Even though the definition of area is straightforward, researchers demonstrate that current and future elementary teachers struggle with this concept of area (Enochs and Gabel, 1984; Simon and Blume 1994; Baturo and Nason, 1996; Reinke, 1997; and Menon, 1998). We, the current authors, were mathematics teacher educators at public universities at the time of the study. Over our collective years of working with pre-service teachers (PTs), we have noticed independently that our PTs struggle with defining and using area units, especially non-standard units. In conversation with each other, we found that our observations were very similar irrespective of our classes being at two different universities in two different states. This led us to our first study (Ghosh Hajra, McNeal, & Bowers, 2016), where we documented many of our PTs have difficulty defining a "square unit" and often reported answers in "square units" when measurements were actually taken using non-standard units. We found a wide gap between PTs' definitions of area and their use of area units. We also found that PTs particularly struggled when they had to find areas of irregular 2D shapes using non-standard units.

Our instructional goals for our PTs' learning include: 1) deepening their understanding of each geometric concept that they will teach and 2) preparing them to articulate fundamental features of each topic by pushing them to think beyond the level of mathematics that they will teach. In our instruction, we have begun to broaden the meaning of area to be the amount of 2D space taken up by a planar figure and measured using *any* two-dimensional object as the area unit. We describe *measurement* as a comparison of the given area unit with the 2D shape, as accomplished by covering the shape with an iteration of the area units and counting how many area units can fit in the shape. For example, consider the hexagon in Figure 1 as an area unit. We can iterate this unit to cover the blue region. The area of the blue region is then the number of hexagons that are needed to cover it, or 9 hexagons. Our area instruction thus aims to prepare our

PTs to respond to the following questions based on our course goals: What makes an appropriate unit of area? How does one use this unit to measure area? How does one report the resulting measurement, whether using a standard or non-standard unit?

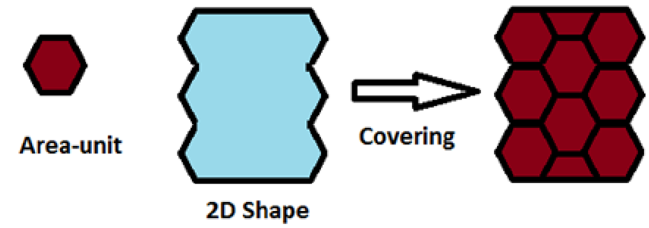

Figure 1: Measuring area using a non-standard area unit.

Like all classroom teachers, we aim to improve our instruction through close study of our students' work. We asked ourselves what effect continued work in class with a variety of non-standard units would have on PTs' understanding of area and its measurement. This led us to develop new area tasks for the students in our classes in Spring 2016. One of the limitations of the first study (Ghosh Hajra et al., 2016) was that we analyzed only students' written responses. The current study is an extension of the Ghosh Hajra et al. (2016) investigation, using data from the new group of students. The ideas expressed in the current paper emerged as the first author engaged in conversation with her students during the spring 2016 class and then in out-of-class interviews about their responses to the newly developed area tasks. Although our informal observations were the basis from which we articulated the points of cognitive conflict in PTs conceptualization of area-units, we undertook this latest study to enrich our understanding of these conflicts by looking more closely at students' thinking through the interviews. We also hoped this would move us toward validating the points of cognitive conflicts PTs have with area and area units. In this paper, we discuss the progress one of the 30 PTs in the study made in the process of measuring area. This particular student was selected because her thinking and points of confusion around the meaning and use of area units reflected the thinking of many other PTs in the class.

Theoretical Framework

The constructivist theory of learning provides the theoretical framework for this study in that it drives both our classroom instruction and our interpretation of the participants' thinking, whether derived from written work or from interviews. From the point of view of constructivism, new ideas are generated by individuals when new situations and experiences, which conflict with existing ideas, cause the individuals to modify their existing ideas (von Glasersfeld, 1995). Based on this theory of learning and in pursuit of our course goals, we pose non-traditional tasks as a regular feature of our instruction. These tasks (initially conceived as instructional materials rather than data tasks) are selected and sequenced to help PTs examine their own thinking and to provide a source of cognitive conflict. We hypothesized that tasks involving non-standard area units would be a significant source of productive conflicts and might cause reorganization of PTs' area concepts when needed.

Methodology

The first author was the PTs' instructor for a geometry course, the second part of a two-course mathematics sequence for elementary teachers. Thirty PTs enrolled in two sections of this course participated in a semester-long research project examining PTs' understanding of area units. The instructor used the Beckmann (2013) mathematics textbook that is aligned with the Common Core State Standards Initiative (2010).

In our first study (Ghosh Hajra et al., 2016), tasks were designed in the middle of the semester and PTs' written responses to those tasks were the focus of the report. PTs were not interviewed for additional clarification of their work. In the current study, we used *Units Task 1* (Figure 2) from Ghosh Hajra et al. (2016) as well as new tasks aligned with our instructional goals. The instructor posed several non-traditional tasks on area and, in class, listened to PTs' real-time responses for informal feedback on their understanding. This feedback was used to design follow-up class activities in a manner reminiscent of Simon and Blume (1994). In-class writing assignments, quizzes, tests, and the final exam were collected from all thirty PTs. A few clinical interviews (Clement, 2000) were conducted with eight of the PTs about their in-class work and other assignments individually. Each of the interviews was videotaped and transcribed, and the written work was digitized.

We used qualitative research methods to analyze our data. Our qualitative analysis drew on the techniques of grounded theory, constant comparison, and retrospective analysis. Our developing theories were grounded in our initial observations as classroom teachers and constantly compared to new classroom observations (Strauss & Corbin, 1990). We provisionally tested our theories in classroom interactions and by conducting interviews while instruction was ongoing. We developed, modified and generated new tasks through engaging in conversations with each other and with the students (PTs). We used the retrospective analysis procedure (Steffe & Thompson, 2000) to analyze videotaped interviews and students' written work to understand students' ways of conceptualizing area and area units after the conclusion of the period of instruction. Each author analyzed the interviews independently and later discussed them together. We followed all PTs closely throughout the semester to examine their conceptions of area and area units. This study reports only the work of one PT, Martha (pseudonym), who performed well in the first course in the sequence with the same instructor, and whose thinking was representative of the rest of the class as demonstrated in the entire data collection. This PT was selected as a case study on the basis of our retrospective analysis and after the conclusion of the instructional period.

Results

How can non-square units be square(d)?

In our first study, we observed PTs' unusual written responses to non-square units. This led us, in the current study, to watch closely how PTs engaged in the same tasks (and some new tasks) during class. Based on their work in class and written responses, individuals were selected for interviews to clarify our understanding of how they were thinking.

Early in the semester, the instructor presented the class with Task 1, shown in Figure 2. The goal of this task is to use the 2D shapes marked *a*, *b*, *c*, and *d* as area units to measure the area of the larger shapes *A*, *B*, *C*, and *D*, respectively. Martha used "unit^2" and "units^2" throughout even though her calculations were based on the given area units. While a "square unit" is defined as a 1-unit by 1-unit square that is used to measure the area of a shape, Martha's use of "units^2" in all tasks seemed to occur without regard to the actual unit given. For example, she wrote "11 unit^2" as her answer to Task 1 b) which asked her to find the area of shape *B* using a triangle.

Task 1: Find the areas of the shapes (A), (B), (C), and (D) using the following 2D shapes (a), (b), (c), and (d).

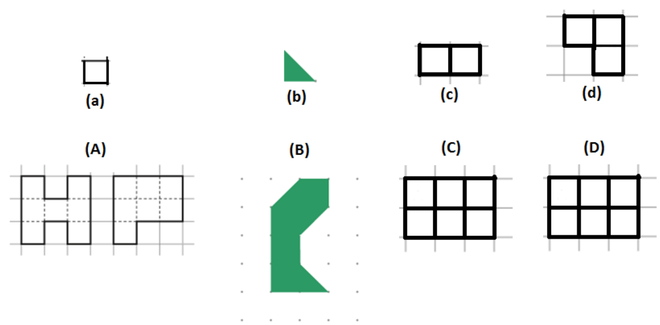

Figure 2: Area task involving standard and non-standard area units.

After several weeks of instruction, Martha reported the area of a shape in terms of the given unit, but still used the "squared" terminology. An example of this came up during the follow-up interview in which she was asked how she would interpret covering a rectangular piece of paper with a specific number of triangles and hexagons. Her responses are cited in Figure 3.

Interviewer: Suppose you have 20 triangles filling the rectangular shape [showing a rectangular piece of paper], what will be the area of the rectangle?
Martha: It will be 20 triangular units.

Interviewer: Say you try to cover this piece [a rectangular sheet of paper] with a hexagonal region [showing a hexagon drawn on a paper], and you need 36 such [hexagonal] pieces, so what will be the area of this [rectangular sheet of] paper?
Martha: It would be 36 hexagonal regions squared.

Figure 3: Martha's responses on task 2 (shown in Fig 4).

Martha used the number of triangular units when stating the area of the sheet of paper, but when she referred to the area of the same region in terms of hexagons, she added the word "*squared*". Martha's reporting of the answer was correct for the triangular units, but her response to the hexagonal unit was technically incorrect. Martha appeared to be uncomfortable with simply reporting the number and type of unit as an area, i.e., saying "36 hexagons". This is indicated by the extraneous (to our ears) use of the word "square". She understood that the unit of measurement should be specified, but clearly did not yet completely understand the meaning of a "square unit". Hence, the use of a non-square unit causes students to experience cognitive conflict and compels them to reconsider the meaning of "1 square unit". Martha and PTs like her do not seem to view a "square unit" as a 1-unit by 1-unit square. That is, saying that something has an area of "6 square inches" does not seem to mean that it has been covered with "six 1-inch by 1-inch squares". Simon and Blume (1994), who studied the multiplicative understandings of pre-service teachers in the context of area, found similar responses and observed, "It is likely that for some of these [PTs], square units do not conjure up an image of a square" (p. 485). In fact, one of our PTs went so far as to write on a quiz that "a square inch is not a square".

How can we find the area of a shape when the area unit is neither square nor polygonal?

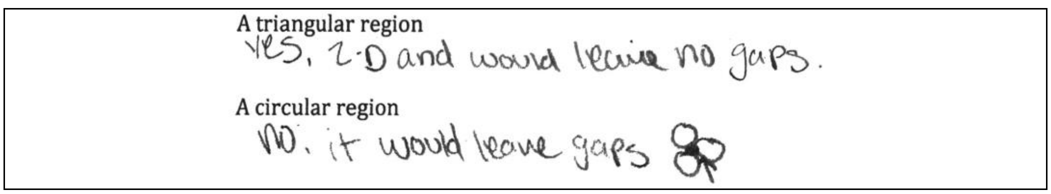
After a couple of weeks of instruction on area, the following task (Figure 4) was presented on a midterm exam.

Task 2: **Which of the following can be an area unit?** Provide reasoning for your choice.

A 1inch-by-1 inch square, a triangular region, a circular region, length of your finger, width of your finger, a finger nail, length and width of your finger, a hexagonal region, a toothpick, and a ribbon.

Figure 4: Area unit task.

Martha responded that all of the listed items could be area units except the circular region, length of your finger, and width of your finger. She correctly described why the triangular region can be an area unit explaining that it is a 2D shape and multiple copies of it can fit together to cover a shape without leaving any gaps (see Figure 5). However, Martha reasoned that a circular region could not be used as an area unit because the units would not fit nicely together without leaving gaps. She makes this conclusion regardless of the particular shape to be measured. Martha's thinking reflects the thinking of many other PTs in this study and others we have encountered in our teaching careers. It seems that most PTs believe area units need to have nice straight edges, i.e. only a polygonal 2D shape can be an area unit.



A triangular region

yes, 2-D and would leave no gaps.

A circular region

No. it would leave gaps

Figure 5. Written response of Martha on the area unit tasks.

When the area unit under consideration is polygonal and the shape to be measured is also polygonal, it is reasonable to Martha that an area unit be decomposed because the area units fit nicely inside the shape without any gaps. The same holds true along the boundary. For example, in Figure 1, we saw that the hexagonal area unit needed to be decomposed into halves to cover the region. This is an application of the moving and additivity principles of area in the measurement of area. The moving principle states that moving an area unit rigidly without stretching maintains its area. The additivity principle states that if we combine a finite number of area units (whole or part units), the area of the resulting shape is the sum of the areas of the individual area units. When faced with a circular unit, the question of whether we can cover our shape with this unit became an issue even before considering the particular shape to be measured.

How can we use square or polygonal area units to measure the area of a shape with curved boundaries?

In the next task (Figure 6), Martha was asked to find the area of the circle using the non-standard polygonal area unit. To answer part (a), Martha wrote that the "exact" area cannot be found using the given area unit. For part (b), she tentatively mentioned that the moving and additivity principles of area could be used, but was not sure how to account for the parts of the circle that cannot be covered by a whole area unit. Martha wrote, "*No it is not possible because the Area unit is using straight edges which would leave parts of the circle unmeasured. If we used the moving and additivity principles to manipulate the area shape to fill in those missing parts we couldn't count the number of 'area units' it created to be exact."* In an interview about this task, she explained that, since the area unit is not the usual square grid, it was not possible to "*know exactly how many will fit in even if you do break it apart*." Note that with the polygonal area unit, she immediately showed understanding that she could break the unit for purposes of covering the circle, but the curved boundary became now the source of cognitive conflict. This part of her response also suggested that, even if the unit could be broken, it could not be used to fill curved spaces.

When the interviewer asked her if she could estimate the area, Martha was able to do so by counting the full area units first, finding that 10 complete area units would fit in the larger shape, and then decomposing the area unit further to obtain a total of approximately 17 area units. When asked if she would like to change her answer to part (b) of task 3, Martha said, "*Yes it's possible but I guess it wouldn't be, like it is possible but it's not possible to give you an exact—like a perfect measurement. Unless you know the exact, how like big that is [the circular region] compared to that [given area unit], like how many of those [given area units] go in here [within the circle] and how many of these [given area units] cause these [leftover parts within the circle] aren't the same.*" Martha seemed to feel that the units could be decomposed a few times, but that the process could not be completed—no straight-edged units could ever completely fill a region with a curved boundary.

Task 3: a) Find the area of the following region bounded by the circle using the given area unit.

Area unit:  The 2D shape: 
b) Is it possible to use the above area unit to measure the area of the above circular region?

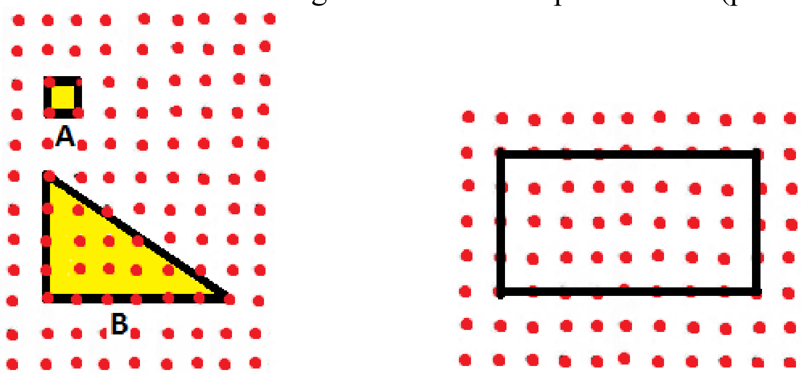
Figure 6. Task 3: Measuring the area of the circular region using a non-standard unit.

When using squares and triangles as area units, Martha was able to articulate the idea clearly. However, with non-polygonal non-standard area units and 2D shapes with curved edges, she had difficulties. Martha assumed her area calculation needed to be exact. Even though she was able to calculate an estimate of the area of the circular region using the non-standard unit, she did not think she could find the exact area.

Discussion and Conclusions

Our repeated questioning of Martha in and out of class over the semester generated cognitive conflicts that ultimately helped her recognize an area measurement as meaningful when obtained by covering a shape with a non-standard unit. Martha's understanding of area unit had thus grown in two ways: 1) identification of any 2D shape as a possible area unit (without regard to efficiency or ease of use) and 2) awareness that an area unit need not have straight edges.

Task 4: Consider the units of area given below as shapes A and B (picture to the left).



For each unit, indicate whether or not the 2D rectangular shape (picture to the right above) has an area with the given unit. If the shape DOES have an area with the unit, explain how you would find it using the unit. If it does not, explain why not.

Figure 7. Final exam question.

Martha continued, however, to have trouble making sense of her work when asked to interpret her "area answer" in terms of that non-standard area unit. On the final exam, when we repeated Task 1b, Martha gave her answer as "*11 triangle units squared*". On the same exam (Task 4 in Figure 7 above), she correctly identified the area unit and mentioned the decomposability of that unit. She wrote that both A and B could be used as area units. She wrote that 32 of unit A would be needed to fill up the space, but using unit B would require that we "*break it [the unit] apart filling in the gaps, which would be a little over 2 times*".

Our analysis suggests that engaging Martha in various tasks generated cognitive conflicts which influenced Martha's understanding of area. Our data also illustrates that we have not generated sufficient conflicts to disrupt her habitual use of square units.

Overall, students' understandings of the process of area measurement (separate from the formula "length times width") and of area units themselves (other than squares) were deeply enriched through tasks involving non-standard area units and through discussion of their responses. We propose two new types of tasks for work with future students. First, we would like to pose tasks that involve covering a shape with non-standard units (such as different-shaped post-it notes) with the idea of engaging PTs in thinking about fitting curved units into polygonal boundaries and polygonal shapes into curved boundaries. Finally, we propose to have PTs use rectangular units to cover larger rectangles as a way to coordinate their meaning of area with the definition of multiplication in the formula for the area of a rectangle.

Contextualizing Symbols in Word Problems

Sayonita Ghosh Hajra
Hamline University

Victoria Kofman
Stella Academy

The Common Core State Standards recommend students to decontextualize word problems using symbols and contextualize symbols by defining the meaning of values. We observed pre-service teachers' difficulties with contextualizing symbols in word problems; hence, we incorporated supplementary word problems' modeling instructions for an arithmetic course with pre-service teachers. After six weeks of instruction, on a midterm exam, our pre-service teachers started using symbols to present arithmetic word problems. However, many of them still could not clearly define the meaning of the symbols they used. After completing the program, students demonstrated improvement in their reasoning with symbols. We believe difficulties with defining symbols are connected to weaknesses with active scientific vocabulary in terms of measurable attributes. Therefore, we propose mathematics courses for prospective teachers to accentuate scientific vocabulary regarding measurable attributes.

Key words: Algebraic reasoning, symbols, pre-service teachers, word problems

One of the main goals of the Common Core State Standards Initiative (CCSSI, 2010) is to promote quantitative reasoning. Thompson (2011) stated quantification as the "process of conceptualizing an object and an attribute of it so the attribute has a unit of measure, and the attribute's measure entails a proportional relationship (linear, bilinear, or multi-linear) with its unit" (p. 37). For example, in the statement, *Ravi bought 3 kilograms of flour*, a qualitative attribute is *weight* and a unit of measure is *kilogram*. Here, the measurable attribute (*weight*) is not specified but can be deducted from the text.

Another aspect of children's education greatly emphasized by CCSSI is early development of algebraic reasoning. According to Kaput and Blanton (2005), algebraic reasoning requires students to "generalize mathematical ideas from a set of particular instances, establish those generalizations through the discourse of argumentation, and express them in increasingly formal and age-appropriate ways" (p. 99). Lins and Kaput (2004) recommend developing algebraic reasoning in elementary grades. The National Mathematics Advisory Panel of the U.S. Department of Education (2008) acknowledged this, since research has shown most students struggle in algebra in secondary grades (Kieran, 1992). An early introduction of algebraic reasoning might help in transition to algebra in later mathematics classes. Low algebraic skills are believed to be a gatekeeper to progress in mathematics and science (Greenes et al., 2001).

One of the features of algebraic reasoning includes an ability to decontextualize word problems, i.e., "to abstract a given situation and represent it symbolically and manipulate the representing symbols as if they have a life of their own, without necessarily attending to their referents" and contextualize symbols by attending to the meaning of quantities, i.e., "to pause as needed during the manipulation process in order to probe into the referents for the symbols involved" (CCSSI, 2010, p. 6). As a symbol, some choose basic letters (A, B, C, X, Y, Z, etc.) (Davydov, 1975; Dougherty & Slovin, 2004), while others use *parameter pointers*, letters or words, that point to key words connected with qualitative characteristics of values (Kofman, 2016). The latter are routinely used in physics (Serway & Faughn, 2006) and chemistry (Dingrando et al., 2006). Parameters, such as *V_1 is the volume of a gas before expansion* or *m is the mass of an obje*ct, are used to remind a problem-solver about the symbols' meaning in challenging word problems, which involve multiple symbols. Shifting gears toward problem-solving (CCCSI, 2010) increased the role of teaching students to use symbols, which help with solving word problems.

According to CCSSI (2010), children should start developing knowledge regarding measurable attributes as early as kindergarten and be able to “describe measurable attributes of objects, such as length or weight” (CCSS.Math.Content.K.MD.A.1, p.12). A well-developed understanding of measurable attributes helps students to develop an active scientific vocabulary—a basis for communicating math ideas needed to successfully solve mathematics word problems. CCSSI (2010) expects 6^{th} graders “to use variables to represent numbers and write expressions when solving a real-word or mathematical problem” and “understand that a variable can represent an unknown number, or, depending on the purpose at hand, any number in a specified set” (CCSS.Math.Content.6.EE.6, p. 44).

Since we want our elementary and middle school students to start developing algebraic reasoning by presenting word problems using symbols, we need to ensure teacher candidates (pre-service teachers) are fluent with this material because, according to Patton et.al. (2008), pre-service teachers “possess naive conceptions believing that teaching mathematics is only about delivering facts and memorizing mathematic procedures” (p. 494). Patton’s finding corroborate with early studies, which demonstrated undergraduates (non-physics majors) display difficulties with algebraic reasoning, particularly with interpreting variables when solving math problems (Rosnick, 1981). Also, MacGregor and Stacey (1997) have shown novice algebra students do not understand the meaning of symbols and commonly misinterpret symbols as representing objects or words.

We hypothesized pre-service teachers might exhibit similar difficulties. Although, the research regarding prospective teachers’ difficulties with generalizing patterns (Brown & Bergman, 2013; Hallagan, Rule, & Carlson, 2009) was undertaken recently, future educators’ active vocabulary with implicitly stated attributes has not been studied, yet.

Based on this, we closely monitored pre-service teachers (our students) performance on contextualizing symbols for simple arithmetic word problems. Observing their difficulties with defining the meaning of symbols in word problems, we undertook this research to analyze how prospective teachers contextualize symbols in word problems. To meet students’ needs, we strongly emphasized developing scientifically valid active vocabulary, which ensured fluent communication in terms of symbols, measurable attributes, and units of measure. Since high-level communication skills are a necessary condition for developing thinking (Vygotsky, 1978), we expected by increasing pre-service teachers’ abilities to communicate using correct terminologies, we could deepen their understanding of word problems; hence positively affect developing communication skills of their future students. Thus, the second stage of the research was to provide specific instructions to improve pre-service teachers’ abilities to identify measurable attributes and clearly define symbols used for presenting arithmetic word problems and acquire preliminary estimation of its impact.

