicated by the concerns voiced by the high school teachers in Weiss et al.'s (2009) study, is that these students were misusing a common technique practiced by mathematicians. Edward was the only student who indicated he knew he should have returned to his assumption to justify it. The other students seemed content with simply adding to the hypotheses, even though some expressed concern over doing so. It is possible that these students were misusing a legitimate strategy they had seen mathematicians use, which may account for their uneasiness. However, these students also expressed a clear understanding of the logical nature of proofs during follow-up questioning, so perhaps their concern resulted from their knowing the assumptions were unwarranted, but not knowing what else to do. This would suggest again that the students' struggles were related to their limited experience with statements of unknown truth value.

Each explicit, unwarranted assumption made by the students in this study was an ungiven hypothesis that was necessary for the statement to be true. Thus, the need for each assumption should have indicated the potential falsity of each statement as well as exactly what was needed in a counterexample. On the Monotonicity Task, Edward assumed the range of the function $\boldsymbol{g}$ was in the interval I. On the Injective Function Task, Jalynn, Inigo, and Jay each assumed the given function $\boldsymbol{f}$ was one-to-one, and on the Global Maximum Task, Evan and Aurelia assumed the domain of the function $\boldsymbol{f}$ was $\mathbb{R}$. For each task, the fact that these assertions are not necessarily true is precisely why the statements are false. If students were accustomed to Burger's (2007) instructions to 'prove and extend or disprove and salvage,' the realization that they needed these assumptions to prove the statements should (a) indicate the statements are false, (b) provide the necessary conditions for a counterexample, and (c) specify an assumption to add to the hypotheses to salvage the statements. This would make the need for the assumption in a proof attempt a powerful tool in solving the task. However, it does not seem as though the students in this study were trained to recognize this power of needed assumptions.

Despite some of the students' concerns regarding their assumptions, prompting from the interviewer to reconsider their "proofs" or assumptions seemed necessary for them to overcome or partially overcome their explicit, unwarranted assumptions. However, this did not work in all cases as Aurelia and Jay were unable to overcome their assumptions. Interestingly, Inigo, Evan, and Jay each indicated during follow-up questioning that prove-or-disprove tasks are more difficult than prove tasks because if they got stuck in the middle of a proof, they would have to question whether they were trying to prove a false statement and consider looking for a counterexample. However, none of these students did this when confronted with the need for an ungiven assumption. Perhaps they did not consider or recognize this as a form of 'getting stuck.' Either way, it seems they possessed knowledge of an appropriate strategy to use the situation, but failed to use it.

The results of this study suggest a couple ideas for dealing with students making explicit, unwarranted assumptions. First and foremost, engage students in evaluating conjectures, including false conjectures. And so often. If students are rarely faced with conjectures, then it will be difficult for them to develop and use appropriate strategies for dealing with situations that are common in conjecturing contexts but not in contexts in which the truth value of a statement is known. Additionally, it seems as though students may not be inclined to question explicit, unwarranted assumptions on their own. They may need prompting from their instructors in order to recognize that needing an ungiven assumption means that they are 'stuck.' And we need to encourage students to explore this special type of being 'stuck' because of its potential power to indicate why a statement is false, what is needed for a counterexample, and what is necessary to make it true. Engaging students in evaluating conjectures and helping them recognize the potential power of a needed assumption may allow them to move ever closer toward thinking like mathematicians think.

Limitations of a "chunky" meaning for slope

Cameron Byerley   Hyunkyoung Yoon   Patrick W. Thompson
Arizona State University

This paper will investigate the question "What mathematical meanings do high school mathematics teachers hold for slope and rate?" It will also investigate to what extent these meanings for slope and rate are multiplicative, that is built on an image of quotient as a measure of relative size. A multiplicative meaning for rate of change is powerful because it allows the teacher to better differentiate between additive and multiplicative situations. The data comes from the administration of the diagnostic instrument named "Meanings for Mathematics Teaching Secondary Math" (MMTsm).