Theoretical Framework

Our theoretical framework is based on the schemata approach. A *schemata* approach subdivides simple addition word problems into logical categories (Combine, Compare, Change, etc.) (Jitendra et al., 2007; 2015) and proposes schema for solving each type of word problem. We believe the schemata approach works because it helps students to concentrate on one learning dimension at a time, while allowing some variations. According to Marton and Pang (2006), namely ‘dimension variation’ elevates quality of the learning process. In the schemata approach, students learn to solve and present one type of problem (one learning dimension), while choosing between arithmetic operations (variation). This approach allowed us to concentrate on teaching students one dimension at a time—students solve one type of problem, while creating algebraic and visual word problems’ models specific for each type.

Contrasting variations were applied in the following aspects:

a) Problems were assigned that can be solved using addition or subtraction in each type of problem (Combine, Compare, and Change problems);
b) Students were taught to continuously differentiate between symbols (capital letters) and units of measure (lower case letters) by denoting them in different ways;
c) Students were taught to define parameter-pointers using precise definitions based on naming attributes (e.g., M is the distance Marta walked), which created a contrast with parameters' associative meaning (e.g., M is Marta).

Using the schemata approach combined with modeling and defining parameter-pointers allowed us to apply the dimension variation method when creating materials designed to improve pre-service teachers' knowledge how to interpret symbols they use.

Methodology

Participants and the word problem-solving (WPS) Treatment

Seventeen pre-service teachers from a western research university enrolled in an arithmetic course for elementary teachers participated in this study. The lead author taught the arithmetic course. This course was the first content course in a two-course sequence for elementary pre-service teachers. This course provided pre-service teachers with a deeper understanding of the real number system and arithmetic operations for whole numbers, fractions, and decimals for Grades K-6. The course textbook was written by Beckmann (2014). Mainly, chapters 1 through 9 were covered during the semester.

Along with standard course materials, supplementary materials on word problem-solving (WPS) were used throughout the semester. These supplementary materials (available upon request) were independently developed by the second author and were chosen because no books concentrating on developing teachers' vocabulary regarding measurable attributes and defining symbols for arithmetic word problems exist to the best of these authors' knowledge. These supplementary materials were self-explanatory workbooks, consisting of 13 chapters. Pre-service teachers read each of the chapters, each chapter comprised of multiple sections, worked on the examples, and completed the assigned problems for each section. The exercises involved presenting arithmetic word problems using multiple models and then solving the problems. The WPS workbooks focused on the following list of measurable attributes: number of objects, amount of money, length-type characteristics (depth, width, distance, height, and length), volume, weight (in terms of *mass*), temperature, and time.

The instructor provided feedback after pre-service teachers handed their assignments to the instructor during each class period. The instructor spent five-ten minutes in class discussing pre-service teachers' work and ideas from each section of the WPS materials. Pre-service teachers were given chances to correct their assignments until 100% fluency was shown with the assignments. When teaching the WPS supplementary program, the instructor constantly monitored pre-service teachers' progress, mistakes, and misconceptions, and focused on extending and sharpening students' mathematical vocabulary. The dimension variation approach was used to teach problem-solving topics. It includes materials teaching identification of the meaning of symbols (Table 1).

After the mid-term exam, pre-service teachers were asked to define each of the symbols they used when presenting word problems. Also, pre-service teachers were divided into groups of two or three and given word problems to work in class—they presented their solutions to the entire class. Pre-service teachers modeled arithmetic problems using visual and algebraic representations. When presenting problems in the form of algebraic equations, pre-service teachers were prompted to use parameter-pointers. For example, T_1 *is the number of flowers Linda had* <u>*at first*</u> or *R is the length of* <u>*Rob's*</u> *wire.*

Table 1
Objectives connected with contextualizing symbols in word problems

Dimensions of learning	Variations
Create models presenting word problems.	After presented separately, different types of problems were mixed together: combine, compare, and change.
Present problems using symbolic equations.	Denote symbols and measurement units for each problem, while using capital letters for parameter-pointers and lower case for measure of units.
Define parameter-pointers in symbolic equations.	Types of attributes (number of objects, amount of money, the distance between, …, etc.) were varied.

In the beginning, the WPS workbook contained word problems with easy to define attributes: "Linda has 5 erasers," and attributes were stated explicitly: "The weight of Linda's chair is 7 lbs." Later in the semester and during the final exam, more difficult, *implicit (not stated directly)* attributes were used in word problems, "Agnes collected 84 liters of rainwater." In such problems, pre-service teachers had to deduce the name of the qualitative attribute (*volume*) connected with the given value, 5 liters.

Data Collection and Analysis

The research design was a mixed-methods study. Data were collected from the pre-service teachers' writing assignments—two pre-tests, WPS workbook, quizzes, a midterm exam, and a final exam and instructors' classroom observations. A strong correlation in students' written work (correct usage of scientific vocabulary) and their usage of the vocabulary in oral presentations in the classroom were observed. For qualitative analysis, the pre-tests, mid-term exam, quizzes, and final exam written data were analyzed following an open, axial coding method (Strauss & Corbin, 1998). Each of the two authors read the written works and created a rubric. Then, we met to discuss our rubrics and created a common rubric (Table 2), based on pre-service teachers' presentations and explanations of the symbols used. For quantitative analysis, we created an excel spreadsheet of the responses for each task in the pre-tests, mid-term and final exam, which allowed us to follow an individual's progress throughout the semester. We recorded the responses using the rubric in Table 2 and counted the number of pre-service teachers in each category.

Table 2
Categories of symbols' descriptions

Coding categories	**Examples**	
Students demonstrate difficulties	Not defining symbols	Writing *Anna = 9*, A= 9, or X=9 and not saying what *A, Anna,* or *X* mean.
	Definition reflecting misconception	Defining symbols using key words from the text. *A means Anna*
Students present conceptually correct definition of symbols	Unclear naming of quality of quantity	Explaining symbols while inaccurately defining the qualitative characteristic of the symbols. *A is the grams of apples.*
	Clear naming of quality of quantity	Clearly associating symbols with their meaning. *A is the weight of apples.*

Results

The pre-tests run on the first two days of the semester demonstrated our pre-service teachers had difficulties to explain the meanings of the symbols they used in the word problems. After observing pre-service teachers' difficulties with CCSSI K-6th grade materials, we used the supplementary WPS materials for six weeks. The WPS sections regarding measurable attributes were thoroughly discussed in the classroom.

After six weeks into the semester working on the WPS materials, we found pre-service teachers continued to struggle with the concept of contextualizing symbols. More than half (9 out of 17) did not contextualize the symbols in the mid-term exam. For a *Combine* addition task, one pre-service teacher wrote "*P = Pearls*" (Figure 1a) instead of writing "*P is the weight of the box with pearls.*" Another wrote "*F = First box*" instead of writing "*F is the weight of the first box*." It is interesting to note, the same students appeared under the same categories for the two tasks (Table 3). It is noted, the materials were also reviewed a day prior to the midterm exam.

The final exam contained word problems with *implicitly* stated quantities (i.e., attributes are implied in the word problem, not directly mentioned) (see problem in Figure 2). In spite of this, we saw an increase in the *conceptually* correct definitions of symbols. The definitions reflected students' understanding of symbols, but were still somewhat unclear with precise defining measurable attributes (e.g., Figure 1b). We classified such answers as unclear, but in terms of symbol definition, conceptually correct. Across four different tasks in the final exam, 16 (15 in tasks involving length) students defined the symbols correctly or at least *conceptually* correctly (see Table 3).

Table 3
Comparison of pre-tests, mid-term, and final exam. The problems' difficulty in terms of contextualizing symbols was higher on the final exam than on the pre-test and mid-term.

<tr><td colspan="5">Note: The numbers above show the number of pre-service teachers under each category for each problem type.</td></tr>
</table>

Students were taught to use any letter but "O" when creating symbols to prevent confusing "O" with *zero*. However, 15 students used "O" as a symbol to represent the weight of onions and only 2 students used other letters. Figure 3 demonstrates how the same symbol, P, has different meanings in a word problem involving volume. Since the measurable attribute was not explicitly mentioned in the problem, four pre-service teachers used the same words used in the word problem, but failed to use the correct attribute name, *volume*, when defining the symbols.

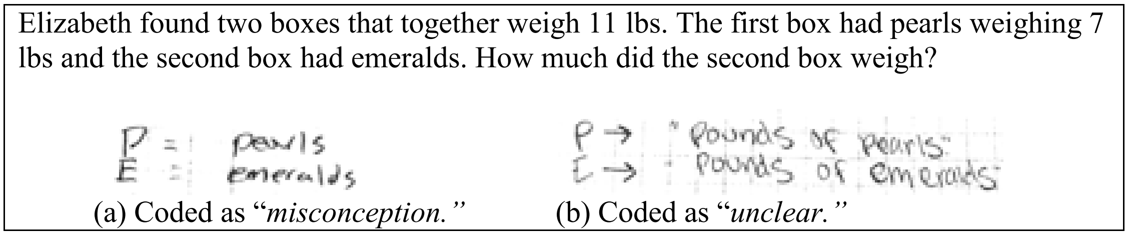

Figure 1. Symbol definition: a) misconceptions regarding parameters, b) missing attributes.

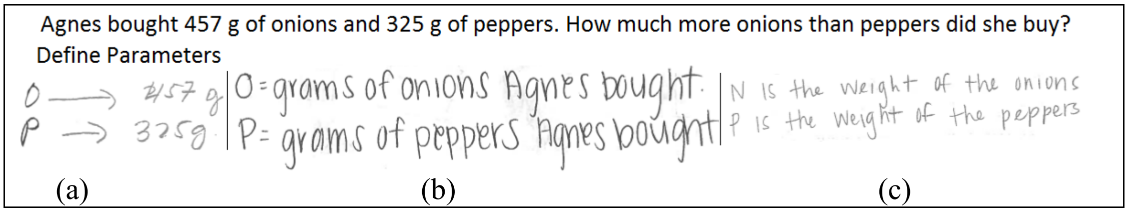

Figure 2. Defining symbols: (a) definition is unavailable; (b) definition is conceptually correct—there is a misconception regarding attribute; (c) correctly defined symbols.

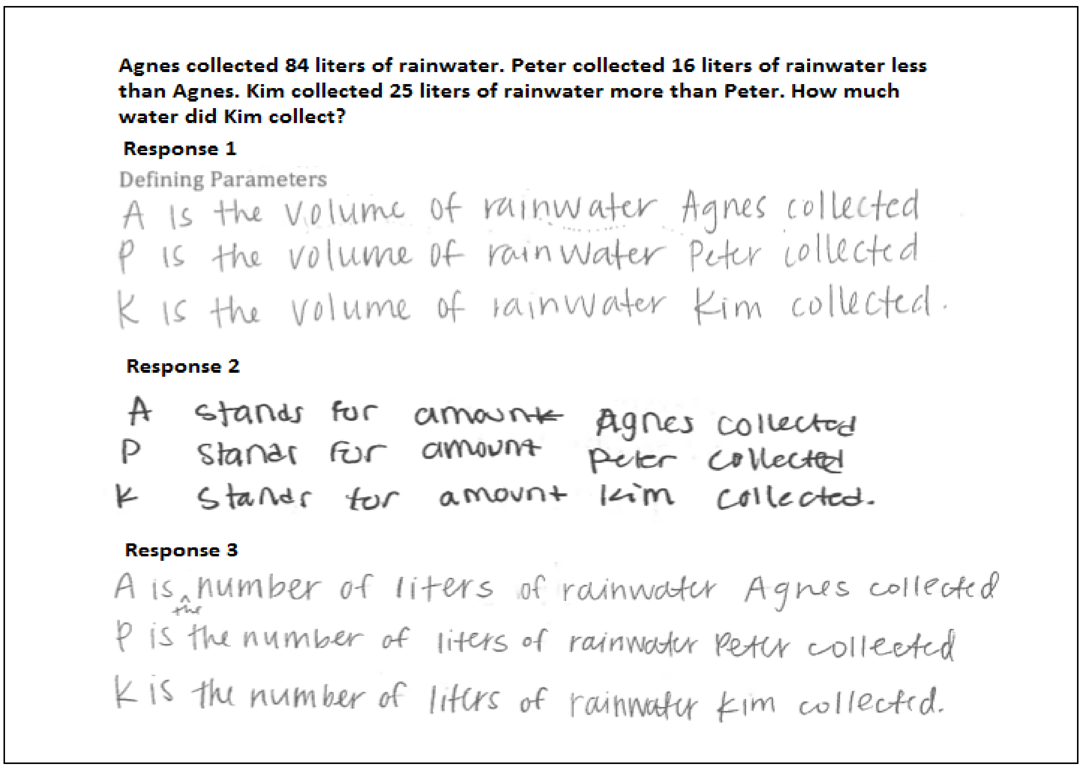

Figure 3. Responses of three pre-service teachers on the same task for the final exam.

Additionally, one student failed to define symbols for all the tasks in the final exam. This student did not complete the supplementary WPS workbook on her own and did not meet with the instructor to receive additional help.

Discussion and Conclusions

Our findings regarding students’ misinterpretation of letters as objects or words are consistent with other studies (Booth, 1988; MacGregor & Stacey, 1997). When presenting 1–2-step arithmetic word problems in symbolic form, our pre-service teachers demonstrated difficulties with defining symbols they used. Their work reflected both—misconceptions in regards to the symbols' meaning (e.g., *G is the green paint*) and misconceptions regarding defining measurable attributes represented by the values (e.g., *P = grams of pepper Agnes bought*). Supplementary instruction in word problem solving allowed us to improve pre-service teachers' precision in defining symbols.

One can argue that the pre-service teachers did not perform well, since they did not understand the task. This can be true for the pre-test. However, this is not true for all later tests. The pre-service teachers were taught throughout the semester using the WPS materials similar to the examples used in this paper. Hence, during the mid-term exam, pre-service teachers were well-aware of the type of questions and expectations for the symbol-meaning tasks.

The data reveal the difficulties demonstrated by pre-service teachers are real in regards to active scientific vocabulary connected with properties of matter measured and/or calculated. About 50% of the pre-service teachers, who already had prolonged instruction on defining symbols by naming the attributes of the values they represent, on the midterm exam, still demonstrated difficulties with the materials and only additional studies helped them improve their performance. The final exam demonstrated the improvements.

We corroborate the progress in pre-service teachers' abilities to define symbols is much greater than presented in Table 3 because (1) the word problems on the final exam were more difficult in terms of symbols' definition than on the mid-term exam and (2) because we compared performance of the pre-service teachers on the mid-term (discarding pre-test results) and final exams. Meanwhile, the performance on the mid-term exam was measured after the students had some WPS instruction regarding defining symbols used to present word problems.

In the future, it would be interesting to examine pre-service teachers' performances using a redesigned pre-test and compare treatment group results with a control group that does not have supplementary instruction. Based on our results, it can be concluded, mathematics courses for elementary teachers must put greater emphasis on teaching pre-service teachers scientifically-correct vocabulary regarding measurable attributes.

Using Oral Presentations and Cooperative Discussions to Facilitate Learning Statistics

Abeer Hasan
Humboldt State University

Sayonita Ghosh Hajra
Hamline University

In this paper we report on a study of assessment-based oral presentation tasks in a statistics course at a public university in the United States. We examine student attitudes towards using oral presentation tasks in learning statistics and their disposition towards statistics as well as their knowledge of the statistical concepts. Our results suggest that use of oral presentation improves students' mastery of statistical concepts and their disposition towards statistics. Moreover, responses to the anonymous course evaluation questionnaire provide insights on the benefits of using oral presentation tasks in statistics courses for students.

Keywords: Attitudes, beliefs, oral presentation, statistical significance

Introduction

There is a long-standing scholarly dialogue on how to deal with recurring concerns about student motivation and achievement, and how to improve student understanding of the role of statistics in providing answers to real-world problems (Meng, 2009). Ograjenšek and Gal (2016) propose re-examining the role of qualitative thinking in the early stages of learning statistics and integrating selected elements of qualitative research methods into statistics curricula. Cobb (2007) calls for further use of technology in teaching and more focus on simulation-based instruction. The use of technology to introduce and reinforce these essential concepts has also been promoted in the Guidelines for Assessment and Instruction in Statistics Education (GAISE) for introductory statistics at the college level (ASA, 2005). Using technology in teaching statistics has been discussed in a series of publications (e.g., Chance, Ben-Zvi, Garfield, and Medina, 2007). Gordon (2004) discusses the unique challenges faced by students and instructors of statistics in a service course. Issues with background deficiencies and lack of motivation are among the most critical factors when teaching occasional users of statistics.

One of the authors teaches statistics as a service course offered for a wide range of science majors. She designed the course with a focus on conceptual understanding and an emphasis on real-world applications and automated computations. These changes enriched students' learning experience and enhanced the overall course instruction. Technology can support conceptual understanding and data visualization. However, we believe that a change in the culture of teaching statistics and the way we interact with our students is needed. In this study, we consider pedagogical strategies that could improve students' conceptual understanding of statistics, thereby also improving their statistical awareness.

One of the strategies we discuss here is use of oral presentations in class for active learning. Fan and Yeo (2007) describe oral presentation as a classroom practice where students share their ideas verbally, and check their own doubts. They discuss that oral presentation provides students an opportunity to share their understanding about a concept in their own words. These verbal communication skills are believed to promote conceptual understanding (Berry and Houston, 1995) and are believed to increase students' confidence (Butler and Stevens, 1997). Recently, in Ghosh Hajra and Hasan (2016), we discussed using assessment-based oral presentation tasks in a mathematics content course for pre-service teachers. We found that our pre-service teachers gained confidence in their ability to teach mathematics and also improved their disposition towards mathematics.

Another strategy we discuss here is the use of cooperative discussions in class for active and meaningful learning. Cooperative learning environments encourage students to interact, critique one another, and learn from each other socially (Slavin, 1996). In this setting, students work in groups, share common goals, and are each responsible for the success of their group (Johnson and Johnson, 1994). Leikin and Zaslavsky (1999) propose four necessary components, which form a cooperative learning environment—learning in small groups, group interdependence, individual accountability within groups, and equal opportunity for interaction and communication for all participants.

Various studies (Meeuwsen, King and Pederson, 2005; Sutton, 1992; Webb, 1991) suggest multiple interpersonal and intrapersonal benefits of cooperative learning. These benefits include improved communication among students and enhanced creative thinking in students. Other studies have shown connection between disposition and learning (Maas and Schlöglmann, 2009; McLeod and Adams, 1989, Philipp, 2007). Disposition is one's attitudes, beliefs, and aptness to act in positive ways (NCTM, 1989). Attitude is a mental concept representing favorable or unfavorable feelings for identifiable entities, and a belief is known or perceived information about an object (Koballa, 1998). For example, statements about likes or dislikes reflect one's feelings toward an object; a statement such as, "*Statistics is hard*" represents one's beliefs. One is most likely to perform an action if one has a favorable attitude towards it (Fishbein and Ajzen, 1975). In particular, if students have favorable feelings and beliefs about oral presentations, they are more likely to use them in their own learning.

In this study, we investigate students' general beliefs and attitudes toward the use of oral presentation tasks in learning statistics. We examine if using oral presentation activities changes student dispositions towards statistics.

Theoretical Framework

Our theoretical framework is based on three theories: theory of constructivism, social constructivism, and multiple intelligence. Theory of constructivism hypothesizes that an individual constructs meanings through his own experiences (von Glasersfeld, 1995). Theory of social constructivism hypothesizes individuals' meanings are constructed through experiences in social interaction (Brooks and Brooks, 1993). From the viewpoint of multiple intelligence theory, every individual has different learning styles. Therefore, each individual needs different forms of learning opportunities (Fan and Yeo, 2007). Hence, we use oral presentations with cooperative discussions as a learning tool in class, in addition to other formal writing assignments, quizzes, and exams. We ask our students to discuss problems in groups and present their solutions to the class.

Methodology

Study participants and course description

This study took place at a public university in the United States of America. Two sections of a statistical modeling class were involved, one designated as control and the other as the treatment group. The two sections had the same instructor, same resources, and same written assessments. The participants were science majors who took an introductory statistics course as a prerequisite to this class. This course was their second course in statistics. The majority of the students were biology majors who took the course either as an elective or as a part of the requirement for their statistics minor. This course was designed as an undergraduate course, but some graduate students took it to supplement their statistical background and to prepare for the quantitative research component for their master's theses.

Study design

We applied an experimental design in this course. One of the two sections was assigned to the treatment group (19 students) and the second section (26 students) was assigned to the control group. This assignment was made before the start of the semester, and the students were unaware of such arrangements. The lecture notes, homework assignments, and tests were identical in both sections. The only difference was that oral presentation with cooperative discussion activities were used for the treatment group and not for the control group during the lecture and statistics lab sessions.

Base groups were formed in the first week of the semester with 3–4 students in each group in the treatment group. Base groups are groups that stay together for the entire course period (Barkley, Cross and Major, 2005). Members in a group were selected randomly according to the class roster after sorting them alphabetically by last name.

The instructor implemented two assessment-based oral presentation tasks in the treatment group: pre-structured oral presentation and impromptu presentation (Fan and Yeo, 2007). Fan and Yeo (2007) described pre-structured oral presentations as tasks that are prepared by the students in advance and impromptu presentations as tasks that are performed without rehearsals. Below, we describe the two tasks in the context of this study.

Task 1: Pre-structured oral presentation: Presentations were used in the treatment group during the lab sessions. In these sessions students were using the software R to perform data analysis. The class was given a handout with a list of solved data analysis problems. Each group was assigned one example to discuss. Twenty minutes were allotted for cooperative discussion. The problems were usually a data set with a research question. Students were given some programming code, description of the dataset, and research question. Students were required to understand, discuss, and interpret the code, along with interpreting the output and answering the research question. Each group had to elect a representative to explain their assigned problem to the class. Each student presented at least twice during the semester. The instructor was available to help during the cooperative discussion, but students were instructed to ask the instructor for help only after the entire group discussed the problem.

Task 2: Impromptu oral presentation: We implemented two forms of spontaneous presentations in the treatment group: a) Student presenters had to answer instant questions related to the presentation from the audience and the instructor after the pre-structured oral presentation. b) Each student had to summarize the day's lesson twice throughout the semester in the form of a 2-minute presentation. The software R was used to randomly choose a presenter at the end of each class. Students had to take notes and be prepared for presenting their 2-minute summary each day because they did not know whose name would be chosen at the end of the class.

We used weighted assessment categories for grading both classes. For the treatment group, oral presentation activities counted 5% and written homework counted 10% of their weighted total grade. For the control group, written homework counted 15% towards the total grade and there was no oral presentation component. Cooperative lab discussions were used only in the treatment group. However, students in both groups had the option to collaborate on some written homework assignments and on a major group projects outside class.

Data collection

We collected data in the form of pre-and post-surveys (modified survey questionnaire from Fan and Yeo (2007) (see Table 1), pre- and post-tests, and end-of-term online course evaluations. The pre- and post-survey consisted of questions on students' general beliefs and attitudes toward the use of oral presentation tasks, their beliefs in their own ability to use statistics in their own research and in their own dispositions towards statistics. The pre-and post-tests/surveys were conducted on the first day and last day of class respectively. Pre-and post-tests had a question with 5 parts on analyzing some R output from a simple linear regression model. We used the anonymous online course evaluation surveys at the end of the semester as our third data source. This survey included 10 questions where students ranked the instructor on a scale of 1–5 and answered two open-ended questions reflecting their thoughts about the most engaging and exciting aspects of the class and any recommendation for improvement.