Key words: Secondary Teacher Preparation, Slope, Rate, Diagnostic Instrument

Coper-Gencturk (2015) followed 21 K-8 teachers for three years to determine how their mathematical knowledge and teaching changed over time. She found that the improvement in teachers' mathematical knowledge as a result of the master's program and their overall level of mathematical knowledge played significant roles in "indicating the extent to which teachers were successful in constructing meanings for mathematical rules and articulating what mathematical ideas students were supposed to learn" (Coper-Gencturk, 2015, p. 314). Teachers with lower content knowledge for teaching made superficial changes to their instruction such as putting students in groups to discuss procedures, or adding real-world or hands-on activities that were not clearly connected to the mathematical ideas being taught (Coper-Gencturk, 2015). It is important to understand and address mathematical weaknesses of teachers to help them implement meaningful changes in their classrooms.

Studies that employed time intensive methods such as interviews to study small samples (less than 10) of teachers described teachers who conveyed computational or additive meanings for slope (Coe, 2007; Stump, 1999). Project Aspire developed the instrument named *Mathematical Meanings for Teaching Secondary Mathematics (MMTsm)* to help professional developers and researchers more quickly and meaningfully diagnose teachers' mathematical thinking. This study builds on prior researchers' understandings of teachers' meanings for slope and rate, by investigating the following questions in a much larger sample of teachers using items related to slope and rate of change from the *MMTsm*.

1. What meanings for slope and rate might teachers' responses convey to their students?
2. To what extent do these meanings build on an image of quotient as a measure of relative size?

Theoretical Perspective

Thompson's (2013, 2015) work on meaning is the theoretical foundation of Project Aspire. Thompson defined "meaning" in the context of earlier research on the development of children's mathematical schemes. Harel and Thompson used the Piagetian notion of scheme to define a *stable* meaning as the "the space of implications that results from having assimilated to a scheme. *The scheme is the meaning*" (Thompson, Carlson, Byerley, & Hatfield, 2014, p. 13). Glasersfeld (1995) identified the three parts of schemes as follows:

1. Recognition of a certain situation.
2. A specific activity associated with that situation.
3. The expectation that the activity produces a certain previously experienced result (p. 65).

A person's meaning for a mathematical idea includes both what comes to mind when they encounter an idea and what is immediately implied by whatever comes to mind—what might come to mind easily next.

Literature Review

The explanations of constructs will use examples from interviews with teachers conducted in prior qualitative research. We will explain one non-multiplicative "chunky" way of thinking about slope and the limitations of this way of thinking. According to Castillo-Garsow (2010; 2012) a "chunky" way of thinking about quantities changing entails imagining completed chunk, that is an unit chunk. Thus, an individual using a "chunky" way of thinking is likely to imagine only changes in chunks instead of continuous change. Stump (2001) interviewed pre-service teachers named Joe, Tracie and Natalie and observed their teaching as part of a study on pre-service teachers' understandings of slope and how they expressed their meanings in the classroom. Joe planned and taught lessons on slope after discussions in a methods course designed to help teachers develop stronger meanings for slope. "Joe eventually defined slope as 'vertical change/horizontal change,' and presented a graph of the line passing through the points (0,0) and (3,2). He emphasized that the slope as a fraction, 2/3, up 2, over 3" (Stump, 2001, p. 216). One student in Joe's class "was having difficulty understanding how the two fractions 5/-6 and -5/6 could both represent the same slope. Although at the time Joe struggled in vain to help her understand, he later described her difficulty with the following insight: 'They think you are describing a movement as opposed to you describing a number, a measurement'" (Stump, 2001, p. 216). Although Joe's personal meanings were sufficient to allow him to see '5/-6' and '-5/6' as the same slope, the meaning for slope he conveyed to the student (namely, slope tells us how to go up and over) limited the student's ability to use slope productively. Further, the meaning for slope Joe conveyed to this student was strongly connected to the conventional Cartesian coordinate system and the act of moving over and up in chunks of 2 and 3. His meaning for slope could not be applied to polar coordinate systems or real world situations where two quantities change together, but do not move horizontally and vertically.

Joe conveyed a chunky, non-multiplicative meaning for slope because he did not say for any size change in x the change in y is 2/3 as large. Other teachers also did not strongly connect the idea of slope to the notion of a quotient as a measure of the relative size of the change in x and the change in y. Coe (2007) asked Peggy "why do we use division to calculate slope?" and she replied that she didn't know because "she never really thought of it as the division operation" (p. 207). Even though Peggy realized that there is a division symbol in the formula for slope she seemed not to have questioned how it related to her meanings for division.

Some teachers' tendency to avoid using a multiplicative meaning for quotient in explanations of slope may be because their meanings for quotient are weak. McDiarmid and Wilson (1989) gave a written instrument to 55 alternatively certified secondary teachers with mathematics degrees. He presented them with four story problems and asked them to choose which story problem could be solved by dividing by ½. Only 33% were able to identify quantitative situation that involved division by a fraction. In interviews by McDiarmid and Wilson (1989) some alternate route secondary teachers could see no real world application for division by fractions.

Ball (1989) asked prospective teachers "to develop a representation—a story, a model, a picture, a real-world situation—of the division statement $1\frac{3}{4} \div \frac{1}{2}$" (p. 21). Five out of 9 prospective secondary teachers and 0 out of 9 elementary teachers were able to generate an appropriate representation (p. 22). Byerley and Hatfield (2013) asked 17 pre-service secondary teachers to draw a picture representing a particular division problem. Six out of 17 were able to represent the relative size of 7.86 and .39 in an image to explain the meaning of a quotient (Byerley & Hatfield, 2013). Without an image of quotient as a measure of relative size, it is hard to build a meaning for slope as a measure of the relative size of the change in x and the change in y.

Item Development

The motivation for Project Aspire was to design items and scoring rubrics that allow researchers and teacher educators to categorize teachers' meanings with a written diagnostic instrument. Thompson (2015) summarized the process of creating items and rubrics for the *MMTsm*:

> (1) Create a draft item, interview teachers (in-service and pre-service) using the draft item. A panel of four mathematicians and six mathematics educators also reviewed draft items at multiple stages of item development. In interviews, we looked for whether teachers interpret the item as being about what we intended. We also looked for whether the item elicits the genre of responses we hoped (e.g., we do not want teachers to think that we simply want them to produce an answer as if to a routine question); (2) Revise the item; interview again if the revision is significant; (3) Administer the collection of items to a large sample of teachers. Analyze teachers' responses in terms of the meanings and ways of thinking they reveal; (4) Retire unusable items; (5) Interview teachers regarding responses that are ambiguous with regard to meaning in cases where it is important to settle the ambiguity; (6) Revise remaining items according to what we learned from teachers' responses, being always alert to opportunities to make multiple-choice options that teachers are likely to find appealing according to the meaning they hold; (7) Administer the set of revised items to a large sample of teachers.

We designed the item in *Figure 1* to reveal teachers' meanings for slope in the context of teaching. The inspiration for the name of the item came from Coe (2007) and his observations that the three teachers he interviewed did not connect the idea of slope with a measurement meaning of division. We designed Part B to prompt teachers to reflect on the relationship between any size change in x and the associated change in y because we anticipated many teachers would give responses to Part A that were similar to the student's explanation in Part B. We wanted to see if teachers could move beyond thinking of slope in terms of one-unit changes in x. Part B of "Slope and Division" gives teachers a chance to extend their meanings for slope to situations where x does not change by one, or alternatively reveal the limitations of their meanings for 3.04.

Mrs. Samber taught an introductory lesson on slope. In the lesson she divided 8.2 by 2.7 to calculate the slope of a line, getting 3.04. Convey to Mrs. Samber's students what 3.04 means. **Part B.** Mrs. Samber taught an introductory lesson on slope. In the lesson she divided 8.2 by 2.7 to calculate the slope of a line, getting 3.04. A student explained the meaning of 3.04 by saying, "It means that every time x changes by 1, y changes by 3.04." Mrs. Samber asked, "What would 3.04 mean if x changes by something other than 1?" What would be a good answer to Mrs. Samber's question?

Figure 1. The item "Slope and Division" was designed to reveal meanings for slope.

Rubric Development

After the first round of data collection from 144 teachers in Summer 2012 we categorized the thinking revealed in the items using a modification of a grounded theory approach (Corbin & Strauss, 2007). The modification is that we began our data analysis with strong theories of understanding magnitudes and rates of change, and of the nature of mathematical meanings and of characteristics that make them productive in instruction. We developed rubrics by grouping grounded codes into levels based on the quality of the mathematical meanings expressed.