Table1
Survey questions.

1.	Oral presentations improves my understanding of statistical concepts
2.	Oral presentation skill is important in learning statistics
3.	Oral presentation skill is important in scientific research
4.	Oral presentation makes me feel inadequate
5.	Listening to other classmates' presentations help me understand other's perspectives
6.	Oral presentation is a waste of time
7.	I am very worried about presenting statistical concepts in front of my classmates
8.	I see statistics as practical and useful
9.	I would like to have more oral presentations for my statistics classes
10.	Preparing for oral presentations helps me gain deeper understanding of statistical concepts
11.	I am confident in my ability to communicate statistical concepts
12.	I feel confident in my ability to use statistics in my research or course projects

Results

Quantitative analysis

Pre-Post Surveys and Tests

To analyze the data from the two surveys, we use a numerical scale to code the responses on a scale of 1–5, where 1=Strongly Disagree and 5=Strongly Agree. Our study is twofold—we aim to investigate changes in student attitudes toward oral presentations and changes in their disposition toward statistics. Hence, we divide the survey into two categories. Questions 1–7 and 9–10 addresses general attitudes and beliefs toward oral presentations. Questions 8, 11, and 12 represent student disposition toward statistics. We create the following score functions:

Oral presentation score = (Sum of responses to questions 1–7 and 9–10)/45*100

Disposition toward statistics score = (Sum of questions 8, 11, and 12)/15*100

Here we note that 45 and 15 are the maximum possible scores for each of the above scores respectively and can be obtained by multiplying the number of questions by 5 which is the score of a *Strongly Agree* response. The numerical scores of questions 4, 6, and 7 were inverted to account for the negative wording of the statement in these questions.

We consider the responses of each student as paired data. We used the averages to replace missing values for students who filled out one survey but missed the other. The paired differences in the three scores passed Anderson-Darling's normality test at the LOS=0.01, thus we apply a paired t-test to see if the observed sample differences are significant. Table 2 summarizes the results of our statistical inference. We have a strong evidence of improvement in the disposition towards statistics in both groups. However, the treatment group showed a 13% mean increase in their disposition towards statistics score compared to a 7% mean increase in the control group. Both the treatment and the control groups did not show a significant improvement in their oral presentation scores.

Table 2

Summary of the statistical tests on the three score function. The data is considered normally distributed if the p-value of Anderson-Darling's test exceeds 0.01. The observed sample difference is significant if the p-value of the paired t-test is less than 0.01.

Group Assignment	Score functions	p-value for the normality test	Mean sample of differences (After-Before)	p-value for the paired t-test
Treatment $n = 19$	Oral presentation score	0.753	-0.662	0.5526
Treatment $n = 19$	Disposition towards statistics score	0.0472	12.918	0.0014
Control $n =26$	Oral presentation score	0.471	-1.345	0.4303
Control $n =26$	Disposition towards statistics score	0.131	7.703	0.0007

Figures 1 and 2 display side-by-side boxplots for each of the two scores we introduced. The graphs show improvement in the disposition towards statistics scores at the end of the semester in both groups. It is interesting that neither of the two groups showed improvement in their attitudes towards oral presentation. On the contrary, some of them had slightly more negative opinion towards oral presentation at the end of the semester. Few students found public speaking stressful despite the fact that they learned a lot from presenting their ideas. It is also worth noting that students in both sections were either seniors or graduate students and at this stage of their career they had fixed ideas on oral presentations. Their overall responses were favorable of the practice and the treatment group had slightly more positive attitude towards oral presentation at the beginning of the semester.

To assess learning in the two groups, we administered a test before and after teaching a unit in the class. Both groups showed significant improvement in the post-test scores compared to their pre-test scores. This can be attributed to the collective learning activities that were used in class. Figure 3 shows a comparison of the pre-test scores and the post-test for the two groups. The treatment group had lower pre-test scores compared to the control group. The post test scores highlight the discrepancy between the two groups as the treatment group outperformed the control group.

To compare the test scores of the two groups, we apply Wilcoxon's rank-sum test with continuity correction. The rank-sum test on the pre-test scores resulted in a p-value = 0.9645. Thus, there was no significant difference in the pre-test scores between the treatment and control groups. Applying the same test to the post-tests resulted in p-value = 4.497×10^{-5}. This provides strong evidence that the post-test scores for the treatment group were significantly higher than those of the control group. The median of the post test scores for the treatment group is 95% compared to 73.75% for the control group.

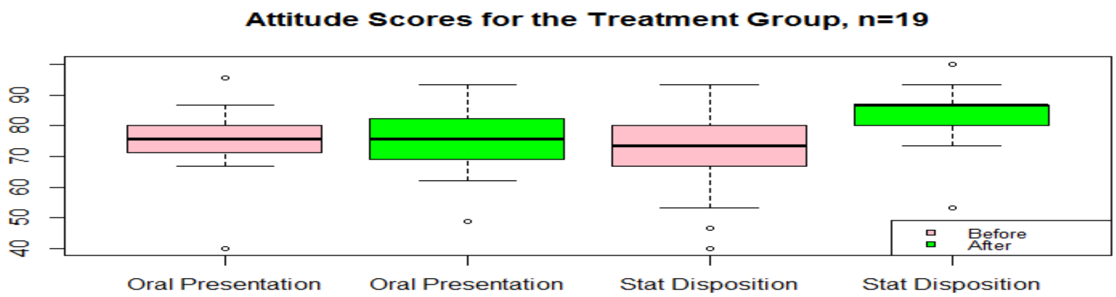

Figure 2: Boxplots for the survey responses on the attitude scores for the treatment group before and after the oral presentation tasks.

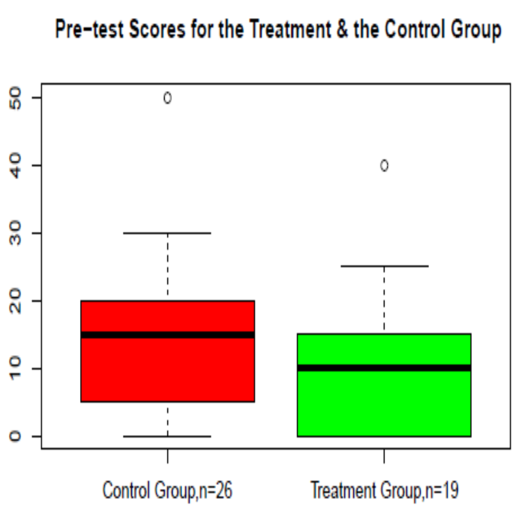

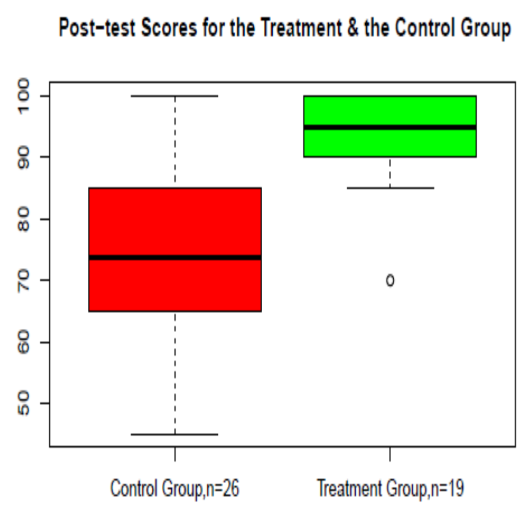

Figure 3: (Left) Comparison of the pre-test scores between the control and treatment groups. (Right) Comparison of the post-test scores between the control and treatment groups.

End-of-Term Online Course Evaluation Surveys

We used University's anonymous voluntary online course evaluation to solicit student feedback on their classes. It was interesting to compare and contrast the survey responses for the treatment and the control groups. The average instructor rating for the treatment group (n = 11) was 4.3 on a 5-point scale with a standard deviation of 0.8. The average for the control group (n = 14) was 3.9 with a standard deviation of 1.2. Overall, the treatment group had more positive comments about their experience in the class compared to the control group. The sample sizes are too small for this difference to be statistically significant. However, a difference of 8% in ranking the same instructor who used the same teaching material is probably due to the only difference in the instructional design, namely, the use of oral presentations and cooperative group discussions. Here are some written comments from the treatment group:

- *"In class it was really nice to consistently experience an active, excited discussion about the limitations and possibilities of statistical analyses."*
- *"Overall, the environment of this course made one feel that there was a strong support system to understand and apply statistics."*
- *"I think forcing all the public speaking was unnecessary and less helpful than other aspects of the class but I recognize that others may have benefited from it more."*

This course was taught again by the same instructor after completing this study. This time only one section was offered, and oral presentations and cooperative discussions were used in the class. Students' resistance to oral presentation activities seemed to diminish when they did not have another section to compare themselves to and they were not informed that they were a part of an experiment.

Conclusions

Our quantitative analyses provide evidence that implementing oral presentation with cooperative discussion tasks in teaching statistics resulted in significant improvement in the student disposition towards statistics as a field as well as their basic knowledge of the course content. Students came to class with a prior opinion on the use of oral presentations which did not change much during the class. It was an interesting coincidence possibly that the treatment group had an already more favorable attitude on the use of oral presentation tasks compared to the control group, and that the overall attitude scores did not change significantly at the end of the semester. This discrepancy could be due to the fact that the treatment group knew that they will be required to present their work before they filled the survey and their responses were influenced by the desire to please their instructor who required this additional activity in class. The students who took the class were mostly senior or graduate students, and they probably had fixed opinions on oral presentations based on their experience with other classes.

Limitations of the study

Due to the nature of the study, it was not feasible to randomly assign the students to either group. However, it is assuring that the pre-test scores indicated no significant difference between the groups. Lurking factors might include the class time (the treatment group met at 9 a.m. while the control group met at 11 a.m.). The course evaluation survey was a voluntary response survey and both sections had response rates below 60% of the total number of enrolled students. Generally, voluntary response sampling schemes tend to over represent people with strong opinions. Based on the course evaluation survey, 92.9% of the respondents in the control group were required to take the course compared to 63.3% in the treatment group. It is possible that students who elected to take the class are more motivated than those who are required to take it.

Exploration of the Factors that Support Learning: Web-based Activity and Testing Systems in Community College Algebra

Shandy Hauk

Larry Thomas
WestEd

A variety of computerized interactive learning platforms exist. Most include instructional supports in the form of problem sets. Feedback to users ranges from a single word like "Correct!" to offers of hints and partially- to fully-worked examples. Behind-the-scenes design of systems varies as well – from static dictionaries of problems to "intelligent" and responsive programming that adapts assignments to users' demonstrated skills within the computerized environment. This report presents background on digital learning contexts and early results of a cluster-randomized controlled trial study in community college elementary algebra classes where the intervention was a particular type of web-based activity and testing system.

Key words: Adaptive Tutoring System, College Algebra, Multi-site Cluster Randomized Controlled Trial

Many students arrive in college underprepared for college level algebra, despite its importance for future success in mathematics (Long, Iatarola, & Conger, 2009; Porter & Polikoff, 2012). Web-based Activity and Testing Systems (WATS) are one approach to supporting equity and excellence in mathematics learning in colleges. When it comes to technology and algebra learning in college, what works? For whom? Under what conditions? These ubiquitous questions plague educational researchers who are assessing the whats, whys, and hows of a technology intervention or addition to a course. Did the instructors have enough support to adequately implement the technology tool? Were the materials adequate to provide enough practice hours for students? Was instruction sufficient to prepare students to pass the final exam?

This preliminary report offers early results from a large project investigating relationships among student achievement and varying conditions of implementation for a web-based activity and testing system (WATS) used in community college algebra. Implementing a particular WATS constitutes the "treatment" condition in this cluster randomized controlled trial study. As described below, there are several ways to distinguish WATS tools. Some systems, like the one at the heart of our study, include adaptive problem sets, instructional videos, and data-driven tools for instructors to use to monitor and scaffold student learning.

Research Questions

Funded by the U.S. Department of Education, we are conducting a large-scale mixed methods study in over 30 community colleges. The study is driven by two research questions:

Research Question 1: What is the impact of a particular digital learning platform on students' algebraic knowledge after instructors have implemented the platform for two semesters?

Research Question 2: What challenges to use-as-intended (by developers) are faculty encountering and how are they responding to the challenges as they implement the learning tool?

Background and Conceptual Framing

First, there are distinctions among cognitive, dynamic, and static learning environments (see Table 1). Web-based Activity and Testing System (WATS) learning environments can vary along at least two dimensions: (1) the extent to which they adaptively respond to student behavior and (2) the extent to which they are based on a careful cognitive model.

Table 1. *Conceptual Framework of the Types of Instruction Based on Adaptability and Basis in a Theory of Learning*

		Static	Dynamic
Is a particular model of learning explicit in design and implementation (structure and processes)?	No	Text and tasks with instructional adaptation external to the materials	Adaptive tutoring systems (Khan Academy, ALEKS, ActiveMath)
	Yes	Textbook design and use driven by fidelity to an explicit theory of learning	“Intelligent” tutoring systems (Cognitive Tutor)

Static learning environments are those that are non-adaptive without reliance on an underlying cognitive model – they deliver content in a fixed order and contain scaffolds or feedback that are identical for all users. The design may be based on intuition, convenience, or aesthetic appeal. An example of this type of environment might be online problem sets from a textbook that give immediate feedback on accuracy to students (e.g., “Correct” or “Incorrect”).

Dynamic learning environments keep track of student behavior (e.g., errors, error rates, or time-on-problem) and use this information in a programmed decision tree that selects problem sets and/or feedback based on students’ estimated mastery of specific skills. An example of a dynamic environment might be a system such as ALEKS or the “mastery challenge” approach now used at the online Khan Academy. For example, at khanacadmy.org a behind-the-scenes data analyzer captures student performance on a “mastery challenge” set of items. Once a student gets six items in a row correct, the next level set of items in a programmed target learning trajectory is offered. Depending on the number and type of items the particular user answers incorrectly (e.g., on the path to six items in a row done correctly), the analyzer program identifies target content and assembles the next “mastery challenge” set of items.

Above and beyond such responsive assignment generation, programming in a “cognitively-based” dynamic environment is informed by a theoretical model that asserts the cognitive processing necessary for acquiring skills (Anderson et al. 1995; Koedinger & Corbett, 2006). For example, instead of specifying only that graphing is important and should be practiced, a cognitively-based environment also will specify the student thinking and skills needed to comprehend graphing (e.g., connecting spatial and verbal information), and provide feedback and scaffolds that support these cognitive processes (e.g., visuo-spatial feedback and graphics that are integrated with text). In cognitively-based environments, scaffolds themselves can also be adaptive (e.g., more scaffolding through examples can be provided early in learning and scaffolding can be faded as a student acquires expertise; Ritter et al., 2007). Like other dynamic systems, cognitively-based systems can also provide summaries of student progress, which better enable teachers to support struggling students.

No fully tested cognitively-based system currently exists for college students learning algebra. As mentioned, several dynamic systems do exist (e.g., ALEKS, Khan Academy “Missions”). The particular WATS investigated in our study is accessed on the internet and is designed primarily for use as replacement for some in-class individual seatwork and some homework. ***Note***: We report here on data collected from the first of two years. The second year of the study – which repeats the design of the first – is currently underway. Hence, we purposefully under-report some details.

Method

The study we report here is a multi-site cluster randomized trial. Half of instructors at each community college site are assigned to use a particular WATS in their instruction (treatment condition), the other half teach as they usually would, barring the use of the Treatment WATS tool (control condition). In addition, faculty participate for two semesters in order to allow instructors to familiarize themselves with implementing the WATS with their local algebra curriculum. Specifically, the Fall semester is a "field" semester to field-test the intervention and the Spring semester of the same academic year is the full "efficacy" study.

Using a stratified sampling approach to recruitment, we first conducted a cluster analysis on all 113 community college sites eligible to participate in the study (e.g., those offering semester-long courses in elementary algebra that met at least some of the time in a physical classroom or learning/computer lab). The cluster analysis was based on college-level characteristics that may be related to student learning (e.g., average age of students at the college, the proportion of adjunct faculty, etc.). This analysis led to five clusters of colleges. Our recruitment efforts then aimed to include a proportionate number of colleges within each cluster. The primary value of this approach is that it allows more appropriate generalization of study findings to the target population (Tipton, 2014). The first cohort of participants was a sample of 38 colleges similar to the overall distribution across clusters that was the target for the sample (see Figure 1).

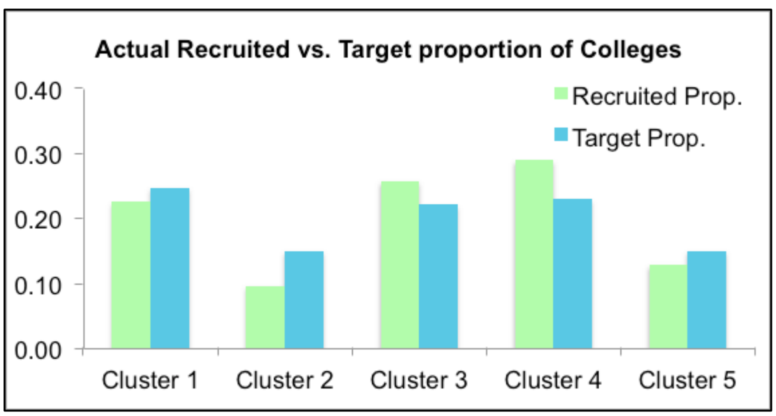

Figure 1. Recruited sample proportions and target sample proportions across clusters.

Sample for this Report

Initial enrollment in the study included 89 teachers across the 38 college sites. For this report on early results, we have used the data from 510 students of 29 instructors across 18 colleges. Student and teacher numbers related to the data reported on here are shown in Table 2.

Table 2. *Counts of Teachers, Students, and Colleges in the Study*

Condition	*Teachers*	*Students*	*Colleges*
Control	17	328	13
Treatment	12	182	11
Total	*29*	*510*	*18*

Results

The primary outcome measure for students' performance is an assessment from the Mathematics Diagnostic Testing Program (MDTP), which is a valid and reliable assessment of students' algebraic knowledge (Gerachis & Manaster, 1995). The primary aim of the quantitative analysis was to address Research Question 1, what is the impact of WATS use on students' outcomes? To this end, we employed Hierarchical Linear Modeling (HLM) (Raudenbush & Bryk, 1998) to predict students' end of semester MDTP scores. The HLM model includes a random effect of teacher to account for the nesting of students within instructors, and covariates that account for students' pretest MDTP scores at both student and teacher levels (i.e., student scores are aggregated at the teacher level; covariates were grand mean centered to achieve the intended covariate-adjustment). Importantly, in the model below, $WATS_j$ represents a dichotomous variable (dummy coded) indicating treatment assignment, and the main effect of the intervention is captured by β_{01}.

Model

$$\gamma_{ij} = \beta_{00} + \beta_{01}\boldsymbol{WATS}_j + \beta_{10}\boldsymbol{StuPre}_{ij} + \beta_{02}\boldsymbol{TeaPre}_j + \xi_{0J}\boldsymbol{Tea}_j + \varepsilon_{I0}\boldsymbol{Stu}_{ij}$$

The random and fixed effects for the model presented above are displayed in Tables 3 and 4, respectively.

Table 3. *Random Effects of the Model*

	Variance	*Standard Deviation*
Teacher ξ_{0J}	6.95	2.64
Level-1 Error ε_{I0}	37.69	6.14

Table 4. *Fixed Effect Results of the Model*

Variable	*B*	*Standard Error*	*p-value*
Intercept β_{00}	21.98	0.74	< .001
WATS β_{01}	2.59	1.17	.04
StuPre β_{10}	0.54	0.04	< .001
TeaPre β_{02}	0.35	0.17	.05

Controlling for students' pretest scores, we found that using WATS corresponded to a 2.59 point increase in students' post-test scores, a statistically significant positive effect ($p < .05$). Since the post-test is out of a 50 point total, the estimate corresponds to about 5 percentage points greater post-test score, on average, for treatment group students (2.59/50). The Hedges *g* value for this effect is 0.32, which is considered a small but noteworthy effect in educational research for studies of this size (Cheung & Slavin, 2015; Hill et al. 2008). The 95% confidence interval of the Hedges *g* value is .14 - .50.

We note this study suffered from high instructor attrition, which may bias the outcome of results. To investigate the robustness of the findings above, we are in the process of repeating this study with a second cohort of participants during the current (2016-17) academic year. Pooling the results of these two studies will help to determine the extent to which study results replicate with different populations. In this same vein, we plan to reanalyze the results using post-test scores that are estimated using item response theory (IRT). IRT is a measurement approach that takes into consideration potential differences in item characteristics when scoring individuals and places scores on a continuous metric. The use of IRT will allow us to take into consideration the difficulty and discriminability of items and represent these in the calculation of post-test scores, which can then be analyzed using the model presented above.

To address Research Question 2, a great deal of textual, observational, and interview data were gathered last year (and will be gathered again for the second iteration of the study). These data allow careful analysis of the intended and actual use of the learning environment and the classroom contexts in which it is enacted – an examination of implementation structures and processes. Indices of specific and generic fidelity derived from this work also will play a role in HLM generation and interpretation in the coming year.

As in many curricular projects, developers of the WATS in our study paid attention to learning theory in determining the content in the web-based system, but the same was not true for determining implementation processes and structures. The pragmatic details of large-scale classroom use were under-specified. Developers articulated their assumptions about what students learned as they completed activities, but the roles of specific components, including the instructor role in the mediation of learning, were not clearly defined. Thus, there was an under-determined "it" to which developers expected implementers (instructors and students) to be faithful.

Fidelity of implementation is the degree to which an intervention or program is delivered as intended (Dusenbury, Brannigan, Falco, & Hansen, 2003). Do implementers understand the trade-offs in the daily decisions they must make "in the wild" and the short and long-term consequences on student learning as a result of compromises in fidelity? As Munter and colleagues (2014) have pointed out, there is no agreement on how to assess fidelity of implementation. However, there is a growing consensus on a component-based approach to measuring its structure and processes (Century & Cassata, 2014). Century and Cassata's summary of research offers five components to consider in fidelity of implementation: Diagnostic, Procedural, Educative, Pedagogical, and Student Engagement (see Table 5).

Table 5. *Components and Focus in a Fidelity of Implementation Study*

Components	*Focus*
Diagnostic	These factors say what the "it" is that is being implemented (e.g., what makes this particular WATS distinct from other activities).
Structural-Procedural	These components tell the user (in this case, the instructor) what to do (e.g., assign intervention x times/week, y minutes/use). These are aspects of the *expected* curriculum.
Structural-Educative	These state the developers' expectations for what the user needs to know relative to the intervention (e.g., types of technological, content, and pedagogical knowledge needed by an instructor).
Interaction-Pedagogical	These capture the actions, behaviors, and interactions users are expected to engage in when using the intervention (e.g., intervention is at least x % of assignments, counts for at least y % of student grade). These are aspects of the *intended* curriculum.
Interaction-Engagement	These components delineate the actions, behaviors, and interactions that students are expected to engage in for successful implementation. These are aspects of the *achieved* curriculum.