We read the teacher's response literally, asking, "If this is what they said to a class, what meanings for the mathematical idea might students' learn?" During team discussions of rubrics and responses, we continually asked ourselves. "How productive would the teacher's response be for a student if this is what she or he said while teaching?" and, "How might students understand what the teacher said were they to take it at face value?"

The summary rubric for Slope and Division is given in Table 1. The rubric was refined many times as the project team conducted multiple rounds of scoring on data collected in Summer 2013.

Table 1. Rubric for Part A of "Slope and Division."

Level A3 Response:	The teacher conveyed that x can change by any amount and that y changes by 3.04 times the change in x.
Level A2a Response:	***Any*** of following: – The teacher wrote that for every change of 1 in x, there is a change of 3.04 in y. – The teacher wrote that for every change of 2.7 in x, there is a change of 8.2 in y. – The teacher wrote that a difference in x values is compared to a difference in y values.
Level A2b Response:	The teacher conveyed in words or graphically that the slope gives information about how to move horizontally and vertically. For example: – If x moves to the right 1 space, y moves up by 3.04. – If x runs by 2.7, y rises by 8.2. – The slope tells us to move horizontally by one and vertically by 3.04.
Level A1 Response:	***Any*** of following: – The teacher conveyed that 3.04 is the result of a calculation. – The teacher used a phrase such as "average rate of change", "constant rate of

	change" or "slantiness" without addressing the question of how 3.04 relates changes in x and changes in y. – The teacher simply stated the idiom "rise over run" without describing the changes.

Level A3 responses convey a multiplicative meaning for slope. A multiplicative meaning for slope builds on the meaning for quotient as a measure of relative size. Level A2a and level A2b responses convey an additive or chunky meaning for slope. Level A2a responses are considered slightly more productive for students than A2b responses because the meaning of slope in Level A2a responses is not constrained to horizontal and vertical motion on a Cartesian graph, but could be used productively in real world situations. Level A1 responses on our rubric represented more than one possible meaning for slope, but each of these meanings are similar in the sense that they convey that the meaning of slope is something to memorize. We scored responses that did not fit any other category at level A0. In cases where teachers responded with multiple meanings for slope in one response we decided to categorize their response according to the highest level meaning they conveyed.

Table 2. Categorization for Part B of "Slope and Division."

Gave reasonable meaning for 3.04	The teacher gave a mathematically reasonable explanation of what 3.04 means. For example "3.04 is the ratio" or "3.04 tells us how many times as large Δy is as Δx."
Gave explicit computations to find Δy	The teacher gave a clear instruction to find the change in y, the change in x should be multiplied by 3.04.
Gave vague computations to find Δy	The teacher answered the question "how to you find the change in y?" but does so without explicitly mentioning the change in y. For example they said "multiply it by 3.04."

The purpose of Part B is to allow teachers to think about the change in x varying continuously instead of in jumps of a fixed amount.

Briefly, common responses to Part B included explaining what 3.04 means, explaining how to find the change in y given an arbitrary change in x, or giving an example of how much y would change by if x changed by two. The quality of responses in each category varied from teachers who gave clear and understandable explanations of the meaning of 3.04 to those who explained what 3.04 meant by saying only "multiply it by 3.04." In scoring Part B we noted mathematical mistakes such as confounding y with Δy in a separate score not reported here. Although a portion of the responses at each level do contain mathematical errors, we categorize responses by the primary meaning conveyed ignoring mathematical mistakes. The categorization in Table 2 is based on our rubric for Part B. We will give the rubric for Part B and data in the longer paper.

Administration and Scoring

We administered the *MMTsm* to 157 high school teachers in two different Southwestern cities in Summer 2014. The high school teachers took the diagnostic exam at the beginning of professional development programs. The first author scored all responses to "Slope and Division." To estimate interrater reliability (IRR) an outside collaborator scored 50 overlapping responses. Scorers had perfect agreement on 84% of responses to Part A and 72% on responses to Part B. Non-perfect agreement was scored as disagreement. These IRR scores are lower than most other items on the *MMTsm* due to the complexity of teachers' responses. Responses were often not written in complete sentences and used pronouns with unclear antecedents so it was difficult to determine whether or not a student could make sense of the teacher's explanation. Because of the probability that the scorers might pick the same level by chance we also computed Cohen's Kappa for Part A (.773) and Part B (.621).

Results

The most common meaning conveyed in our sample was a chunky, additive meaning for slope (See Table 3).

Table 3. Responses to Part A "Slope and Division."

Response	Math Majors	Math Ed Majors	Other Majors	Total
A3-relative size	0	0	3	3
A2a-chunky	12	8	21	41
A2b-chunky graphical	19	29	30	78
A1-memorized	4	11	13	28
A0-other/IDK	1	1	2	4
No response	0	0	3	3
Total	36	49	71	157

Only three teachers out of 157 used a multiplicative meaning for quotient in explanations of slope in Part A. Approximately 76% of teachers showed a chunky or additive meaning for slope. Interestingly, about 86% of teachers who majored in mathematics and 82% of teachers who majored in mathematics education answered a chunky, additive meaning. Although chunky meanings for slope can be used productively in some situations, the responses to Part B often indicated that the teachers struggled to extend their chunky meaning to situations where the change in x is not equal to one. The response in Figure 2 conveys that slope gives information about how to move vertically and horizontally on a graph. The response conveys a chunky meaning for slope because the changes occur in chunks of one and 3.04. The meaning of 3.04 seems to be tightly tied to the change in y and only loosely connected to the associated change in x.

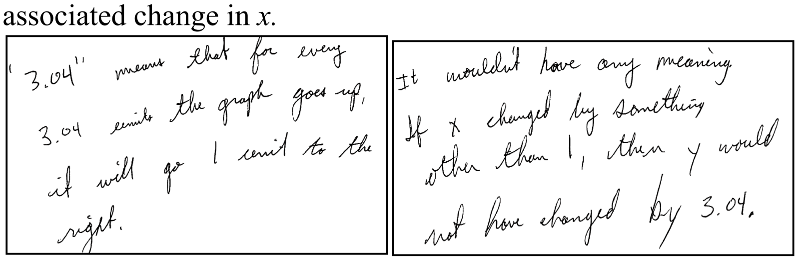

Figure 2. One teacher's "chunky" response to Part A and B.

The Part B response provides confirmation that for this teacher 3.04 is more strongly associated with the change in y, then a comparison of the relative size of the change in y and a change in x. It might convey to students that the slope gives information about vertical and horizontal motion on the graph and that the number 3.04 is only associated with the change in y and not with a comparison of changes in x and y.

The response in Figure 3 conveys that the slope is strongly associated with the change in y. In this case, the response incorrectly confounds the change in y with the slope. When the meaning for slope conveyed emphasizes that x changes by one the value of the slope and the change in y are identical and it becomes easier to confuse the two concepts.

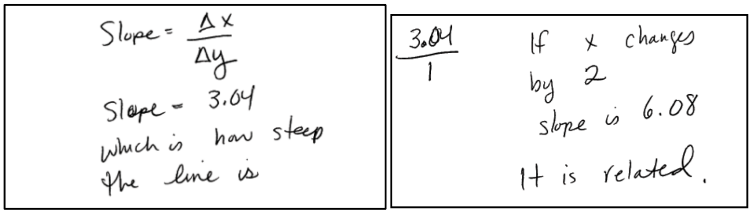

Figure 3. One teacher's response to Part A and associated chunky Part B response.

Some chunky responses conveyed that the only points on the line that "mattered" were the points obtained by the process of moving over and up in fixed chunks (see Figure 4). This response is not consistent with imagining that between any two points on the line there are infinitely many points.

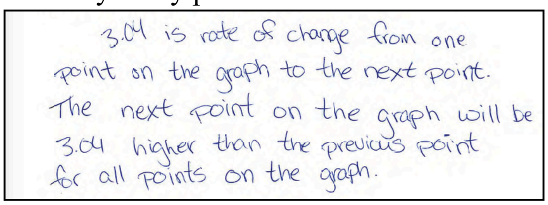

Figure 4. Chunky response conveying that the points on the line only occur at fixed intervals.