The components in Table 5 are operationalized through a rubric, the guide for collecting and reporting data in our implementation study. A rubric articulates the expectations for a category by listing the criteria, or what counts, and describes the levels of quality from low to high. Each component has several factors that define the component. The research team has developed a rubric for fidelity of implementation that identify measurable attributes for each component (for example, see Table 6 for some detail on the "educative" component).

Table 6. *Example Rubric Descriptors for Levels of Fidelity, Structural-Educative Component.*

Educative: These components state the developers' expectations for what the user (instructor) needs to know relative to the intervention.			
	High Level of Fidelity	*Moderate Fidelity*	*Low Level of Fidelity*
Users' proficiency in math content	Instructor is proficient to highly proficient in the subject matter.	Instructor has some gaps in proficiency in the subject matter.	Instructor does not have basic knowledge and/or skills in the subject area.
Users' proficiency in TPCK	Instructor regularly integrates content, pedagogical, and technological knowledge in classroom instruction. Communicates with students through WATS.	Instructor struggles to integrate CK, PK, and TK in instruction. Occasionally sends digital messages to students using WATS tools.	Instructor CK, PK, and/or TK sparse or applied in a haphazard manner in classroom instruction. Rarely uses WATS tools to communicate with students.
Users' knowledge of requirements of the intervention	Instructor understands philosophy of WATS resources (practice items, "mastery mechanics," analytics, and coaching tools),	Instructor understanding of the philosophy of WATS tool has some gaps. NOTE: Disagreeing is okay, this is about instructor knowledge of it.	Instructor does not understand philosophy of WATS resources. NOTE: Disagreeing is okay, this is about instructor knowledge of it.
Users' knowledge of requirements of the intervention	Instructor understands the purpose, procedures, and/or the desired outcomes of the project (i.e., "mastery")	Instructor understanding of project has some gaps (e.g., may know purpose, but not all procedures, or desired outcomes).	Instructor does not understand the purpose, procedures, and/or desired outcomes. Problems are typical.

Defining and Refining Measures for the Fidelity of Implementation Rubric

The ultimate purpose of a fidelity of implementation rubric is to articulate how to determine what works, for whom, under what conditions. In addition to allowing identification of alignment between developer expectations and classroom enactment, it provides the opportunity to discover where productive adaptations may be made by instructors, adaptations that boost student achievement beyond that associated with an implementation faithful to the developers' view.

In using the rubric, we assign a number to each level of fidelity. This can be as simple as a 3 for a high level of fidelity, 2 for a moderate level of fidelity, or a 1 for a low level; or the items can be weighted. The general score for the intervention will be the total number of points assigned in completing the rubric as a ratio of the total possible, across all instructors. It will also be possible to create a fidelity of implementation score on each row for each instructor – these data will be used in statistical modeling of the impact of the intervention as part of a "specific fidelity index" (Hulleman & Cordray, 2009). We first total points for the item, then the component, and finally all components for a single score as an index of implementation.

Next Steps

In upcoming work, we will analyze a host of data on students, teachers, and colleges that may influence learning with WATS, including issues of feasibility of use in differing contexts, and measures associated with the nature of alignment or "fidelity" of implementation to WATS developers' expectations. Such analysis will help to inform important questions such as how and for whom WATS are most effective.

As indicated above, we will continue this study with a second cohort of new participants who will repeat the year-long study in the 2016-2017 academic year. Also, between now and the conference we will do more complex modeling of the data, with the introduction of IRT-informed scores and specific fidelity indices. Our specific objectives in the coming six months are to (1) continue analyses from the Spring 2016 efficacy study, and (2) conduct the field-test semester of the study with second cohort of participants.

Supporting Instructional Change in Mathematics: The Role of Online and In-person Communities

Charles N. Hayward and Sandra L. Laursen
Ethnography & Evaluation Research, University of Colorado Boulder

While studies continually show benefits of active learning strategies like inquiry-based learning (IBL), it is difficult to get faculty to adopt these methods. Particularly challenging is the third and final stage in Paulsen and Feldman's (1995) model, 'refreezing,' when instructors use feedback and support to decide whether to continue with the instructional changes they have made or return to their previous methods. In this paper, we show how a workshop to teach college mathematics instructors to implement IBL used both online and in-person communities to help provide the ongoing feedback and support necessary for 'refreezing.' We offer lessons for how to increase the relevance of and participation in online support communities. We also use an innovative analytical approach, Social Network Analysis, to understand the ongoing processes of how e-mail exchanges provide feedback and both intellectual and emotional support to workshop participants.

Keywords: Inquiry-Based Learning, Pedagogy, Instructional Change, Professional Development

Numerous studies have found benefits for the use of active learning methods in science, technology, engineering and mathematics (STEM) fields (Freeman et al., 2014). Freeman et al. (2014) stated that the benefits are so strong that, "If the experiments analyzed here had been conducted as randomized controlled trials of medical interventions, they may have been stopped for benefit—meaning that enrolling patients in the control condition might be discontinued because the treatment being tested was clearly more beneficial" (p. 4). While the evidence in support of the use of active learning strategies is strong, getting large numbers of faculty to adopt new methods is difficult (Fairweather, 2008; Henderson & Dancy, 2007; 2008; 2011). Professional development workshops are one strategy for helping instructors to adopt research-supported teaching methods. Workshops are the preferred method of National Science Foundation (NSF) program directors, particularly when they are multi-day, immersive workshops and include follow-up interaction between participants and organizers (Khatri, Henderson, Cole, & Froyd, 2013). Professional developers often include follow-up interactions in their designs through group email lists, reunion meetings, and mentoring (Council of Scientific Society Presidents, 2012), but there is almost no evidence that these plans are acted upon or whether they matter. In one study of a series of three workshops, only one of them successfully implemented the plan to engage participants in an email group (Hayward, Kogan, & Laursen, 2016).

In this report, we present findings from a weeklong, intensive workshop that engaged almost all participants in follow-up activities. This workshop was designed to help college mathematics faculty implement Inquiry-Based Learning (IBL) in their classes. IBL has its roots in the teaching methods of mathematician R.L. Moore (1882-1974) (Mahavier, 1999), but the term IBL is now used more broadly to include various practices that share the spirit of student inquiry through the core features of (1) deep engagement with rich mathematics and (2) collaboration with peers (Yoshinobu & Jones, 2013).

Conceptual Framework

Rather than impose a conceptual framework from the start, we let one emerge from the analysis and found a good fit to a three-stage model of instructor change developed by Paulsen and Feldman (1995), based on Lewin's (1947) theory of change. These authors described three stages: (1) *unfreezing*, (2) *changing*, and (3) *refreezing*. During *unfreezing* instructors gain motivation to change through experiencing incongruence between their goals and the outcomes of their teaching practices. In *changing*, instructors learn, apply, and reflect on new teaching strategies to help align their behaviors with desired outcomes. While teaching strategies may be fluid during this stage, in the final stage, *refreezing*, either the new strategies are 'reconfirmed' through positive feedback and support, or the instructors return to their original strategies.

In this paper, we present data to show that participants have applied their learning from the workshop by implementing IBL techniques and have therefore completed a crucial step of stage two, *changing*. However, our main focus in this paper is on how this workshop supported instructors through the *refreezing* stage by providing ongoing support and positive feedback, since little is known about this third stage (Connolly & Millar, 2006). Follow-up support can be challenging when workshop participants are from geographically diverse institutions and cannot easily reconnect face to face, but here organizers of this workshop leveraged other IBL-related resources and events and a group email list to help workshop participants through the *refreezing* stage. Some authors have argued that these "external networks of like-minded colleagues… can be important forces in promoting instructional reform" (Fairweather, 2008, p. 27), as they "provide a trusted community for faculty who may [have] no other support" (Stains, Pilarz, & Chakraverty, 2015, p. 1474). This is especially important given evidence that collegial interactions influence changes in instructional practices, even more than direct participation in professional development for some teachers (Penuel, Sun, Frank, & Gallagher, 2012). We explore the following research questions about *refreezing*:

(1) What resources can workshops use to support participants through *refreezing*?
(2) How can participation in online support resources be maximized?
(3) What are the processes of providing 'reconfirmation' through positive feedback and emotional and intellectual support?

Methods

This paper comes from a larger study of four workshops on IBL for college mathematics instructors held between 2013-2015. Each of the workshops was four days long and featured a mix of sessions designed to help participants learn about IBL and prepare to implement it in their classrooms. The workshop included four types of sessions that all featuring active participation and self-reflection, which are characteristics of effective professional development (Cormas & Barufaldi, 2011; Garet, Porter, Desimone, Birman, & Yoon, 2001). The sessions were: (1) Reading sessions to discuss research, (2) Video sessions to watch and analyze IBL classes, (3) Nuts & Bolts sessions to develop plans for how to structure and run an IBL class, and (4) Course Content sessions to work in small groups to develop IBL materials for their own courses. Data in this study come from the second of these four workshops, though all were very similar and post-workshop listserv cohorts functioned similarly as well.

We use a mixed-methods approach to understand how the workshop supported participants through *refreezing.* Through our quantitative analysis of survey data and tracking of email group activity, we share results about participants' engagement with support resources. We are currently conducting an innovative analysis of activity in the post-workshop email listserv to reveal the processes of *how* the email listserv helped to provide positive feedback and support participants both emotionally and intellectually. We are applying techniques of social network analysis (SNA) to examine the interactions between participants and staff via e-mail. SNA is appropriate for this context since emails are inherently social connections and these methods allow us to examine support processes as they develop over time.

For all four workshops, we collected surveys pre-workshop, post-workshop, and one academic year later. The surveys included all of the same items as workshop surveys published and presented previously (Hayward, Kogan, & Laursen, 2016), as well as some new items to assess participants' engagement with support resources. Survey data were analyzed using SPSS v. 21. Open-ended items were coded in Microsoft Excel. We tracked and coded listserv messages using Microsoft Excel, and we are performing a social network analysis on this message data in the statistical program *R* using the packages, *Social Network Analysis* and *iGraph.*

Results

The workshops served 35 participants. Of these, 54% identified as women and 43% as men (3% did not respond). They represented a variety of career stages and institution types, though most were untenured faculty (54%) and from four-year colleges (69%). Most were early in their careers with 2-5 years of teaching experience (51%) or less than 2 years (17%). All 35 participants (100%) completed the pre- and post-workshop surveys and 28 (80%) completed the one-year follow-up survey. Surveys were matched by respondent using anonymous identifiers.

Implementation of IBL

In order to assess whether participants had gone through the stage of *changing* their instructional methods, we assessed implementation of IBL in a number of different ways. On one-year follow-up surveys, 26 (93%) of 28 respondents reported using IBL methods in their classes, ranging from "some IBL methods" (25%) to "more than one full course" (39%). Seven did not answer the survey. In messages sent on the listserv, 30 of the 35 participants (86%) made comments indicating that they were using IBL methods. Combining these measures reveals that at least 31 participants (89%) were using at least some IBL methods. Changes in teaching practices from pre-workshop to one-year follow-up were consistent with IBL practice as well: decreases in instructor-led activities and increases in some student-centered activities, as detailed in Figure 1. Overall, these multiple data sources indicate very high usage of IBL methods.

Follow-up Activities, Resources, and Supports

Making a change (i.e. implementation of IBL) indicates completion of stage two of Paulsen and Feldman's instructional change model. Stage three, *refreezing,* is characterized by sustained use of new instructional methods reinforced by positive, ongoing support and feedback. To assess support and feedback, we asked participants on follow-up surveys to report their engagement with various IBL-related events and resources.

IBL events. Of the 28 respondents to the follow-up survey, 68% had participated in another IBL-related event in the year following the workshop. Events included IBL sessions at JMM, MAA meetings, MathFest, and the annual IBL conference. Some also presented at these events (7, 25%). Together, this means 22 participants (79%) attended or presented at another event.

While some events were more popular than others, it appears that the variety of related events made it possible for many participants to engage in at least one.

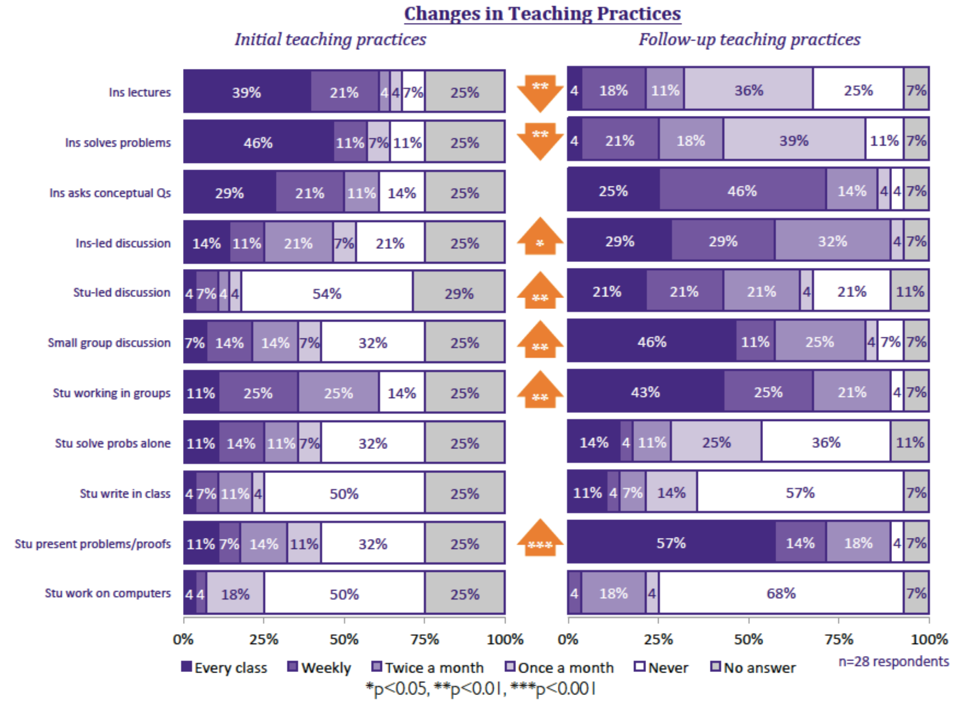

Figure 1. Comparison of teaching practices from pre-workshop to one-year follow-up.

IBL resources. Most respondents to the follow-up survey (25, 89%) reported using IBL resources. The resources used most frequently were the workshop listserv (21, 75%) and the *Journal of Inquiry Based Learning in Mathematics* (12, 43%). A few participants used the mentor program and mini-grants, which were both provided by the Academy of Inquiry Based Learning (AIBL). Again, participants engaged with a number of different resources, and the variety available may help to meet the various needs of different participants.

IBL support. On the follow-up survey, we asked participants to report the level of support they received from their institutions. Overall, the majority of participants felt supported at their institutions and rated key individuals as 'mostly supportive,' including department heads/chairs (64%) and departmental colleagues (50%). In describing how they were supported, some participants reported active support (12, 43%) through either encouragement or financial support, while others reported the absence of obstacles: they were 'free to do what they wanted' (5, 18%). Only a few reported feeling doubted or discouraged by colleagues (3, 11%). While these numbers suggest that collegial resistance is not a barrier for most, only 43% of respondents received the active support crucial to *refreezing*.

Participation in Online Follow-Up Activities

Past efforts by professional developers to engage workshop participants in online follow-up communications have failed (e.g. Hayward, Kogan, & Laursen, 2016). Social networking platforms like Facebook or Google+ seem like a good way to keep in touch, but those efforts too were unsuccessful for this workshop. In a semi-official capacity, one participant of the workshop created a private group on a social networking platform, and 24 people (55%) from the workshop joined it. Only 4 people (9%) exchanged 8 messages in the 2 days following the workshop, and in the two years since then, the group has had no activity. In contrast, 32 (91%) of workshop participants were active on the official group listserv at some point in the year after the workshop. In total, they exchanged 282 messages over the year. These observations suggest that 'push' technologies that deliver messages directly are more successful than requiring participants to log in and seek them out. Below, we share some other findings about why this group listserv was able to successfully engage participants in follow-up when other approaches have failed.

Promoting participation. Organizers sometimes prompted the list to generate discussions, but all members were free to send messages to the entire group at any time. The list was closed but un-moderated. Frequencies of individuals' participation are shown in Figure 2 below.

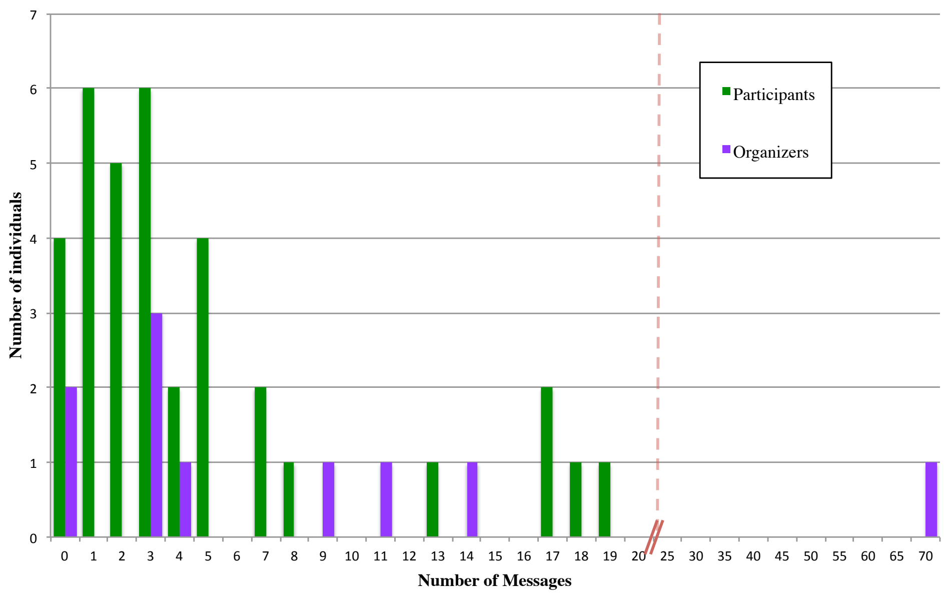

Figure 2. Frequencies of individuals' participation.

Most individuals sent fewer than 10 messages to the list in the year following the workshop. In fact, 27 participants (77%) sent 5 or fewer messages. Among organizers, most also sent fewer than 10 messages to the list. However, one organizer sent 66 messages, or about ¼ of all messages on the list. Many of these were announcements of upcoming events or resources, while others were prompts inviting check-ins from participants and raising topics for discussion. Such organizer prompts were often followed by flourishes of activity, including from participants who had not yet been active in the listserv, as shown in Figure 3.

In February, organizers also prompted individuals who had not yet been active in the group listserv. They checked in individually with these quiet participants in order to see how things were going and to offer assistance. Most of these participants responded individually, and two also later participated in the group list. In total, 94% of all 35 workshop participants were active in online 'e-mentoring,' either individually or as a group.

Relevance and helpfulness of discussions. As shown in Figure 3, organizers frequently prompted the list. The timing and content of these prompts are important. The biggest concentration of activity was in the fall (August through mid-October) soon after the summer workshop. This is an important time as many instructors prepare and then begin teaching their first IBL class. Organizers prompted the list with relevant topics, such as asking participants to share their 'first day plans,' offering advice, and checking in about how 'first-day' activities went. The listserv was relatively quiet again until another small burst of activity in January. Again, organizers provided relevant prompts by asking participants to reflect back on what did and did not go well during their first term using IBL, and querying participants' plans for the upcoming term. For the rest of the academic year, activity came in short bursts for a day or two as participants responded to a specific question or announcement. Over time, participants became more likely to initiate new exchanges, though organizers continued to pose occasional prompts.

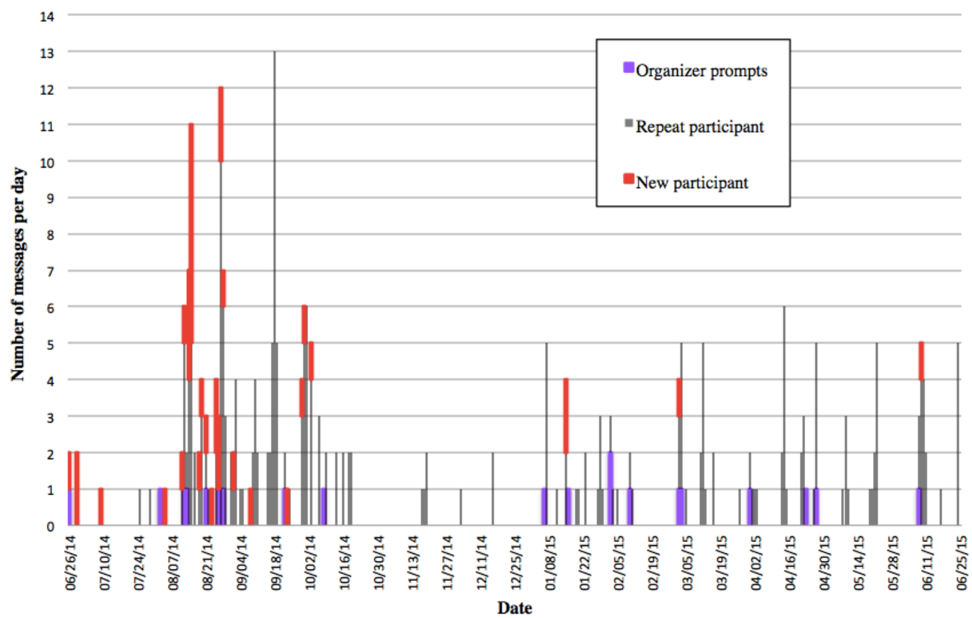

Figure 3. Chronological activity on the group email listserv.

On follow-up surveys, 39% said the list was a "great help," and 22% said it was "much help." None reported that it was "no help." Individually, most participants only sent a handful of messages and some did not engage with the list for a long time. However, evidence suggests that the collective discussions still helped even when they were not active participants: a few of the latest 'new participants' offered long, thoughtful reflections that included references to earlier discussions, suggesting they had been actively tracking and mentally engaging in the online cohort even though they had not posted. Moreover, some new participants stated that they had been 'lurking' and found ongoing discussions helpful.

Networks formed through email exchanges. While we have provided evidence of use of follow-up support resources, the ongoing process of reconfirmation through positive feedback is harder to assess with a one-time follow-up survey. However, while observing listserv traffic throughout the course of the year, we noticed that feedback loops sometimes developed: participants might raise a concern to the group, others would provide suggestions, and then the original participant would report back after testing out the suggestions. Such social exchanges prompted us to analyze not only the frequency but the content of messages sent on the listserv, using SNA methods to reveal the *process* of refreezing. We are coding each message to reveal its function and content, and to document how it relates to previous messages. For example, one message's content may be to celebrate (e.g. "My IBL class went so well today…") while another message may function as a connection by celebrating somebody else (e.g. "That sounds like an awesome class! Good job!"). Our coding scheme attends to the emotional function of messages—such as celebrating or commiserating—as well as intellectual content, such as trouble-shooting and idea-sharing, because we observe the list traffic to include a perhaps surprising degree of emotion-related messages. We suspect this interpersonal support may be particularly helpful in normalizing challenges of new implementers. The tone set by organizers also appears crucial to establishing the trust needed to share and seek help about teaching challenges.