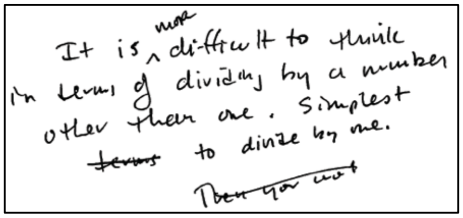
There are a variety of consequences of conveying that points on the line only occur at fixed intervals. If points only occur at fixed intervals it is possible to conceptualize slope as the distance between two points on a line. Some teachers in our sample explicitly responded that the slope is a distance between two points and some Calculus students who were interviewed on "Slope and Division" also told us explicitly that slope is the distance between the two points used in the slope formula. After confirming that, to the student, slope is a length, the interviewer asked the student, "Why do you divide the change in *y* and the change in *x* to get a length?" The student responded, "Because, it's you've got the one *x* here and the other one here and so you are trying to find the way which they both get to each other basically."

Table 4. Responses to Part A and Part B of "Slope and Division."

		Part B Response					
		Gave reasonable meaning for 3.04	Gave explicit computations to find Δy.	Gave vague computation s to find Δy.	Other	IDK Blank	Total
Part A	A3-relative size	1	2	0	0	0	3
	A2a/A2b chunky	30	31	18	40	0	119
	A1-memorized	2	8	6	8	4	28
	A0-other	2	0	0	0	1	3
	IDK/blank	0	0	1	0	3	4
	Total	35	41	25	48	8	157

In the case of the 48 responses categorized as "other" it was clear that the teacher struggled to respond to a situation with a change of *x* not equal to one. Note that 40 out of the 119 teachers who conveyed a chunky meaning in Part A were unable to cope with Part B in even a limited way.



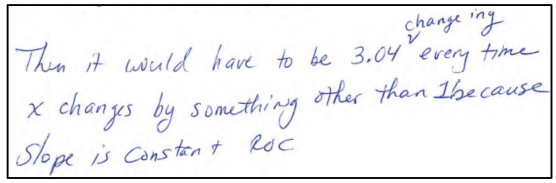


Figure 5. Two teachers (who conveyed chunky meanings in Part A)' responses to Part B

The two teachers in Figure 5 wrote chunky meanings in Part A and had difficulty explaining what 3.04 means when x changes by something other than 1. This is evidence that holding a chunky meaning for slope does not necessarily enable a teacher or learner to understand the proportional relationship between changes in x and changes in y.

Conclusions

The results show that many teachers have chunky meanings for slope that do not appear to be connected to an image of the relative size of Δx and Δy. If their meaning for slope was based on an understanding of the relative size of Δy and Δx, it should be easy to note that Δy is always 3.04 times as large as an arbitrary Δx in Part B. An inability to deal with an arbitrary sized Δx is problematic because in Calculus Δx becomes arbitrarily small yet retains a relationship of relative size with Δy. Although the results are not from a nationally representative sample of teachers, the sample size is large enough to strongly suggest that Stump's (1999;2001) and Coe's (2007) descriptions of a few teachers' meanings for slope are apparent in a much larger sample of teachers. Further investigations could use this instrument to research a nationally representative sample of teachers.

Separating issues in the learning of algebra from mathematical problem solving

R. Cavender Campbell	Kathryn Rhoads	James A. Mendoza Epperson
The University of Texas at Arlington	The University of Texas at Arlington	The University of Texas at Arlington

Students' difficulty in learning school algebra has motivated a plethora of research on knowledge and skills needed for success in algebra and subsequent undergraduate mathematics courses. However, in gateway mathematics courses for science, technology, engineering, and mathematics majors, student success rates remain low. One reason for this may be to the lack of understanding of thresholds in student mathematical problem solving (MPS) practices necessary for success in later courses. Building from our synthesis of the literature in MPS, we developed Likert scale items to assess undergraduate students' MPS. We used this emerging assessment and individual, task-based interviews to better understand students' MPS. Preliminary results suggest that students' issues in algebra do not prohibit them from using their typical problem solving methods. Thus, the assessment items reflect students' MPS, regardless of possible misconceptions in algebra, and provide a mechanism for examining MPS capacity separate from procedural and conceptual issues in algebra.