We are exploring the relationships between content of messages and the type of connections that follow it in order to help understand *how* the participants and staff used the listserv during the *refreezing* stage. For example, we hypothesize that messages that seek information or help will tend to be followed by many messages in which others share opinions, advice, and resources, whereas a broadcast announcement will be followed up by fewer messages, largely to say thanks or expand on the initial announcement. This coding is painstaking but is well underway and will be finished by the RUME meeting in February, where we will present additional findings on the nature of listserv communications and how they support *refreezing*.

Discussion

Evidence from both the follow-up surveys and activity on the group listserv indicates that the workshop was largely successful in helping instructors through *changing* by beginning to use IBL practices in their classes in the year following the workshop. The third and final stage of Paulsen and Feldman's (1995) theory of instructor change, *refreezing*, often presents the biggest challenges, so support and positive feedback during this time are crucial so that participants do not return to their original strategies (Connolly & Millar, 2006). Feedback and support are most readily available at one's home institution, but only about 43% of participants described active support from colleagues. While support is essential during *refreezing*, more than half of survey respondents reported no active, local support.

Workshop participants and organizers can serve as another source of support for instructional change, but geographic distances make this challenging. The workshop organizers incorporated various methods to overcome these distances to help support participants through the *refreezing* stage, and participants reported high rates of IBL implementation. Participants took advantage of various IBL-related events and IBL-related resources. Some participants took part in in-person events, but the group e-mail listserv was the most widely used support. Both survey responses and participants' comments in emails indicate that the listserv was helpful.

The findings here show why this method of online support was successful when others have failed, and offer some lessons for those looking to support instructors involved in changing their teaching practices: First, online communication can be an effective way to help instructors interact with like-minded, supportive colleagues, especially if they do not have any at their home institutions. Second, listservs and other 'push' technologies that deliver relevant messages directly to participants seem to make it more likely that participants will engage, in comparison to methods that require participants to actively seek out information and help, such as online communities or forums. These findings are encouraging because listservs are relatively easy and inexpensive to set up and manage. Third, listservs function better when somebody is providing prompts that both encourage participation and keep discussions relevant to participants' experiences, in effect enabling list participants to provide each other with "just-in-time" implementation support as they try the new teaching strategies.

Ongoing analysis of listserv messages will reveal how participants and staff engaged in two important processes of the *refreezing* stage: (1) supporting each other emotionally and intellectually and (2) providing positive feedback by improving their implementation of IBL practices through trouble-shooting and idea-sharing.

Student Proficiency with Transformational Geometry After a College Proof-Based Geometry Class

Meredith Hegg and Timothy Fukawa-Connelly
Temple University

This report explores pre-service teachers' proficiency with concepts of transformational geometry at the end of a semester-long advanced geometry course. During the course, the instructor presented transformational geometry content, including congruence proofs, in an attempt to align with the Common Core State Standards for Mathematics. At the end of the course, the students, all pre-service teachers, appeared to mix ideas from the traditional approach involving triangle congruence criteria (SAS, ASA, SSS, AAS) and transformational approaches, and struggled with conceiving of transformation functions as objects. These difficulties appear to compound in their proof-writing attempts such that after citing appropriate transformational geometry ideas, such as the angle- or distance-preservation property, they would then supplement with congruence-based approaches in order to finish the proof. This has implications, especially for professional development, as this is the final mathematics class that these preservice teachers will take concerning transformational geometry prior to beginning their classroom instruction.

Key words: transformational geometry, proof

Identifying what prospective teachers know about geometric transformations gains new significance when we consider the prominence these functions are given in the Common Core State Standards in Mathematics (CCSSM). The draft of the Progressions for CCSSM in Geometry, 7-8, High School (Common Core Standards Writing Team, 2016) states that congruence should be defined in terms of rigid transformations, and that the traditional triangle congruence conditions (SAS, ASA, SSS, AAS) should then be proven using this definition. That is, students are expected to:

> *Explain how the criteria for triangle congruence (ASA, SAS, and SSS) follow from the definition of congruence in terms of rigid motions.*

The Progressions borrow heavily from Wu (2013), who points out that this approach allows one to define congruence independently of polygons and who also argues that the transformational approach connects the formal definition taught in high school geometry to the intuitive understanding of congruence that students develop in middle school. While there are important mathematical reasons to make such a change, it represents a substantial break from past practice and has significant implications for curriculum, inservice teacher education, and preservice teacher education. This contributed report approaches this complex issue of curricular change at a very granular level; exploring how preservice teachers in a university-based geometry course make sense of and write proofs about transformational geometry, as well as coping strategies they exhibit.

Harel (2014) cautions against heavy reliance on plane transformations due to the difficulties students and teachers have in understanding the transformations themselves. Some of these challenges and misconceptions include identifying the domain of a transformation as some subset of the plane rather than the plane itself (Hollebrands, 2003; Harel, 2014; Yanik, 2011), having an action or process conception of function rather than an object conception (Harel, 2014;

Hollebrands, 2003; Portnoy, et al., 2006), having a motion rather than mapping conception of transformations (Yanik, 2011), struggling to understand parameters such as the vector that defines a translation (Hollebrands, 2003; Yanik, 2011), and viewing geometric objects as perceived rather than conceived (Portnoy, et al., 2006) or drawings rather than figures (Hollebrands, 2003). In particular, Portnoy, et al. interviewed prospective high school teachers in a college geometry course and found that the students' conceptions of geometric objects as perceived objects and their process conceptions of transformations hindered their abilities to prove congruence using transformations rather than corresponding congruent parts.

We also note that this work is situated in the context of proof-based advanced mathematics classes and draws on student's proof-writing proficiency. For the sake of brevity, we do not report all of this research here, rather we note that there are multiple handbook chapters (e.g., Harel & Sowder 2007; Stylanides, Stylanides, & Weber, in press) describing the literature, and a comprehensive summary of undergraduate mathematics majors' difficulties with proof is given in Selden and Selden (2008) as well as Weber (2003). Student's difficulty with proof is well-documented (Moore, 1994, Weber, 2001). In both reading (e.g., Hodds, Alcock, & Inglis, 2014) and writing proofs (e.g., Raman, 2003; Weber & Alcock, 2004), they are more likely to focus on symbol-manipulation rather than the logical connections or connecting proofs to informal ideas (e.g., Raman, 2003). These certainly limit their ability to write proofs, but also to gain understanding from proofs that they produce (e.g., Weber, 2005; Weber & Alcock, 2009). Another important source of difficulty for students in writing proofs is that they do not appear to appreciate the fact that proofs are based on definitions of concepts (Alcock & Simpson, 2002; Bills & Tall, 1988). Finally, there is more recent research examining what students learn from lectures in advanced mathematics and why they appear to learn different things than the professors intend (e.g., Lew, et al., 2016). Students misunderstood terms that the professor used to convey content, focused on the symbolic manipulations that the professor wrote on the board, while ignoring or forgetting the conceptual explanations and ways of thinking about content and proofs that the professor said aloud (and described as the salient points of the lecture). That is, there appear to be several mismatches in communication styles between students and professors that inhibit student's comprehension of lectures about proofs. Thus, this study investigates the following research questions:

1) What resources (knowledge, skill) have students demonstrated, in terms of content, from their undergraduate geometry course to write proofs about transformational geometry, and are those sufficient to write proofs about congruence via transformations?
2) When writing proofs about congruence via a transformational approach, what proficiencies do students display? What difficulties do they display?
3) What are coping strategies that they exhibit when they encounter difficulties?

Theoretical Commitments

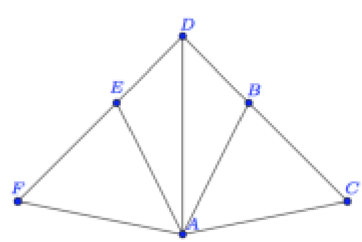
We hold three important theoretical commitments; the first is that students, and others, make decisions to act via practical rationality (c.f., Herbst & Chazan, 2003), making decisions about how to act in circumstances in order to achieve the best possible outcome in a given situation within the constraints that they perceive. In the case of students in this study, the context that most shapes their behavior is the fact that this is a proof-based collegiate mathematics class. As a result, we also draw on the notion of the *didactical contract* (Brousseau, 1986/1997), which can be understood as structuring the economy of the classroom in which students exchange work for grades (especially on exams). This student work addresses prompts that professors set, where research suggests (e.g., Herbst, 2003; Voigt, 1994) that there is frequent negotiation, often tacit, between professors and students about how to engage in a particular task. We claim that the use of partial credit when grading is one such form of negotiation--professors can, bluntly, give students a measure of how close they have come to fulfilling the expected role. In terms of what work, on the student's part, fulfills the expectations for proof within a particular domain, this negotiation typically begins with a professor's classroom presentation of proofs about and drawing on particular ideas and continues with the student's completion of homework about the topic (Thurston, 1994), indicating the needed elements and appropriate detail for a proof. The professor then grades the homework, using scores to indicate whether, and how close, the work comes to fulfilling the professor's understanding of the student responsibilities. The students can then use these marks to further calibrate their understanding of the didactical contract. This process is repeated on exams--although in the case of final exams, the marking will no longer serve as formative feedback to the students, only a summative evaluation of the professor's evaluation of how close the student came to fulfilling their responsibilities.

Methods

The Institution, Class, and Participants

Data from this study was collected in an undergraduate geometry class at a mid-sized urban doctoral-granting institution along the east coast. The course was an advanced, proof-based geometry course with an introduction to proof (or equivalent) prerequisite. The researchers solicited consent from the students to use data from the final exam after the end of the course and after grades had been submitted, and 17 of the students agreed to participate. The course description indicated that the course served as an introduction to Euclidean and non-Euclidean geometries, emphasizing proofs. The catalog also describes the course as targeted at pre-service secondary mathematics teachers. Because of this, the instructor (the first author) purposefully introduced transformational geometry, defining congruence and similarity via transformations. The instructor also stated and proved a variety of theorems about and with transformations. She also did examples of the types proofs that students would be expected to produce using a transformational approach. The data from this study is drawn from one three-part problem on the final exam. (Three out of nine problems on the exam focused on transformational geometry.)

Assume in the figure below that $\angle FDA \cong \angle CDA$ and $\angle DAE \cong \angle DAB$. Let R_1 be an isometry that maps $\triangle DEA$ to $\triangle DBA$.



(a) What could R_1 be? Define R_1 in terms of the given figure. (*You do not need to justify your definition at this point.)*

(b) Is R_1 unique? Why or why not?
(c) Using your definition of R_1, justify that $R_1(E) = B$. (*You should NOT refer to triangle congruence theorems!*)

In line with the expectations of the CCSSM, this task was designed to assess whether students could produce a proof based solely on the properties of transformations. In part (a), students had to identify the appropriate transformation as a reflection across line DA. Part (b) was intended as an independent question addressing the idea that the images of three non-collinear points uniquely define an isometry. Finally, part (c) required that students first cite the angle-preservation property of transformations to state that ray DF maps to ray DC and that ray AE maps to ray AB. The proof would then be completed by observing that while E represents the intersection of ray DF with ray AE, B represents the intersection of ray DC with ray AB, and therefore, the uniqueness of the intersection requires that the image of E is B. There is no way to ask this kind of question without giving students sufficient information to do it; that is, students cannot be asked to prove that triangles are congruent without giving them sufficient information to prove that the triangles are congruent. However, by giving them enough information and then focusing entirely on the justification, it may seem strange in part (c) to justify that R(E) = B when, in the preamble to question (c), R maps E to B by definition. The goal of (a) and (c) was to have the students create a definition in part (a) that they would draw on in developing their proof for part (c).

Methodology for Analysis

To analyze the definitions of R_1 that the students offered, we first examined whether they correctly identified the appropriate transformation as a reflection. Second, we analyzed whether the student specified a line (or line segment) to serve as the axis of reflection, which we then described as mathematically appropriate or not. Finally, we noted whether the students identified the images of particular points under the isometry. To analyze student responses to part (b), we first parsed whether the students correctly stated whether the transformation is unique, marking their responses as correct or incorrect. Subsequently, we evaluated the offered justifications; positing ways of thinking about the figure and transformations that would be consistent with the combination of the given justification and uniqueness response. For this work, we engaged in thematic analysis (Braun & Clarke, 2006), looking for conceptions such as having a motion rather than mapping conception of transformations (Yanik, 2011), and viewing geometric objects as perceived rather than conceived (Portnoy, et al., 2006) or drawings rather than figures. We used our analysis of parts (a) and (b) as an indicator of their understanding of transformations. Finally, to analyze students' proofs in part (c), we first indicated whether each student used a transformational approach, particularly the transformation that the student defined in (a). If the student did not, we described what approach the student took, specifically looking at the rate at which the inappropriate approaches drew on triangle congruence criteria (even though specifically warned not to). We noted whether the student carried out a direct or indirect proof, which properties the student drew on, such as distance preservation, and any claims that were needed but omitted (for example, about the intersection of rays). Finally, we gave a holistic evaluation of the proof-attempt; indicating what about it was productive and what was unproductive--where, by productive, we mean whether we could hypothesize a direct way for the work to lead to a correct proof. When students performed unproductive actions, we noted what was problematic. For each student, we read across their responses (and our analysis) to the three prompts and developed a summative description of their work, and hypothesized a conceptual model of transformations that the student might hold that would lead them to produce the exhibited work.

Data and Results

We first present summaries of student performance on items (a) and (b), then the analysis of their work on item (b), followed by a description and analysis of their proof-productions. Thus, we first note that 16 of the 17 students correctly identified that R_1 could be a reflection across the line DA. The one student who did not state that R_1 was a reflection stated:

R(D) = D, R(E) = B, R(A) = A

In this case, the student determined the images of three points under the transformation. Since the class had discussed that the images of three non-collinear points define a transformation, the evidence suggests that the student was claiming that the transformation was a reflection. The other 16 students made three different types of claims:

- 9 students made a claim that "R could be a reflection across the line DA" (or AD). One student added, "This would reflect everything on the left of AD to the right of AD but AD is fixed."

The first clause gives little insight into student thinking. The phrasing raises the question of whether the student imagines part, or all, of the figure moving (e.g., half at a time).

- 4 students made a claim similar to "Reflection with line of symmetry DA such that R(D) = D and R(A) = A" where they both named the line of symmetry and stated images of particular points.
- 1 student stated: "R would be a reflection across line DA. R(triangle DEA) = triangle DBA" (which implicitly draws on triangle congruence)

On Item (b), 9 students stated that the transformation was not unique, while 8 stated that it was, but only 4 students gave a correct justification. An example of such a justification:

No! This same isometry could have been done as a glide reflection and translation, etc. Three reflections could have worked.

In this case, the student gave a correct statement, and indicated knowledge of the three-reflections theorem that the professor presented in class, which stated that any isometry is equivalent to one, two, or three reflections. The students who gave incorrect justifications gave responses that indicated a variety of ways of understanding reflections and transformations generally.

Seven students gave a response that indicated that their understanding of unique implies that only one 'move' can be used (ignoring the idea that a composition of transformations is a transformation). These students wrote claims such as, "Yes because any other isometry would require more than one isometry." This type of claim suggests that the student has a conception that an isometry must be only one 'move,' rather than a composition of possible transformations. This way of thinking suggests that students have a definition of isometry as a 'move' rather than as a map. Similarly, one student wrote, "Yes, by definition isometries are onto and one-to-one which imply uniqueness." This claim that "onto and one-to-one" implies uniqueness is interesting, but not mathematically correct. There were two instances where students claimed that a rotation would suffice; one claiming a rotation of 180 degrees and another student claimed a rotation of 360 degrees. These students' responses do not give much insight into their thinking, but one hypothesis is that the first believes a rotation of 180 and reflection to be equivalent. The second may have been attempting to 'land' the figure back in the original image, but have not attended to the position of the points—essentially attending to the appropriate relationship between figure and ground, while ignoring others. Finally, there were two responses that suggest the students were writing a justification because one was asked for, but with no relationship that the researchers could hypothesize to the claims, for example, "it bisects $\angle D$ and $\angle A$." That is, apart from the students who gave correct responses and justifications and the two students who seemed to be attempting an answer, it appears that the students' justifications show that the concept of uniqueness of transformations is difficult for students. It appears that they are focused on the way of 'moving' the points rather than the outcome of the transformations. To relate this to the literature, they may be making the figure/plane distinction that Yanik (2011) identified, or, may (also) have a process-oriented understanding such as Portnoy, Grundmeier, and Graham (2006) described. A process-oriented conception would suggest that the individual focuses on the means of the transformation, imagining a particular output, without physically manipulating points, while an object-conception would allow the students to focus on the output of multiple processes simultaneously and then be able to compare those outputs for uniqueness. We note that this explanation, that students concurrently hold these two problematic conceptions, is speculative, based on their written production. We treat it as a hypothesis that would require further testing, and only one possible explanation for the work that they exhibited.

Looking to part (c), a correct proof uses the angle preservation property on both pairs of angles to show that the image of E must be at the intersection of the rays DC and AB and therefore must be B. First, one of the students, whose work on (b) appeared to be aimed at earning credit, wrote a collection of statements that were all related to the prompt, but which we could not interpret in any coherent manner, again suggesting that the work was aimed at earning partial credit. Second, four students drew on notions of triangle congruence; two of whom did so explicitly. For example, arguing that "Since triangle DAE is congruent to triangle DAB, we know DE = DB, and AE = AB." These students typically used triangle congruence to claim segment congruence.

All of the students used the distance preservation property or angle preservation property in some way; some only used these properties implicitly, while others correctly stated them and yet did not productively use them. Multiple students made false claims based on the distance preservation property, such as the claim that unequal points cannot be equidistant from the line of reflection. Many correctly used the angle preservation property, but omitted the needed claims about the intersection of rays; the following is a representative such proof:

> Since $\angle FDA$ is congruent to $\angle CDA$ and $\angle DAE$ is congruent to $\angle DAB$, then R(ray DE) will match to ray DB and R(ray AE) will match to ray AB respectively. Since this is an isometry length is invariant, so DE = DB and AE = AB. Thus R(E) = B.

Note that the first line begins by identifying two pairs of congruent angles and making a claim about where a pair of rays is mapped, indicating that the student has used the angle preservation property twice, although without stating it. However, the student omits any claims about the intersection of rays. Instead, the student then draws on the distance preservation property to state that length is invariant under an isometry and names line segments that are equal. Though accurate, this statement has not been justified and, in fact, relies implicitly on the fact that the triangles are congruent. The proof is complete without this statement, but the student possibly believes that citing length invariance is important. Four students only used the angle preservation property on one pair of angles, then attempted to 'repair' the result using other notions, such as that the preimage and image of a point are the same for reflections, or that a pair of segments would be parallel, while two of these students then used triangle congruence. Finally, four students gave correct proofs, though two of them used, without stating, both the angle preservation property and the intersection of rays.

Discussion

We argue that one important finding is that the majority of the students (future teachers) do not appear to be fluent with transformational geometry at the end of their one-semester course. This is an important finding from both the perspective of teacher education and undergraduate mathematics. From the perspective of undergraduate mathematics it reinforces the claim that students find advanced courses difficult and struggle with proof-writing (Selden & Selden, 2008), and supports an argument that they need significantly more time with the material to develop appropriate fluency. From the perspective of teacher education, this finding is important because it suggests that even teachers whose geometry class includes a transformational approach are not adequately prepared to teach it. It raises significant questions about their future instruction, their future students' learning, and policy questions about what additional levers for change need to be attempted.

A second important finding that we highlight is the fact that many students *implicitly* drew on triangle congruence ideas and sometimes did so explicitly, and, especially for part (c). We suggest that the notions of the classroom economy and students' practical rationality may have made this likely. In particular, we hypothesize that the students were attempting to maximize the points that they earned, and that, while the directions might indicate not to use congruence theorems, the students may believe submitting this proof is better than the alternative of possibly not submitting a proof. That is, they are trying to earn partial credit as a means to maximize their grade. We further claim that drawing on congruence theorems may be a form of coping--reverting to a more familiar and practiced set of content for proving, and away from the newer and less familiar content.

We also note two curious correlations that may be interesting to further explore. Students often use ideas implicitly, i.e., without stating them or warranting their use, and it is not clear whether they are omitting the name and warrant because they are hurried in an exam setting, because they find it obvious, or because they do not realize they need to warrant the use. There were only three cases where students transparently made an unsupported statement. Secondly, the students who did best on part c did not do especially well on part b. Most importantly, we note that this was a first study of students' understanding of transformational geometry and that we have drawn some preliminary hypotheses that can help explain the types of performances that they exhibited on their exam. We note that we did not interview the students; we did not, at the time, anticipate that this question would produce interesting data. Thus, one follow-up study will be to explore which of the proposed hypotheses for student difficulty are the most plausible by engaging in task-based interviews, as well as interviewing students at the completion of their final exam in a similar class. Moreover, because these are future teachers, asking for the kinds of explanations of ideas that they would give their students has value in both giving researchers insight into their understanding of the content and giving policy-makers a better understanding of what additional supports will be needed going forward.

Exploring Experts' Covariational Reasoning

Natalie L.F. Hobson
University of Georgia

Kevin C. Moore
University of Georgia

In this paper, we discuss two experts' reasoning abilities when tasked with drawing a graph that relates two varying quantities. We present evidence that in some cases, these experts had constructed and coordinated the amounts of change of the quantities (while interpreting and constructing graphs). By comparing each experts' activities and corroborating previous researchers' findings, we argue that constructing a multiplicative object is critical to conceiving a graph and situation as constituted by covarying quantities. We identify particular complexities involved in the development of covariational reasoning including the conceptualization, coordination, and referent accumulation of the amounts of change of two quantities.

Key words: Covariational Reasoning, Multiplicative Object, Graphing

Many researchers have illustrated the importance of covariational reasoning in order for students and teachers to construct and represent relationships graphically, understand families of relationships (e.g., linear, quadratic, trigonometric, exponential), and develop mathematical ideas in calculus (e.g., limits, rates of change, differential equations) (Ellis, Özgür, Kulow, Williams, & Amidon, 2015; Moore, 2010; Moore & Thompson, 2015; Strom, 2008). In recent decades, researchers have developed constructs in order to characterize students' and teachers' quantitative and covariational reasoning. The results of such work has included frameworks of mental actions (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Thompson & Carlson, 2016), refined characterizations of observed behavior (Castillo-Garsow, 2010, 2012), and examples of students' and children's reasoning about dynamic quantities (Ellis et al., 2015; Lobato, Rhodehamel, & Hohensee, 2012; Moore, Paoletti, Stevens, & Hobson, 2016). Researchers have also shown the importance and necessity of certain cognitive objects that an individual must construct in reasoning covariationally. In particular, Thompson and colleagues described that constructing a multiplicative object is critical to an individual constructing and representing covariational relationships (Thompson & Carlson, 2016; Thompson, Hatfield, Joshua, Yoon, & Byerley, 2016).

In this study, we extend the aforementioned body of research to include examples of experts reasoning in a dynamic situation. We use the covariational framework developed by Carlson et al., 2002 with particular attention to *amounts of change* to characterize the mental actions we inferred from the work of these experts. By comparing their reasoning and activity, we provide evidence of the importance of joining two quantities' amounts of change into a multiplicative object for interpreting and graphing relationships involving varying quantities.