Keywords: college algebra, problem solving, algebra learning

Issues in Algebra

Research shows several sources of difficulty in learning algebra. For example, students struggle in understanding the meaning of variables. In algebra instruction, x is frequently called a *variable*, accompanied with statements such as "x can be anything." But this conception is particularly misleading for equations such as $2x + 7 = 13$, in which x is actually an unknown quantity (Kieran, 2007). Additionally, in functions, variables stand for inputs and outputs. Many students use x and y to write equations and functions but do not actually attend to the meaning of those symbols; Students use these letters solely as a placeholder in equations and functions to replicate examples they have seen (Chazan, 2000). This confusion increases student difficulty converting word problems into equations (Kieran, 1992).

Algebra students also struggle with the meaning of the equal sign. Although the equal sign is often used to indicate a relationship between two quantities, for a function, the equal sign represents a naming of an object. Further, many students view the equal sign as a connector or operation, with little meaning beyond indicating the direction of the solution path (Schoenfeld & Arcavi, 1988). This connector usage leads to student concatenating operations using an equals sign as if they are using a calculator (i.e. 4 + 7 = 11 + 3 = 14). In elementary school, students use a "guess and check" method of solving equations. However, formal procedures taught in algebra can be difficult for students to internalize, as they have not previously needed to maintain symmetry across the equal sign (Kieran 1992). Further, in solving $2 + \_\_ = 5$, elementary students place 3 in the blank, which appears to add 3 to only one side of the equation.

Although Kieran (2007) asserts that the use of technology in the algebra classroom improves student understanding of functions, technology can also lead to some misunderstandings about equations. Though the equations $y = 2x + 8$ and $-2x + y = 8$ are equivalent, if such an equations are part of a system of equations, x and y correspond to specific values in a solution set rather than inputs and outputs (Chazan & Yerushalmy, 2003).

Studying mathematical problem solving

Nationwide, more than 40% of undergraduates pursuing science, technology, engineering, and mathematics (STEM) majors failed to complete their degrees (President's Council of

Advisors on Science and Technology, 2012), and for many students, progress is blocked by their lack of success in foundational mathematics courses. For example, as few as 10% of calculus-bound STEM intended College Algebra students reach calculus (Dunbar, 2005). Though important skills and procedures needed for success in calculus are identified in the research (e.g., Carlson, Oehrtman, & Engelke, 2010), the specific knowledge and skills emphasized in gateway mathematics courses seems insufficient for students' progression in STEM majors. Students appear to lack the necessary mathematical problem solving (MPS) skills and reasoning to be successful. MPS is at the forefront of instructional goals in mathematics education (e.g., National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010; National Council of Teachers of Mathematics, 2000); however, little is understood the thresholds students must meet at various levels to ensure success in subsequent courses.

Campbell (2014) synthesized the research literature in MPS and separated MPS into five components. These components are sense-making, representing/connecting, reviewing, justification, and challenge/difficulty. Building from this work, we developed items to assess student's MPS in these areas. The MPS components or domains attend to three of the six problem solving components identified by Jonassen (1997) and the other components are controlled for in the design of the items. The roles of different components of MPS are largely unstudied due to the time and effort that must be invested to use existing tools (e.g. Oregon Department of Education, 2000; Dawkins & Epperson, 2014). By contrast, the goal of the emerging tool is to create a set of problem solving items that can be machine scored to quickly learn about students' problem solving techniques and practices. In the instrument, students complete a series of problems and then items targeting specific components of MPS. The items and instrument development are explained fully in Epperson, Rhoads, and Campbell (in press).

Student understandings in MPS and Algebra

This research takes place at a large, public university in the Southwest. We administered the MPS instrument to 70 (calculus-bound) College Algebra students and selected 11 for individual, one-hour problem-solving video-recorded interviews. In an interview, the researcher asks the student to explain his or her usual problem solving approaches and the specific MPS used on the problems and items from the assessment. The interview participants also complete a new problem and associated items. The recorded interviews were transcribed for analysis. The research adopts a mixed grounded theory approach to characterize the MPS used by the participants (Corbin & Strauss, 2008; Charmaz, 2006).