Background

Our understanding of covariation stems from Saldanha and Thompson's (1998) description of "someone holding in mind a sustained image of two quantities' values (magnitudes) simultaneously… coupling the two quantities, so that in one's understanding, a multiplicative object is formed of the two" (p. 299). To further understand the notion of multiplicative object, we leverage Thompson's (1994) characterization of accumulations and accruals. Thompson described that a sophisticated conception of covariation and rate involves the construction and coordination between two quantities' accumulations and the accruals that make up these accumulations. We note that an accrual is understood in terms of a smooth accumulation itself and as a quantity whose magnitude is a difference between two states of another quantity's magnitude. We interpret Thompson's (1994) articulation of this relationship between covarying quantities' accumulations and accruals to involve forming interrelated multiplicative objects both between corresponding accumulated amounts of quantities and changes between these quantities.

Carlson and colleagues proposed a framework articulating levels of images of covariation and mental operations that support each level (Carlson et al., 2002). These mental actions can be described with regard to the elements that one is coordinating and the aspects of these elements one is attaining to. For example, amounts of change (Mental Action 3) are one such element that we focus on here. In regards to amounts of change, Carlson et al. (2002) observed students' lack of propensity to reason with these elements, indicating the difficulty of coordinating amounts of change into a multiplicative object. Corroborating the findings of Carlson et al., Johnson (2012a, 2012b) illustrated that maintaining an image of simultaneous accruals is non-trivial for students. For instance, Johnson described children's tendencies to reason about associated changes in magnitudes as happening independently in each quantity, which may be problematic for their ability to make sense of variation in rates of change. Furthermore, other studies have investigated students' construction of a multiplicative object uniting quantities' values (Thompson et al., 2016; Stalvey & Vidakovic, 2015; Frank, 2016). Thompson and colleagues (2016) investigated teachers' graphs representing animated magnitudes that were displayed on orthogonal axes. These researchers illustrated that a teacher's ability to unite the axes magnitudes into a multiplicative object was essential to her or his graphing the varying quantities.

Data Collection and Methods

The two participants of this study, Jake and Dan, were first year students in a mathematics education PhD program in a southeastern US university. Each participant had previously completed a Bachelor's degree in mathematics and taught secondary school mathematics for at least two years. These participants' interviews were part of a larger study aimed at investigating teachers' and college students' quantitative and covariational reasoning (see goo.gl/dAA7Re). The research team of this larger study (which includes the authors of this paper) conducted 60-minute semi-structured clinical interviews (Ginsburg, 1997) with 10 experts from the same university. By expert, we mean an individual who is enrolled in a doctoral program in mathematics or mathematics education with teaching experience in secondary or undergraduate mathematics. Thus, we mean expert as someone who one might expect to have sufficient experience engaging in tasks involving representing and reasoning about quantities.

One or two members of the research team led each interview. Each interview was video- and audio-recorded and each participant's work was digitized. We analyzed the data using grounded approach (Strauss & Corbin, 1998) combined with Thompson's (2000, 2008) notion of conceptual analysis. The data was first transcribed and instances offering insights into the experts' thinking were identified. After discussions with the full research team, Jake's and Dan's activity seemed to provide the most enlightening comparison for us, as both participants' behavior focused on quantities and did not resort to thematic associations or memorized formulas. Focusing on these two experts, we performed a conceptual analysis (Thompson, 2000) of their thinking in order to generate and test models of their thinking so that these models provided viable explanations of their behaviors.

Tasks

Each interview task began with having the participant watch a short (about 20 second) animated clip. The first interview was focused on *Going Around Gainesville (GAG)* (see Figure 1) and the animation played a "car" moving back-and-forth along the path indicated in the figure. The second interview was focused on *Taking a Ride* (see Figure 2). The first part of this task played a circle wheel spinning around the axle and the second part of the task involved an animation of a fixed square "wheel" in which the carts traversed along the frame of the "wheel." All three of these animations played so that the motion was at a constant speed.

Going Around Gainesville Part I

Some Georgia students have decided to road trip to Tampa Bay for Spring Break. Of course, this means traveling around Gainesville on their way down and back. The animation represents a simplification of their trip there and back. Create a graph that relates their total distance traveled and their distance from Gainesville during the trip.

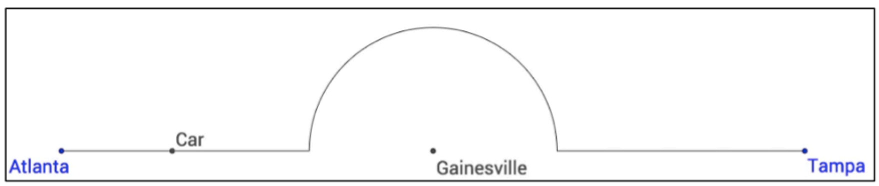

Figure 1. The *Going Around Gainesville* (*GAG*) task.[1]

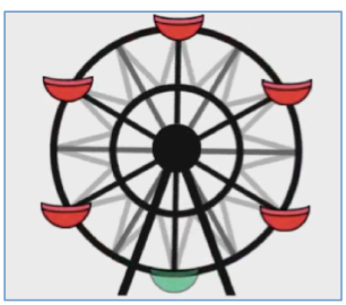

Taking a Circle Ride
Graph the relationship between the total distance the rider has traveled *around* the Ferris wheel and the rider's distance from the ground.

Taking a Square Ride
Graph the relationship between the total distance the rider has traveled *around* the Square Wheel and the rider's distance from the ground.

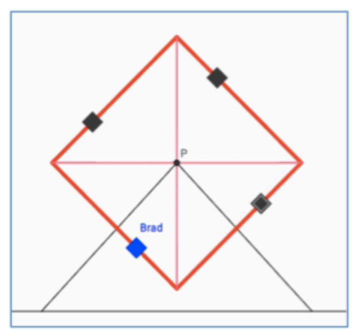

Figure 2. The *Taking a Circle* and *Square Ride* task.

We designed the situations in these animations to illustrate multiple measurable attributes and the tasks to prompt students to graph various relationships between two quantities without explicit reference to numerical values. Since we were interested in students' *images* of covariation, we did not want them to rely on learned facts or formulas to relate the quantities' magnitudes (Saldanha & Thompson, 1998). The focus on novel attributes and multiple orientations of graphs were intended to perturb students' ways of thinking about graphs (Moore, Silverman, Paoletti, & LaForest, 2014). We avoided time as one of the quantities for students to relate as they can often reason uni-variationally when time is one of the quantities under consideration (Leinhardt, Zaslavsky, & Stein, 1990).

[1] This task is a modification of the task provided by Saldanha and Thompson (1998).

Results

In this section, we compare and contrast Jake's and Dan's actions in responding to the interview tasks. Due to space constraints, we do not report on the entirety of their actions, but instead focus on particular aspects that were critical to their responses or instances in which we inferred marked differences in their actions.

Going Around Gainesville (GAG)

Both Jake's and Dan's activities in this task began in a similar way. After reading the task out loud, they each created and labeled axes and traced, what we perceived to be, an accurate graph (see Figure 3 and Figure 4). In each case, the interviewer then proceeded by asking the participant why he drew a graph composed of straight lines (or segments).

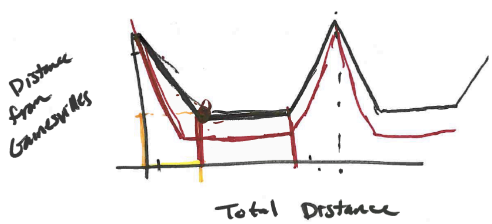

Figure 3. Jake's graph in GAG.

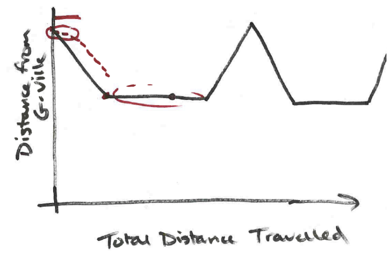

Figure 4. Dan's graph in GAG.

Each participant initially contended that the straight lines in his graphs were a consequence of the constant speed in the situation. Their initial verbal responses did not indicate their conceptions of two covarying distances, and we infer their constructing a thematic association (Thompson, 2016)—constant speed necessarily implies line—between their graphs and the situation. Upon further questioning from the interviewers, each participant concluded that the shape of his graph was actually not influenced by time or constant speed. Each explained,

> **Jake:** It's still like a, I guess, one to one relationship… for every one mile you move towards the total distance towards Tampa you're still getting that one mile closer to Gainesville at least for this part of the graph [*referring to the first linear segment of the graph*].
>
> **Dan:** There's a relationship between as the car's moving, it's consistently getting closer to Gainesville and it's also consistently traveling a distance. So, whatever it is doing distance-wise is also happening to its distance to Gainesville… 10 miles total distance traveled and it's also 10 miles closer to Gainesville.

In both responses, the participants identified a *relationship* between the quantities' *total distance* and *distance from Gainesville* by reasoning with an explicit amount of change in *each* quantity respectively. From their language ("for every" and "consistently"), we infer that this relationship resulted from participants' awareness that such an explicit amount of change could be constructed along any section of the first part of the road or first segment in the graph.

Taking a Ride

In the second interview, Jake's and Dan's activities unfolded in distinguishable ways, and thus we focus the majority of the results section here. Despite the participants' initially drawn graphs being noticeably similar, their ways of reasoning over the course of this task unfolded quite differently.

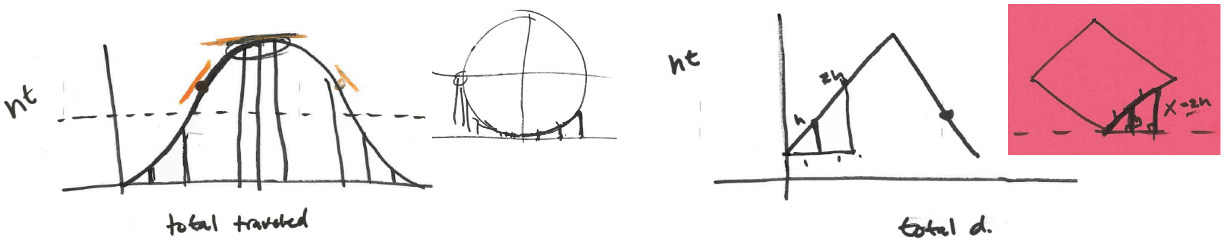

Figure 5. Jake's graph and diagram for *Taking a Circle* (a and b) and *Square* (c and d) *Ride.*

Jake—Taking a Circle Ride. Jake justified the curvature of his graph by claiming, "it's not a constant rate of change." The interview continued with Jake justifying this claim, concluding the situation instead involved "increasing rates of change," and then reasoning that this phenomenon was reflected in his graph. To explain why the situation was not a constant rate of change, Jake partitioned an arc around the circle wheel into equal parts (see Figure 5b). He then drew in segments to the "ground" from the points he marked on the wheel to indicate the corresponding "height of the rider" at each location on the wheel. He continued,

> "…so all of those are congruent, I guess, arcs [*referring to the arcs in Figure 5b*]. You see that the height is a lot different in comparison to these arcs being the same, um, so it's not linear. If it was linear we would expect these heights to all be the same for each arc along the circle that you move."

Due to Jake's construction and emphasis on the "congruent" arcs, we interpret Jake's activity to indicate that he was coordinating *changes* in arc length with *total* height at the terminal point of each partitioned arc. After further questioning, Jake continued to claim, "Because these heights aren't the same, we had kind of changing rates of change." We subsequently asked Jake to represent this phenomenon (of changing rates of change) on the *graph*. He responded, "Oh, well, I guess I mean, you can just look at tangents to the curve if you want." At this point in the interview, Jake had not engaged in behaviors we interpret to indicate his coordinating amounts of change in the context of the graph or situation, instead referring to "rates of change" and slopes of tangent lines. Thus, we were curious about Jake's mental actions associated with these phrases. We asked Jake if he could say more about tangents and slope. Jake responded,

> "So if you take the tangent of the curve at this point to be that [*drawing first orange segment on graph in Figure 5a*], the rate of change is increasing, whereas maybe as you take it through the maximum point [*drawing second orange segment on graph*] your rate of change is zero at that instant…. [Increasing rate of change] means … as you're moving along the wheel, as your total distance is changing, your height is also changing as well in the same direction but positive."

Jake claimed (1) a positively sloped tangent line at a point indicates the rate of change is increasing at that point and (2) the rate of change increasing means both quantities are increasing. As the interview progressed, Jake persistently repeated these two claims and he did not engage in activity that suggested his unpacking the tangent line as the result of "smaller and smaller refinements of the average rate of change" (Carlson et al., 2002, p. 358). Jake did not associate tangent lines or "rate of change" with coordinating what we perceived to be associated amounts of change of two quantities. Jake's coordination of *congruent arcs* around the wheel and *total height* where problematic in his constructing rate of change from coordinating *changes* in *both* quantities.

Jake— Taking a Square Ride. After watching the animation, and like the previous task, Jake immediately drew what we perceived to be an accurate graph (see Figure 5c). Jake explained the shape of his graph by claiming the rider was “increasing at a constant rate.” Jake, however, was perturbed by how to illustrate this relationship on the situation. After various attempts to do so, he redrew the square wheel (see Figure 5d), identified similar triangles, and explained that the quantities’ magnitudes maintained a fixed ratio. Jake explained, *“*For each unit that I move up, along the square, whatever this height is [*motioning to the total amount of height corresponding to the first “unit up”*] is going to be twice the original height, or if you want to call it a unit height.” Jake seemed confidant that this justified his linear graph, but subsequently expressed skepticism in using this argument to justify the statement: “height is changing by a constant rate.” We do not include this example in order to discredit Jake’s thinking, but instead to further illustrate that across the tasks in this interview, Jake did not persistently coordinate *amounts of change* of the quantities in ways that indicated his constructing a multiplicative object composed of amounts of change.

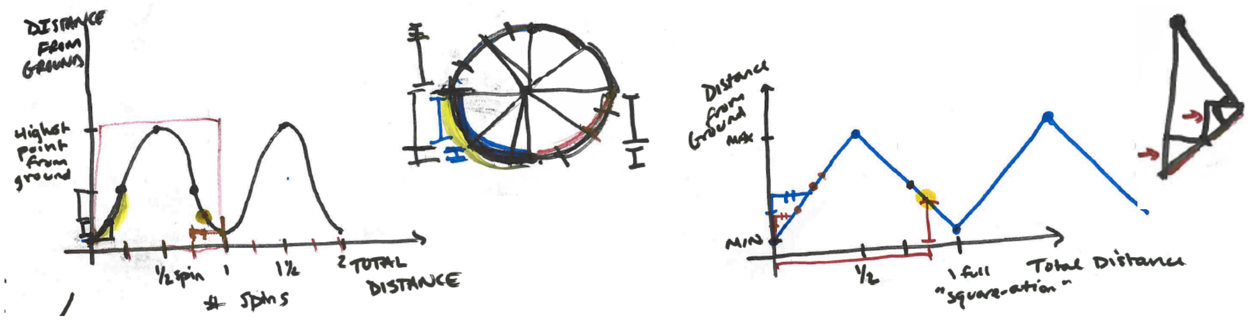

Figure 6. Dan’s graph and diagram for *Taking a Circle* (a and b) and *Square* (c and d) *Ride.*

Dan— Taking a Circle Ride. After watching the video Dan drew a set of axes, marked the minimum and maximum height along the vertical (height) axis and then partitioned the horizontal axis of his graph into half rotations of the wheel (see Figure 6a). He then plotted points on his graph corresponding to the rider’s height at each half rotation. He next questioned how to trace the graph between these points, “The question I'm having is, will this be a straight line [*motioning a straight line between the first two points he marked on his graph*] or will there be any curve in it.” This behavior is in contrast to Jake’s in that Dan focused on pairing two quantities’ values and considering how these quantities’ magnitudes vary between two pairs of magnitudes *before* drawing a graph.

Continuing, Dan drew a diagram of the wheel (see Figure 6b), marked a point at a quarter spin along the wheel and drew a vertical segment corresponding to the rider’s height at this location; this segment is “halfway as high as he can get.” He then referred to a “quarter spin” being “halfway” along both axes and plotted this point on his axes. Dan then partitioned the first quarter arc of the wheel into two equal arcs and drew vertical segments corresponding to the change of height of the rider along each arc (Figure 6b). He explicitly identified that these two arcs were equal and then compared the associated vertical segments; he stated that the first segment was “less change” than the second segment. He subsequently drew the first part of his graph corresponding to the rider’s trip along the first quarter of the wheel. Dan finished his graph by using this same strategy for each remaining quarter of the wheel.

We asked Dan how his graph related to his reasoning with the diagram. Dan explained by indicating a coordination of the amounts of change of total distance and the amounts of change of height from ground (i.e., reasoning with accruals). Dan explained,

> “These [*tracing along the arcs in Figure 6b*]... are all the same amounts on the same axis. So those are uniform tick marks … [*marking over the points on the horizontal axis*

corresponding to the arcs]. But … then you notice in the first *x* interval [*holding fingers around first interval on horizontal*], there's very little change in *y* [*points to vertical segment in Figure 6b corresponding to first change of height*] ... But then if you look at the next same amount of *x* [*holding fingers around the second interval on horizontal axis*], you get a much bigger change in *y* [*points to vertical segment corresponding to second change of height*]."

In this dialog, we infer that Dan was constructing the quantities on his graph by coordinating, along the axes, the accruals by which accumulations occurred (Thompson, 1994).

Dan—Taking a Square Ride. In this task, Dan acknowledged that he could construct his graph using the "same logic" as in the previous task. He partitioned each quarter of the square wheel into two equal parts and identified the corresponding change of height of the rider along each segment. Next, Dan identified a relationship between these changes in height by asking himself out loud, "… is this right here [*drawing arrow in Figure 6d pointing to a change in lowest height segment*] the same as this right here [*drawing second arrow in Figure 6d*]? And the answer is yes. So, and this is, I said for an eighth but you could do this for any arbitrary piece of the square." We infer that Dan held in mind that two arbitrary, but equal, distances traveled along the square wheel had corresponding changes in height that were also equal.

Conclusion

In this study, the participant's ability to construct and coordinate amounts of change was essential to his ability to reason covariationally about the shape of his graph. In the first interview, both Jake and Dan constructed amounts of change of each quantity in the situation and were able to use this construction to explain the relationship between the quantities. However, in the second interview, Jake did not construct associated amounts of change of the quantities. In these tasks, Jake instead relied on reasoning with tangent lines (*Taking a Circle Ride*) or the geometry of his drawn diagram of the situation (*Taking a Square Ride*). Jake did not unpack his constructed tangent line in terms of amounts of change or construct amounts of change from the geometry he described in his diagram. In both tasks Jake did not reach what he considered a satisfactory justification for his drawn graph.

In contrast, Dan's activity in the second interview was to construct equal changes of one quantity and compare corresponding changes in the other quantity. Dan represented the coupled changes of quantities on a graph by conceiving simultaneously accumulated amounts in terms of simultaneous accruals. The collection of these activities is an indication that Dan had constructed *amounts of changes* into a multiplicative object (Thompson, 1994).

This report extends previous observations from Carlson et al. (2002) and Johnson (2012a, 2012b) on the difficulties college-level students and children have in constructing and coordinating amounts of change of quantities. Indeed, we illustrate that maintaining an image of simultaneous accruals is also not trivial for experts. Furthermore, the evidence suggests that it was the construction of corresponding amounts of change that afforded Jake and Dan the ability to represent and interpret the animations covariationally.

How Students Interpret Line and Vector Integrals Expressions: Domains, Integrands, Differentials, and Outputs

Steven R. Jones
Brigham Young University

Omar Naranjo
Brigham Young University

This study expands on research happening in multivariate calculus education to an exploration of student understanding of line and vector integrals. We describe how students interpreted these types of integrals, including the various symbols in their expressions and their relationships to each other. We found that while students were able to associate mathematical objects with the individual symbols in the integral expressions, the main issues came in trying to coordinate these objects into a comprehensive whole for the entire integral expression. While the literature has discussed connections between the integrand, differential, and integral symbol, we also found that connecting the domain to the other parts of the integral expression was difficult as well. Thus, to give more attention to the domain in addition to these other parts, we have incorporated it into a general "domain-chop-evaluate-add" framework for reading integrals.

Key words: multivariate calculus, line integral, vector integral, domain, framework

Undergraduate education research has recently taken an interest in multivariate calculus, which is an important required course for many mathematics, science, and engineering majors (e.g., Harvard University, 2016; Massachusetts Institute of Technology, 2014). This research has begun to examine student understanding of function (Dorko & Weber, 2014; Martinez-Planell & Trigueros-Gaisman, 2012), graphing (Martinez-Planell & Trigueros-Gaisman, 2013; Weber & Thompson, 2014), partial derivatives (Martinez-Planell, Trigueros-Gaisman, & McGee, 2015; McGee & Moore-Russo, 2015), and integration (Jones & Dorko, 2015; McGee & Martinez-Planell, 2014). However, the studies dealing with multivariate integration have focused only on how students understand real-valued multiple integrals (Jones & Dorko, 2015), or on teaching strategies that may help students learn this specific type of integral (McGee & Martinez-Planell, 2014). There is no research we could find on other important types of integrals from the multivariate calculus curriculum, such as line integrals and vector integrals. By line integrals we mean integrals of a real-valued function over a curved line, *C*, as in $\int_C f(x,y)\,ds$. By vector integrals we mean integrals with a vector field for the integrand, such as $\int_C \vec{V} \cdot d\vec{r}$. Line and vector integrals are important both for later mathematical study (e.g., contour integrals) and later science and engineering study (e.g., work, flux, or circulation). Due to the lack in the research literature on student understanding of these important subtopics within multivariate integration, in this paper we seek to shed light on the following question: How do students interpret line and vector integral expressions, including the various symbols within those expressions?

Semiotics

Since this study deals with students interpreting symbols, we employed a semiotics framing and analysis (Peirce, 1998; Presmeg, Radford, Roth, & Kadunz, 2016; Radford, Schubring, & Seeger, 2008). Semiotics deals with how symbols or signifiers are used to refer to objects, in this case *mathematical* objects. Peirce (1998) defined a "sign" as containing three components: an *object*, or the actual thing represented by a symbol or signifier; a *representamen*, or the symbol or signifier used to refer to the object; and an *interpretant*, or one's understanding of the relationship between representamen and object. Note that an *interpretant* is not the *interpreter*. That is, an interpreter of the symbol or image creates an *interpretant* through the connections they see between the signifier and the signified. Peirce explained a difference between the *intentional* intepretant created by the one who generates the symbol or image, and the *effectual* interpretant created by one who "reads" the symbol or image. For the purposes of this paper, we focus mainly on *effectual* interpretants, or those created by students as they interpret the symbols in the integral expressions. Peirce also described that signs can potentially be *iconic* (physical resemblance), *indexical* (physical connection), *or symbolic* (conventional symbol) in nature. For the purposes of this paper, since we are using conventional symbolic notations of integral expressions, we are only examining signs that are *symbolic* in nature.

For successful communication using signs, the object and representamen must be known to go together by the one who interprets the representamen, such as an exclamation mark inside a triangle indicating danger, or that a stick figure is meant to represent a person. However, in mathematics it may be the case that a symbol has been invented to capture a particular idea – such as Leibniz introducing the integral symbol, $\int$, to refer to a summation, in which there is an implication that integrals are inherently sums (Katz, 2008) – but that a student is not aware of that intention. In that case, the student may associate that symbol with a different mathematical object, say, geometric area, implying that integrals denote areas within shapes. In this case Leibniz's *intentional* interpretant and the student's *effectual* interpretant do not match up. In this study, we were interested both in what objects students might perceive the line and integral symbols as referring to, and the interpretants created by the students in that interpretation process. That is, we are not necessarily assuming "successful communication" regarding the signs involved in the integral expression in terms of their normative, intentional meanings. Rather, we are interested in open-endedly seeing the objects that students determine a particular symbol to refer to and what the implications of that association are. We use the term "interpret a symbol" to mean that a student has linked the symbol to a mathematical object, through which an interpretant, or implication of that interpretation, might also exist.

Methods

The data used for this report were generated from semi-structured interviews on different types of integrals with 10 university students of varied backgrounds. Six students (A–F) had just completed multivariate calculus, coming from three different instructors. Two students (G and H) were further in their undergraduate mathematics studies, and two students (I and J) were graduate students in mathematics education. This diversity in background was deliberate in order to broaden the potential interpretations of symbols we might observe in the results. For this conference report, we focus on two of the questions from the interview protocol, which asked the students to describe a generic line integral expression and a generic vector integral expression, as follows: "What does $\int_C f(x,y)\,ds$ mean, where C is a curve (i.e. curved line) in the x-y plane?" and "What does $\int_C \overline{V} \cdot d\vec{r}$ mean, where $\overline{V}$ represents a vector field and C represents a curve (i.e. curved line)?" Standard follow-up questions were used to probe student thinking.

For our analysis, we considered each symbol of each integral expression, *C*, *f(x,y), V, ds, dr,* and $\int$, to constitute a separate *representamen* that could potentially refer to some mathematical object. The object was not specified for the students, so they could make their own interpretation of each symbol. After the interviews, we independently went through the data, one student at a time, to identify the mathematical objects they associated with each individual symbol. We then brought our separate analyses together to compare our results, which we found to be fairly consistent with each other, and to resolve any discrepancies. Once we had done this for each student regarding each symbol in both types of integrals, we went through the entire data set one more time to check if we had missed any objects in light of our joint discussions. For each symbol, we then identified which students shared the same interpretation. Lastly, after identifying the mathematical objects each student associated with each symbol, we then went back through the data, one student at a time, to see how the objects associated with each symbol, and the implications of those associated objects, fit together to give rise to an *overall* object for the entire integral expression.

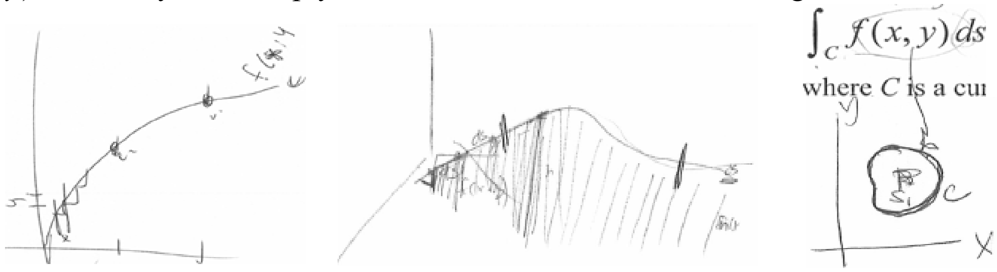
Results

We organize our results by first describing the students' interpretations of each symbol, in terms of the objects associated with the symbols, and the implications of those associations. We do so first for the line integral, and second for the vector integral. Also, within each integral expression, we describe how the individual objects associated with the symbols gave rise to an overall object associated with the entire integral expression, and the consequent implications.

Line integrals

Student interpretations of the integrand, f(x,y), and the domain, C. Since the interview prompt for the line integrals explicitly stated that *C* was a "curved line," it is not surprising that most students interpreted the symbol *C* as referring to a curved line. What is interesting, though, is that nine of the students (all except J) commonly interpreted the symbol $f(x,y)$ as *also* referring a curved line, and not to a curved plane. Only Student J consistently interpreted $f(x,y)$ as referring to a curved plane, though Students E and I also did so at certain points in the interview.

The students varied in how they interpreted the relationship between the objects associated with the symbols *C* and $f(x,y)$. The majority of the students (A, B, F, G, I, and J) interpreted both *C* and $f(x,y)$ as essentially representing the same mathematical object. For example, three of the students (B, G, and I) believed $f(x,y)$ represented a long (possibly infinite) curved line, and that *C* represented a certain finite segment of that same curved line, as seen in Figure 1a and 1b. Note that 1a shows $f(x,y)$ in the *x-y* plane (Student G), while 1b shows $f(x,y)$ in 3-space (Students B and I). Two other students (A and F) made an even stronger connection between $f(x,y)$ and *C* by representing them as the exact same closed loop in the *x-y* plane (Figure 1c). These students initially drew *C*, alone, as a closed loop in the *x-y* plane, but as the interviewer asked about where $f(x,y)$ fit in, they both simply indicated it would be the same thing as *C*.



(a) (b) (c)

Figure 1: Interpretations of *f*(*x,y*) and *C* as representing the same mathematical object

Student J and Student I (at a different time) both interpreted *f*(*x,y*) as referring to a curved plane, with *C* as a curved line *coinciding* with the plane *f*. While Student I thought *C* might refer to a closed loop traced out *inside* the curved plane itself (Figure 2a), Student J drew *C running through f* (Figure 2b). Interestingly, Student J actually described *f* as a finite object that bounded *C*, essentially flipping the roles of *f*(*x,y*) and *C*, as though the integral were $\int_{f(x,y)} C\, ds$.

Student J: I don't know… I would imagine that, probably, where your function is [*f*(*x,y*)], this plane right here tells you what part of the curve [*C*] you're integrating, or something.

(a) (b)

Figure 2: *C* as a curved line (a) *inside f*(*x,y*) and (b) *running through f*(*x,y*)

Student interpretations of the differential, ds. Eight of the students in this study (A, B, E, F, G, H, I, and J) interpreted the differential, *ds*, as referring to a small arc length, or a small portion of *C*, which agrees with the Δs in the Riemann sum that often forms the basis of the mathematical definition of the line integral. Three of these students (E, G, and H) further specified that the *ds* could be thought of as the *infinitesimal hypotenuse* of a right triangle with *dx* and *dy* as the legs. However, one of the students (C) interpreted *ds* as referring to small pieces of *area* instead of *length*, based on his idea of the integral as calculating the area underneath a portion of an *f*(*x,y*) graph. The tenth student (D) made no meaningful interpretation of *ds*, even when prompted by the interviewer.

Interestingly, half of the students (A, B, C, E, and F) attempted to alter the *ds* symbol in the line integral expression into other types of differentials, such as *dt*, *dx* and *dy*, *dA*, or *dr* and *dθ*. This seems to suggest that the symbol *ds* was deemed insufficient by these students in representing the mathematical object they believed *ds* referred to. By analogy, this may be like a stick figure that, while referring to a person, is inadequate for specifying the person's age. Presumably this may be due to the fact that computing a line integral by hand using anti-derivatives typically requires either a parameterization or a change to other types of coordinate systems. Thus, the *procedure* for computing line integrals seems to have influenced how several of the students fundamentally interpreted the differential, *ds*, of a line integral expression.

Student interpretations of the overall integral. Six of the students (B, C, D, E, H, and I), at one point or another, pieced the individual objects together to come up with an overall interpretation of the line integral as representing the surface area of a "curved sheet" stretching between *C* and *f*(*x,y*), matching the normative geometric interpretation of line integrals. However, only two of the students (E and H) had what could be considered a *stable* interpretation of the overall line integral (see Thompson, Carlson, Byerley, & Hatfield, 2014), as exemplified by Student H:

Student H: [Draws a parabolic curved line in the *x-y* plane, see Figure 3]. There's my curved line [*C*]… Then whatever my *f*(*x,y*) is [draws a curved line in 3-space above *C*]… I'm finding this region right here [shades in between *C* and *f*]… If my curve under here [*C*] is just a single line, I'm not going to have a volume, I'm just going to have an area. That could be, I mean, an area that ends up being curved and all this kind of stuff, but it's an area.

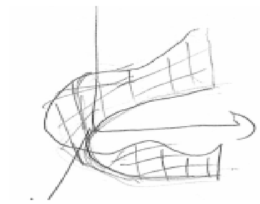


Figure 3: A line integral representing the surface area of a curved sheet between *C* and *f*

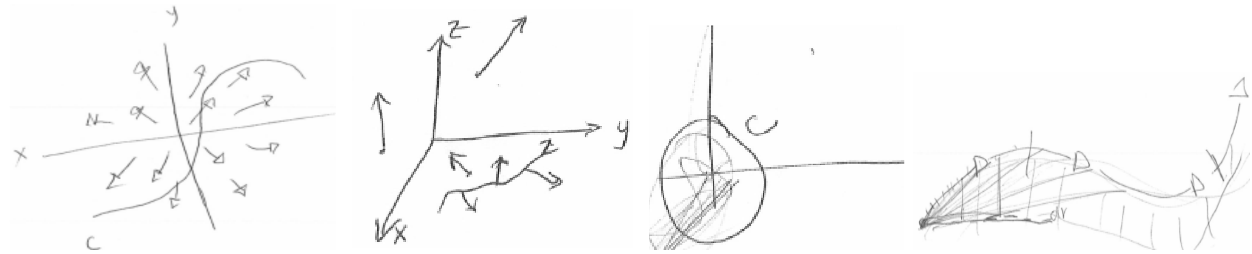
The other students who came up with this interpretation (B, C, D, and I) were clearly hesitant about it, and often began the prompt by making other interpretations instead. Student B initially described the line integral as a more "succinct" way of writing the multivariate integral $\iint_R f(x,y)\,dA$. Student C initially attempted to interpret this integral as the manifestation of some theorem, naming Green's theorem, Stoke's theorem, and the divergence theorem as possibilities. Student D frankly admitted, "I don't know, I'm guessing on this one." Student I was initially convinced that the line integral should represent the volume contained between the *x-y* plane and the region created by a closed loop, *C*, traced out inside of *f*(*x,y*) (see Figure 2a). Almost half of the students (A, G, J, and I) stated the line integral might represent the arc length of either *C* or *f*(*x,y*). Finally, two students (A and F) believed the line integral represented the area of the region inside of the closed loop they had drawn in the *x-y* plane, as seen in Figure 1c.

Vector integrals

Student interpretations of the integrand, $\vec{V}$, and the domain, C. For the vector integral expression, the students were split into three overlapping groups in terms of how they interpreted the integrand, $\vec{V}$. Five of the students (C, D, E, H, and J) interpreted $\vec{V}$ as a collection of literal "arrows" in that they drew several arrows pointing in different directions. Four of the students (E, F, G, and I) interpreted $\vec{V}$ as representing a *physical* phenomenon, such as the flow of water, wind currents, or the force of gravity. Three of the students (A, B, and C) represented the integrand as an algebraic function, including as $\langle -\cos t, \sin t, t\rangle$, *f*(*x,y*), and *F*(*r*(*t*)), respectively. This result is not to say that students in one group would be unaware of or unable to make interpretations from another group, but this result rather demonstrates the various approaches taken by the students to interpret $\vec{V}$.

All of the students interpreted *C* as a curved line, though in somewhat different ways, as seen in Figure 4. Three students (E, H, and J) drew a 2-dimensional vector field and represented *C* as a curved line passing through it (Figure 4a). Three students (C, D, and E) actually drew a 3-dimensional vector field, but then only drew *C* as a curved line on the 2-dimensional "*x-y*" plane (Figure 4b). Two students (A and F) thought of *C* as a closed loop in the *x-y* plane, without much reference to a vector field at all (Figure 4c). Another student (I) interpreted *C* as a collection of vectors from $\vec{V}$ lined up from tail to tip (Figure 4d). Finally, two students (B and G), while stating that *C* was a curved line, as specified in the prompt, never articulated exactly what it was or how it fit in with the other pieces of the integral expression.



(a) (b) (c) (d)

Figure 4: Various types of interpretations of *C* in relation to the integrand, *V*

Student interpretations of the differential, $d\vec{r}$. The students were most diverse in their various interpretations of the differential, $d\vec{r}$. There were a total of fifteen different types of interpretations the students gave to $d\vec{r}$, with some students coming up with more than one interpretation at different times as they struggled to give meaning to the vector integral. In fact, one student (I) came up with seven different interpretations for $d\vec{r}$ at different times! There were only three interpretations, however, that were shared by at least three separate students. First, Students F, I, and J stated that $d\vec{r}$ represented an "infinitesimal vector," agreeing with the $\Delta\vec{r}$ in the Riemann sum that often forms the basis of the mathematical definition of the vector integral. Students C, D, and I, however, wondered at times whether $d\vec{r}$ might actually represent the distance from the origin to points on the curve, *C*, as seen in Figure 5 and Figure 4d. Yet, the most common interpretation, made by five students (A, B, C, E, and F), was that $d\vec{r}$ needed to be converted to a different type of differential, including a conversion to *dt*, *dx-dy-dz*, *ds*, or *dr-dθ*. As with the line integral, the computation of vector integrals by hand using anti-derivatives may have influenced these students' fundamental interpretations of what a differential represents.

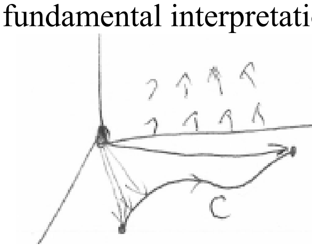


Figure 5: The differential, $d\vec{r}$, as representing distances from the origin to *C*

Student interpretations of the overall integral. The students were generally unsure about what overall object might possibly link all of the objects associated with the individual symbols. While five students (A, C, D, F, and G) stated that a vector integral might mean "work," they only seemed to state it from memory, explaining that they remembered having seen "work" examples in class. They confessed not knowing *why* the integral might calculate work, nor what work even meant in this context. Most of the students were explicit with the interviewer that they had no idea what the vector integral might represent, making statements such as, "Integrating over a vector field, um, I still don't really understand that part" (Student C) and "I don't know—I'm just trying to think of, like, values that might have some meaning in a vector field" (Student J). At the urging of the interviewer, the students attempted to imagine on overall object, which ranged ranged from a possible "surface area" (I), to an "average magnitude" of the vector field (G and J), to some kind of area underneath an unknown curve (B, H, and J), to an arc length (G and I), to an "overall direction" of the vector field (J).

Discussion

The students who participated in this study varied considerably in terms of how they interpreted the symbols in line and vector integrals. In many cases, the students associated the symbols with mathematical objects that align with typical *intended* objects, such as *C* representing a curved line, *f* representing a curve of some kind, or *ds* representing a small segment of a curve. However, the students were not always able to grasp the implications of these objects in relation to each other, and often struggled to amalgamate the objects defined by their own interpretations into an overall object referred to by the entire integral expression. For example, students struggled with the implications of *C* and *f* both being "curves," and sometimes reduced them to being the same mathematical object. Similarly, the students often struggled with the relationship between *C* and *V* in the vector integral, not knowing how to combine such distinct objects. Students also typically seemed unsure of how to relate the object represented by the integrand, *f* or *V*, with the object represented by the differential, *ds*.

Thus, the results of this study seem to imply that issues in understanding line and vector integrals do not necessarily come in the form of identifying the specific mathematical objects that the individual symbols refer to, but rather in combining these objects together to form a coherent object for the entire integral symbolic expression. This is similar to the idea of semiotic chains (Presmeg, 2006), though semiotic chains are used to describe the increasing abstraction or generality of a single mathematical object. In our case, the "chaining" has more to do with linking separate objects together into a new object that is referenced by the entire expression involving all of the individual symbols. Past research has looked at how students understand the connections between the symbols such as the integrand and the differential (Hu & Rebello, 2013; Jones, 2015; Sealey, 2014; Von Korff & Rebello, 2014), or the summation or accumulation of the quantities obtained from their product (Jones, 2015; Kouropatov & Dreyfus, 2013; Thompson & Silverman, 2008). From this arises a "chop, evaluate, and add" interpretation, in which little pieces represented by the differential are multiplied by objects represented by the integrand, which are then added up (a cue from the integral symbol). Yet, this interpretation does not involve the *domain* over which the integral happens. In our study, students also had issues incorporating the object represented by "*C*" with the differential and integrand. Thus, in order to help students see how *all* of the pieces of the integral relate to one another, *including* the domain, and to successfully chain the mathematical objects into a comprehensive whole represented by the entire integral expression, we recommend an interpretive framework for *reading* the symbols in an integral expression through a four-part process: (1) identifying the domain, (2) chopping the domain according to the differential, (3) evaluating the product of the integrand and differential within each piece, and (4) summing/accumulating this product across all of the pieces. This framework, depicted in Figure 6, shows how a student might need to visually break down the compact integral symbolic structure in order to make sense of the various pieces of the expression, how they fit together, and how they ultimately give rise to a meaning for the overall integral's value.

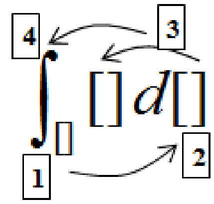

Figure 6: Domain-chop-evaluate-add framework for reading integral expressions

Definite Integrals Versus Indefinite Integrals: How do Students See Them as the Same or as Different?

Steven R. Jones
Brigham Young University

Cache Thompson
Brigham Young University

Much of the calculus education research on student understanding of integrals has been separated into definite-integral-focused studies and indefinite-integral-focused studies. This means that research may not be capturing how students might see these two types of integrals in relation to one another, as opposed to in isolation of each other. This study examines whether students see these two types of integrals as representing the same basic concept, distinct concepts, or as sharing some concepts while diverging in others. The results show that a large majority of students ascribe the exact same underlying conceptions to both types of integrals, even describing the indefinite integral as representing the area under a curve also. We relate what aspects of each type of conception students saw as common to both types of integrals, and what features of the conception the students saw as different between them.

Key words: calculus, definite integral, indefinite integral, concept images

There has been growing interest in recent years on first-year calculus students' understanding of the definite integral. In particular, researchers have examined students' general understanding (Jones, 2013; Sealey, 2014), students' understanding of differentials and infinitesimals (Ely, 2010; Hu & Rebello, 2013a), students' understanding of accumulation and the fundamental theorem of calculus (Thompson, 1994; Thompson & Silverman, 2008), how students apply integrals to science and engineering (Hu & Rebello, 2013b; Jones, 2015a; Nguyen & Rebello, 2011), and ways to teach definite integrals to promote deeper understanding (Jones, Lim, & Chandler, in press; Kouropatov & Dreyfus, 2014; Thompson, Byerley, & Hatfield, 2013). In addition to this research focused on *definite* integrals, there has also been some attention given to student understanding of *indefinite* integrals as well. This smaller subset of the literature has examined student understanding of accumulation in connection with indefinite integrals, as well as student understanding of features such as zeroes, extrema, and inflection points (Swidan, 2011; Swidan & Yerushalmy, 2014; Yerushalmy & Swidan, 2012).

Yet, so far, the research literature on first-year integration has tended to be separated into *definite*-integral-focused studies and *indefinite*-integral-focused studies. This separation, unfortunately, does not speak to the way in which definite and indefinite integrals are often taught in close association with one another, with instruction on each happening within the same set of lessons. Thus, there remain important questions about how students themselves see these two types of integrals in relation to one another, as opposed to in isolation of each other. As a result, this report is meant to shed light on the following two questions: (1) Do first-year calculus students tend to see definite and indefinite integrals as representing the same basic concept, distinct basic concepts, or as sharing some concepts while diverging in others? (2) Given whether students see them as the same or different, in what ways do the students see them as representing the same or different ideas? These questions are important, because otherwise research may end up only speaking to compartmentalized portions of students' overall understanding of "integration" from first-year calculus.

Concept Images

This study is framed by Tall and Vinner's (1981) construct of *concept images*. A concept image is defined as "the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes" (p. 152). For this paper, the "concept" under consideration is that which is termed "integral" in first-year calculus. We consider both definite and indefinite integrals to fall under the umbrella concept "integral" for the following reasons: (a) both are literally called "integrals," (b) both make use of the exact same symbols, "∫," and "*dx*" (or another differential), (c) students are taught to calculate both using similar methods, and (d) because they are often taught in close proximity to each other (Stewart, 2014; Thomas, Weir, & Hass, 2009).

Using this theoretical lens means that what students understand of *definite* integrals and what students understand of *indefinite* integrals together form a student's complete concept image for "integral" at the first-semester calculus level. Note that within a student's concept image for integral, any of the following conditions may hold. First, a student might have merged the two types of integral into a single idea, with no distinction between them. In this case, the student's concept image would have only one set of pictures, properties, and processes that encompass both types. Second, a student might have compartmentalized these two types of integrals. In this case, the student's overall concept image may have two distinct sets of pictures, properties, and processes, one for each type. Third, a student might have some kind of blending between the two, in which some pictures, properties, or processes might be shared by both types, and where other pictures, properties, or processes might be unique to each type. This study is meant to examine how students' concept images might fit under these different cases.

Data and Analysis

The body of data used for this study consists of surveys (described to the students as an introductory quiz) administered to 132 students on the first day of second-semester calculus at a large university in the United States. The purpose of surveying second-semester calculus students, as opposed to first-semester students, was that (a) these students were all guaranteed to have successfully completed a first-semester calculus course, and (b) these students came from a range of different instructors for first-semester calculus, making the sample more randomized than would occur by surveying students in first-semester calculus. In fact, the majority of students at the university come from locations outside of the school's home state. Interviews were also conducted with select individuals, but for the purpose of this abbreviated conference report, only the survey data is reported on.

The survey was divided into two parts, with a multiple-option section (Part 1) and an open-response section (Part 2). The purpose of having two parts was to create two separate opportunities to code a student into the categories "same," "different," or "mixed," according to what they perceived as the relationship between definite and indefinite integrals. Furthermore, Part 2 allowed for an analysis of which specific conceptions the students ascribed to both a definite and an indefinite integral.

In Part 1, the students were presented with four statements regarding the generic expressions $\int f(x)\,dx$ and $\int_a^b f(x)\,dx$, and were asked to mark any they agreed with. Two statements (A and C) were intended to suggest that they had similar meanings, with the only differences being superficial (as in statement A). The other statements (B and D) were meant to suggest that they were different in conceptual meaning. The four statements were given as:

> (A) The fundamental difference between the meanings of the two integrals is that you need to plug *a* and *b* into your answer for the second one, but you don't have any numbers to plug in for the first one.
> (B) These two integrals are quite different from each other and represent different ideas.
> (C) The final answers you get for the two integrals might look different from each other, but the integrals essentially represent the same idea.
> (D) Even though you can use anti-derivatives to find answers for both of these kinds of integrals, the final answers you get mean very different things.

The multiple option Part 1 is obviously insufficient, alone, for constructing a picture of the relationship a student believes to exist between definite and indefinite integrals, or for knowing what conceptions are actually ascribed to each kind of integrals. Thus, a second, open-response section was included on the survey. In this second part, the students were given the prompt,

> Explain as much as you can what $\int f(x)\,dx$ means. Similarly, explain what $\int_a^b f(x)\,dx$ means. Use words, pictures, formulas, or whatever you want to help explain what they mean. How are they different? How are they similar? Please explain in as much detail as possible.