Interviews show interesting trends in students' MPS. First, participants only used diagrams and representing/connecting practices at the beginning of the problem solving process and did not incorporate them later. In addition, participants fixated on the problem statement, spending extra time rereading or rewriting the problem statement before attempting to solve the problem. These activities aligned with MPS capacity identified by their work on the MPS items. Participants' difficulties in algebra arose in the interviews. Students used confusing language pertaining to variable or unknown, such as "running through variables" to mean checking multiple values. A student also suggested that the needed *function* was an *inequality*. Despite these difficulties with algebra, students showed reluctance to use less analytical approaches. The students desired elegant functions or equations even if they proposed adequate solution paths using other logical means. However, many eventually used their less-preferred approach. These results indicate that students' limitations in algebra do not necessarily halt their problem solving practices. The implications of equal sign confusion are also under investigation. Separating the challenges of algebra learning from problem solving can provide a window into aspects of MPS necessary for student success in gateway mathematics courses for STEM.

Calculus students' deductive reasoning and strategies when working with abstract propositions and calculus theorems

Joshua Case
University of Maine
jpcase@mix.wvu.edu

Natasha Speer
University of Maine
speer@math.umaine.edu

In undergraduate mathematics, deductive reasoning is an important skill for learning theoretical ideas and is primarily characterized by the concept of logical implication. This plays roles whenever theorems are applied, i.e., one must first check if a theorem's hypotheses are satisfied and then make correct inferences. In calculus, students must learn how to apply theorems. However, most undergraduates have not received instruction in propositional logic. How do these students comprehend the abstract notion of logical implication and how do they reason conditionally with calculus theorems? Results from our study indicated that students struggled with notions of logical implication in abstract contexts, but performed better when working in calculus contexts. Strategies students used (successfully and unsuccessfully) were characterized. Findings indicate that some students use "example generating" strategies to successfully determine the validity of calculus implications. Background on current literature, results of our study, further avenues of inquiry, and instructional implications are discussed.

Key words: Logic, Implication, Calculus, Theorems, Conditionals

Background and Research Question

Calculus plays a fundamental role in many science, technology, engineering, and mathematics (STEM) areas such as physics and engineering. Thus, many STEM majors will take at least one semester of calculus as part of their major, during which they will encounter propositions, lemmas, and theorems. For example, students encounter the "If a function is differentiable at a point, then it is continuous at that point" theorem. Students must then apply this theorem in a variety of situations, such as when they are given a function that is differentiable or when they are given a function that is continuous. This deductive process, characterized by logical implication, is a hallmark of mathematical thinking. It seems natural to assume that to use a theorem effectively, a student must comprehend logical implication, which requires the understanding of the four classic reasoning patterns. These patterns are provided below with the assumption that the rule "A implies B" holds.

Modus ponens: Suppose A is True. Then B is True.
Inverse: Suppose A is False. Then it is not known whether B is True or False.
Contrapositive: Suppose B is False. Then A is False.
Converse: Suppose B is True. Then it is not known whether A is True or False.

Applying this reasoning can enable a student to know, for example, that a function being continuous at a point does not necessarily imply that it is differentiable at that point.

It is well-established that both children and adults struggle with these kinds of logical reasoning tasks (O'Brien, Shapiro, & Reali, 1971; Wason, 1968). However, it appears that people are more successful when the questions are posed in a context (as opposed to abstractly) (Stylianides, Stylianides, Philippou, 2004). Also, it is well known that students struggle with calculus ideas such as limits, differentiation, and integration (e.g., Carlson & Rasmussen, 2008; Tall, 1993; Orton, 1983; Zandieh, 2000). The instruction students receive about these key calculus ideas often includes theorem or theorem-like statements and students are expected to reason logically from them. Although much work has been done separately on the issues of logical implication and calculus learning, we know little about how students engage with logic tasks that are set in a calculus context. In particular, we were interested in whether calculus students had the same kinds of difficulties with calculus-based tasks as they did with the purely abstract tasks. In other words, are calculus theorems enough of a "context" to support students' productive reasoning or are those tasks treated in the same way as the classical, abstract tasks? This research project was designed to examine the following questions: How successful are calculus students with logical implication tasks set in calculus and abstract contexts? What strategies do students use when engaged in calculus theorem tasks involving logical implications? Answers to these questions can provide insights into student sense-making that can be then used to inform instructional design aimed at improving student understanding of theorems and definitions in calculus.

Research Methods