Part 1 and Part 2 of the survey were analyzed independently and then compared. For Part 1, students were coded as "same" if they marked only A, only C, or both A and C. Students were coded as "different" if they marked only B, only D, or both B and D. Students who selected at least one statement from A or C and one from B or D were coded as "mixed." Since Part 1 already dealt with *explicit* statements as to whether the two integrals are the same or different, Part 2 was not analyzed by whether the student *explicitly* stated they were the same or different. Rather, we coded a student's description of each kind of integral according to the conceptualization the statement seemed to assign to that integral. Based on previous research (Jones, 2013, 2015b), a student's description of each type of integral was categorized into (a) area, (b) anti-derivative, (c) summation/MBS, or (d) other. For a description of the MBS conception, see Jones (2015a). Each response coded into "other" was examined for the type of conception it represented, creating new categories (see Results). If the conception(s) contained in a student's explanation of the definite integral exactly matched the conception(s) contained in their explanation of the indefinite integral, the student's response was coded as "same." If there was no overlap in the conceptions contained in the explanations of the two integrals, the response was coded as "different." If a student ascribed at least one conception to both, but then also explained one of the integrals using a conception *not* ascribed to the other, the response was coded as "mixed."

Results

Part 2 of the survey

We organize this section by first describing the results from open-response Part 2 of the survey and then comparing them with the results from Part 1. Of the 124 completed responses to Part 2—meaning the students made statements for both types of integrals—most of the students (93 students, 75.0%) had descriptions of the definite and indefinite integrals using the exact same base conception(s). Table 1 shows a breakdown of the shared conceptions these 93 students applied to both definite and indefinite integrals. The “unspecified function” category was used for responses in which the student simply indicated that the integrals both represented functions, without specifying what that function was, including whether it was an anti-derivative. The “derivative” category was for students who claimed that the integrals represented *derivatives*, rather than an anti-derivative, though there is a possibility that some of those students could have made a mistake in what they wrote down. The “other” category contained unique meanings from the students, like a kinematics interpretations, or uninterpretable responses, like the “path on a graph.” Note that 11 of these 93 students gave more than one meaning to *both* integrals and are hence double-counted in Table 1. Nine of these 11 students claimed that both the definite and indefinite integrals represented both the area under a curve and an anti-derivative.

Table 1
Number of students in “same” that applied a given conception to both integrals

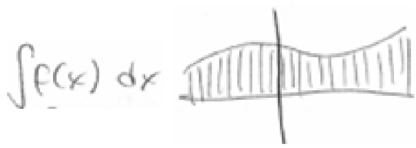
Area	Anti-derivative	Summation/ MBS	Unspecified function	Derivative	Other
65	22	2	4	5	6

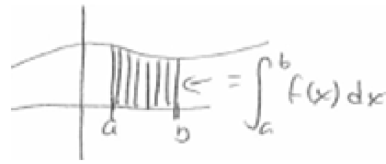
Given the numbers of students ascribing the “area” conception and the “anti-derivative” conception to both types of integrals, we present representative examples from the surveys to illustrate how these conceptions were simultaneously applied to both integrals. First, students often used “area under a curve” to describe both, wherein the main conceptual difference was the interval over which the area was taken. For indefinite integrals, the area was taken under the *entire* curve. While this may seem similar to what Hall (2010) called “potential area,” many students in this study were clearly thinking of *literal* area, and, in fact, seemed to equate $\int f(x)\,dx$ with $\int_{-\infty}^{\infty} f(x)\,dx$. The following two quotes and two sets of images (Figures 1a and 1b) are representative descriptions and drawings taken from among the surveys. Note that to save space in this paper, in Figure 1 some of the written integral expressions have been cut-and-pasted closer to the corresponding graphical images than they were in the original student written work.

Example survey response 1: $\int f(x)\,dx$ means find the area under the entire graph whereas $\int_a^b f(x)\,dx$ means find the area only between points *a* and *b* on a graph.

Example survey response 2: $\int f(x)\,dx$ means the area under the whole curve from $-\infty$ to $+\infty$… Meanwhile $\int_a^b f(x)\,dx$ is the area of a part of that curve.

(a)





(b)

Figure 1: Representative graphical depictions of the indefinite and definite integrals

A smaller subset of the students (22), interpreted both types of integrals as meaning an anti-derivative. The following two quotes are representative descriptions taken from the survey responses fitting into this category.

> *Example survey response 3*: They are similar in that you find the anti-derivative of *f*(*x*). They are different in that for the indefinite integral you are done after finding the anti-derivative while for the definite integral you plug in the values of *a* & *b*.
>
> *Example survey response 4*: $f(x)=3x^2$. $\int f(x)=x^3$. $\int_0^3 f(x)=(3)^3-(0)^3=27$. The integral of a formula provides you with a new formula capable of showing several properties about the original function. $\int_a^b f(x)\,dx$ is an equation that helps us learn more.

For responses in this category, both definite and indefinite integrals seemed to be represented as an anti-derivative function, and the essential difference seemed to be whether inputs needed to be inserted into the algebraic function or not.

We now briefly turn our attention to the 24 students coded as "different" for Part 2 (19.4%) and the seven students coded as "mixed" (5.6%). Of the 24 "different" students, the vast majority (21 students) described the definite integral as meaning the area under a curve and the indefinite integral as meaning an anti-derivative. These interpretations match with curricular meanings often given to the two types of integrals (e.g., Stewart, 2014)—which makes it interesting to note that only about a fifth of the students in this study made this particular interpretation for the two integrals. Among the "different" students, there was only one single student who described the definite integral as a Riemann sum (and the indefinite integral as an anti-derivative).

Of the seven "mixed" students, four said that both integrals shared the *anti-derivative* meaning, but that only the definite integral represented area under a curve. Two of the students described both integrals as sharing the *area* meaning, and that only the indefinite integral represented an anti-derivative. The final student indicated they both represented unspecified functions, with the definite integral representing area also.

Comparison with Part 1 of the survey

Part 2 of the survey demonstrated that a large majority of students' concept images hold the definite and indefinite integrals as representing the exact same basic concept, even as they note possible minor differences within that particular concept regarding each integral type. This result resonates with the options selected by the students on the multiple option Part 1 of the survey. Of the 132 students, 82 students (62.2%) were coded as "same," 20 students (15.2%) were coded as "different," and 30 students (22.7%) were coded as "mixed." To compare the options the students selected for Part 1 with whether they used the same or different conception(s) to describe the integrals in Part 2, Table 2 shows the breakdown of the students coded into "same," “different,” or “mixed” for both Parts 1 and 2. Note that “blank” in Part 2 indicates that the student did not write anything for that part of the survey.

Table 2
Students coded into each category for both Parts 1 and 2 of the survey

	Part 2 “same”	Part 2 “different”	Part 2 “mixed”	Part 2 “blank”
Part 1 “same”	69	4	4	5
Part 1 “different”	4	13	1	2
Part 1 “mixed”	20	7	2	1

Table 2 shows that most of the students who described the two integrals as representing the same concept in Part 2 also selected only statements in Part 1 that suggested they meant the same basic concept. Similarly, most students coded as “different” in Part 2 had also selected only statements in Part 2 portraying the integrals as different. The main discrepancy between Part 1 and Part 2 is the portion of students who were coded as “mixed” for Part 1, but that ended up invoking the exact same conception(s) for both types of integrals in Part 2. This result says something interesting about what some students may see as being *same* or *different*.

Discussion

Indefinite and definite integrals representing the same concept

Most students in this study seemed to conceive of both types of integrals as representing the same underlying conception. Most students described both integrals as representing the area under a curve, or both as representing an anti-derivative. In other words, it appears that many students’ concept images for “integral” may have merged both types of integrals into essentially the same mathematical object—as a geometric area, or as an algebraic function, or both. This suggests that we, as calculus educators, need to decide if we are comfortable with this conceptual merging of these two types of integrals, as implied by this study, or whether we would want to emphasize different meanings or conceptual objects for each type of integral. For example, many textbooks (e.g., Stewart, 2014; Thomas et al., 2009) describe them differently in that definite integrals arise from areas under curves and are defined as the limit of Riemann sums. On the other hand, indefinite integrals are typically presented as a family of functions with the related property of having all their derivatives equaling the integrand. Further, past research has suggested that Riemann-sum-based understandings of definite integrals may be important for applying integration to science and engineering (Jones, 2015a), and that anti-derivatives may relate well to continuous accumulation (Swidan, 2011; Yerushalmy & Swidan, 2012). With these various possible meanings, it may be worth our effort to decide carefully and explicitly what meanings we might want our students to closely associate with *definite* integrals and what meanings we might want them to closely associate with *indefinite* integrals. It is also important to decide what meanings should be given to *both* and what meanings should be *exclusive* to one or the other. As it stands, it could be problematic for the bulk of students to have fundamentally combined the two into, essentially, a single construct. This may limit the applicability of these two types of integrals to only situations that match the exact conception given to both.

Why are they believed to be the same?

One might initially believe that the reason many students ascribe very similar meanings to both types of integrals is because of the calculational similarity between them, through anti-derivatives. That is, because of the fact that students work out lots of exercises computing both definite and indefinite integrals through anti-differentiation, they may come to see them as the same basic thing. Yet, interestingly, this study's data does not support this possible conclusion. Rather, the majority of students interpreted both indefinite and definite integrals through the concept of *area under a curve*, even though this meaning is generally not given explicitly to indefinite integrals. What might account for this? We wonder if it is the case that students simply do not have much of a conceptual meaning for indefinite integrals, and that students consequently simply rely on their conception of definite integrals to invent a meaning for indefinite integrals. Past research has found that the "area under the curve" tends to be the most common conception students associate with definite integrals (Jones, 2015b), which matches the conception the students in this study gave to indefinite integrals as well. Thus, we conjecture that many students may be trying to find ways to simply extend the familiar "area under a curve" concept to the indefinite integral. They may have done so by extending the "bounded" definite integral to a "boundless" indefinite integral, which they then conceived of as representing the entire area under the whole curve, possibly from $-\infty$ to ∞. If our hypothesis is right, then much work needs to be done in promoting better possible conceptual understandings of the indefinite integral itself (e.g., see the work of Swidan & Yerushalmy, 2014; Yerushalmy & Swidan, 2012).

What some students may focus on for "same" or "different"

Finally, it is interesting to note that a subset of the students had selected statements in Part 1 of the survey indicating that definite and indefinite integrals were fundamentally different, but then described them both using the exact same conception in Part 2. While on the surface this may seem contradictory, it is actually quite reasonable. It appears that it matters what the *grain size* of difference is. For example, two equilateral triangles of different size could either be said to be the same since they are both the same basic shape, or different since they are not exactly congruent. Therefore, some students seemed to focus on certain aspects *within* a conceptualization as determining whether the two types of integrals were exactly identical or not. It certainly is a difference for one type of integral to be over the interval $(-\infty,\infty)$ and the other type of be over the interval $[a,b]$! Furthermore, it is different for one type of integral to require the insertion of inputs into a function, when the other does not. Thus, many of the students who were coded as "mixed" in Part 1 may really see integrals through the same basic conceptual lens, but then were more attentive to whether they felt those features *within* the conception were identical or not. It may be, then, that some of the "mixed" students on Part 1 were actually more closely associated with the "same" students than Table 2 depicts.

Using Video in Online Work Groups to Support Faculty Collaboration

Nicholas Fortune Karen Keene William Hall
North Carolina State University

Faculty in undergraduate mathematics departments are currently involved in making changes to their instruction, particularly by introducing different modes of student-centered type instruction. In this paper, we analyze a situation where faculty are involved in online collaboration using video of their own classrooms. We found that showing the video during the online work groups promotes more discussion of pedagogy rooted in instructional components than instructors watching the videos alone before. Pedagogy and students' mathematics also become important discussion points that encouraged and supported the instructors. Providing instructional components as a frame proved to be successful in supporting the video discussions as they stay centered on instruction.

Key words: Inquiry-oriented instruction, faculty collaboration, video, differential equations

Introduction

Recently, practitioners and researchers have turned their focus to the study of online resources meant to improve collaboration among faculty as a means to improve STEM education at the university level. For example, at a recent conference sponsored by AAAS and NSF, the Envisioning the Future of Undergraduate STEM Education Symposium, there were several sessions about faculty collaboration. Collaboration among faculty in different STEM disciplines at one university, among faculty in the same disciplines at different universities, and using technology of all types to facilitate and enhance collaboration were different foci considered at the conference. Online collaboration is particularly of interest as the technology to support this has made huge improvement in the last 10 years.

In this paper, we have chosen to consider one specific collaboration category. We will describe the use of videos from faculty classrooms during the implementation of faculty online work groups. This research is one component of a larger NSF funded project that is intended to build and conduct research on supports for instructors seeking to change their instruction. In this NSF project, the three supports (online work groups, curricular materials, and summer workshops) are studied together in order to support faculty as they implement one kind of active learning, inquiry-oriented mathematics (Rasmussen & Kwon, 2007). Later publications will report on the other supports and the effect on student outcomes.

Literature Review

When instruction that supports students' conceptual understanding is enacted, access to expertise and ongoing collegial support are important for sustaining that kind of instruction (Coburn, Russell, Kaufman, & Stein, 2012). At the K-12 level, a common support for teachers as they move to improve their teaching practice is professional development (PD). K-12 research points to a number of characteristics of effective PD programs. Impactful programs and supports need to be ongoing and sustained (Darling-Hammond, Wei, Andree, Richardson, & Orphanos, 2009; Gallucci, 2008; Garet, Porter, Desimone, Birman, & Yoon, 2001; Hill, 2007; Kazemi &

Hubbard, 2008), be focused on subject matter, in terms of the mathematics, the students' mathematical thinking, and the instructional goals (Hill, 2007; Kazemi & Franke, 2004; Kazemi & Hubbard, 2008), be integrated into teacher's daily work (Darling-Hammond & McLaughlin, 1995; Franke, Kazemi, & Battey, 2007; Putnam & Borko, 2000) and provide teachers with feedback (Elmore, 2002).

Research on instructional change strategies at the undergraduate STEM level provides further insights. In a review of literature on instructional change strategies, Henderson, Beach, and Finkelstein (2011) identified two common but ineffective approaches: (1) top-down policies meant to influence instructional practices and (2) merely making "best practice" curricular materials available to faculty. In contrast, Henderson et al. found that effective change strategies which align with or seek to change beliefs of individuals involved, involve long-term interventions and are compatible with the institutional context are the most effective.

As far as research on using video, according to Borko, Koellner, Jacobs, and Seago (2011), "... by choosing video clips, posing substantive questions, and, facilitating productive conversations, professional developers can guide teachers to examine central aspects of learning and instruction" (p. 176). Borko and her colleagues describe using video of teachers in two ways: the teachers' own videos and videos from other classrooms. They found that the selection of goals for the video use was very important as was the selection of the video clips. The facilitator selected the videos which is different than our work, where the instructors selected their videos.

As one analysis framework, we used work by Sherin and van Es (2009). Their research focused on using videos to study teacher professional vision. Sherin and van Es analyzed the meetings focused around videos for the following categories: Management, Climate, Student Thinking, and Pedagogy. Their analysis using these and other codes showed that participating teachers did grow in their knowledge based reasoning, change their ways of paying attention to students and student thinking, and changed their instruction in the classroom.

Research Goal and Framework

Our research goal was to characterize the conversations that occur during an inquiry-oriented differential equations online work group when the participants are sharing videos of their instruction. As the project where the research was done has evolved, the team has developed a framework (Kuster, Johnson, Andrews-Larson, & Keene, under review) to analyze instructors implementing inquiry-oriented instruction. Four components of instruction have emerged which served as an additional framework for our analysis (table 1).

Table 1
Focal Instructional Components

Component	Definition
Generating Student Reasoning	Facilitating student engagement in meaningful tasks and mathematical activity related to an important mathematical point, eliciting student reasoning and contributions, actively inquiring into student thinking
Building on Student Thinking	Being responsive to student contributions and use student contributions to inform the lesson, guiding and managing the development of the mathematical agenda
Developing a **Shared** Understanding	Engaging students in one another's thinking
Connecting to Standard Mathematical Language and Notation	Teachers introducing language and notation when appropriate, teachers supporting formalizing of student ideas/contributions

Methods

Research Context and Participants

For one semester, instructors participated in a weekly online work group (OWG). The main goals of the OWG were to: 1) aid instructors in making sense of the materials (i.e., thinking through the sequences of tasks, how students might approach the tasks, how to structure instruction around the tasks to support student learning), and 2) assist instructors in developing and enhancing their instructional practices. In particular, attention was focused on the focal instructional components mentioned above.

The OWG included two multi-week lesson studies. Lesson studies are composed of approximately four week-long segments that have instructors doing the math that they will have their students do in class (week 1); discussing the possible student thinking (week 2); and sharing videos of themselves teaching the unit with attention to the focal instructional components (weeks 3 and 4). In those last two weeks, instructors seek feedback from the group to improve their teaching methods; they use the video clips of their classroom teaching to facilitate that discussion. Due to logistics of filming video in classes, video was shared during weeks 4, 5, 8, 9, and 10 of the OWG; with 4 and 5 as part of the first lesson study on one unit (autonomous differential equations) and for weeks 8, 9, and 10 (systems of differential equations).

Participants were interested in exploring instructional change and came from smaller universities across the US. In the inquiry-oriented differential equations (IODE) OWG there were four participant instructors (instructors teaching differential equations at the time of the OWG), one previous participant instructor (instructor who partook in the pilot OWG but was not currently teaching differential equations), two graduate research assistants, and one facilitator.

Data Collection

Each of the 12 OWG sessions took place via Google Hangouts as instructors were at their universities across the country throughout the semester. All OWGs were screen recorded by one of the researchers to be able to capture both audio and video of the OWG. As part of the OWG, instructors were to create videos of themselves teaching the same unit at two different times during the semester. The instructors then self-selected clips (cf. Borko et al., 2011) they wished to bring to the OWG, knowing that clips should be focused on the focal instructional components if possible. Clips ranged from 2-6 minutes in length and usually 2-3 were watched for each participant at a time.

Data Analysis

This study focuses only on the conversations in the OWG when the participants were sharing or discussing the shared videos (5 of the 12 total meetings). Two researchers watched the entirety of the OWGs and marked all the timestamps when video was discussed. To give perspective, Table 2 shows the percentage of the total time of the OWG sessions (approximately one hour each) that discussion of the videos specifically occurred.

Table 2

Percent of Coded Time of Discussion

Week	4	5	8	9	10
% of Coded Time	45.86%	53.78%	40.51%	40.16%	26.18%

We created content logs to summarize in detail the conversations of the OWGs. The content logs had multiple columns for us to be able to characterize the conversations (i.e., timestamps, topic of conversation, focal instructional components, speaker, and detailed notes). We began by coding two full OWGs together. To code the topic of conversation, we used a priori codes that were influenced by previous research on video clubs (Sherin & van Es, 2009). Using a constant comparative method (Strauss & Corbin, 1998) we open coded and also created new emerging codes to fully characterize the conversations in the OWGs. The focal instructional components were also used as an analytical framework for analysis of the conversation.

We watched the video until one researcher felt that the conversation had shifted directions and changed topics significantly. That chunk of time then became a row (or time block) in the content log, where we coded the topic of conversation and focal instructional components (if applicable). Whenever possible, video was divided so that each time block had as few topic of conversations as possible. However, multiple topics of conversation and focal instructional components often happened in one utterance so those could not be parsed out and the time block was coded as all applicable topics. For perspective, the average time block was 47 seconds across all five coded segments of the OWGs. We developed and refined a codebook with detailed definitions based on the a priori codes, as well as the new codes that emerged during analysis (see table 3 for the topic of conversation a priori codes). Collectively all disagreements were worked out. Finally, two researchers coded the three remaining OWGs and left any disagreements between them to be resolved by the third researcher.

Table 3
Topic of Conversation A Priori Codes

Codes	Definition
Pedagogy	Teacher instructional moves or ideas about teacher instructional moves
Student Mathematical Thinking	Evaluating and/or discussing students' thinking about mathematical concepts
Mathematical Content	Discussion of mathematics, IODE material, difficulty of mathematics
Social and Sociomathematical Norms	Discussion about getting students used to participating in group work; includes quality of group work and interaction
Environment	Classroom behavior, classroom setup, access to tools and technology

It is important to note that all time durations reported in results will be over estimates based on the way we divided up the video into the time blocks. Multiple codes could occur at the same time but may not have been used for the entire time block. However, as noted, we kept the time block as small as possible while still maintaining the integrity of the analysis; this aided in alleviating the limitation of the overestimates.

Results

First, we present a characterization of the conversation through the two perspectives (topics of conversations and focal instructional components). These results will be broken down by week and also shown as a synthesis across the five weeks of the OWG. Second, we discuss the role of when video was watched and how that influenced the conversation that occurred and the richness of said conversation.

Topic of Conversation and Focal Instructional Components

Table 4 includes the four new topic of conversation codes which emerged.

Table 4
Topic of Conversation Emergent Codes

Codes	Definition
OWG Logistics	How to record videos; what clips to share/select; what to watch; remembering video
Orienting	Setting the stage for the video that will be shown
Appraisal	Participants give value judgments about events from the videos, instructional moves

As noted, when codes were discussed they oftentimes were not alone. Here is an excerpt from the week 5 OWG where pedagogy, appraisal, norms, environment, orienting, OWG logistics, and student mathematical thinking were all coded. Note, this excerpt spanned four time blocks.

> *Instructor 1:* … So if we go to the video that is Instructor1_Owl_2. We'll start at 6:15. So this is, we had just spent some time talking about whether if we started with the owl population below 5 if they were going to go extinct or not. My students seemed to have that idea that because the derivative is negative the population is going to decrease and it is going to decrease down until it hits 0. Right - they kind of had a handle on that. So starting at 6:15, we want to talk about what happens for P between 5 and 8 … What I want you to look for, is that I bring up the Uniqueness Theorem myself. I didn't really give the students an opportunity to see it. And that is maybe based on past experience where they just aren't used to arguing with it yet. So I want you to look at how I brought that up and maybe if you think I brought it up too soon or what you have done if you're thinking, 'oh maybe, they're not going to get the Uniqueness Theorem.' So I'm going to stop talking so you can watch the video now.
>
> *Video watching occurred and additional conversation for approximately 8 minutes.*
>
> *Facilitator:* It would have been interesting, just as a suggestion to think about, you could have students come up to the front and present their ideas. It would have encouraged them to be more open about what they were thinking about.
>
> *Instructor 1:* Yeah, I don't have the students come up to the board too often in this class. The room is a little bit, I don't know, it doesn't quite fit for me somehow. It is also maybe that I have created a culture where that doesn't happen very often. Although, whenever I do have them come up to the board, they come quite willingly.
>
> *Instructor 2:* They were participating, they were bringing up things and you were writing them down. And you did a nice job of hearing what one person was starting to say and finishing up the other.

In the first lesson study, when video was watched during the OWG, there was a higher amount of time spent on OWG logistics. Particularly, much of the logistics were issues that participants had in finding the clips to watch. Videos of instruction were not screen-shared (a common feature of online collaboration tools) because audio was typically quiet and participants were not able to hear the video. Thus a shared video folder on an online server was made, as well as an online agenda that contained all relevant links. However, participants still had technology issues. For example,

> *Facilitator:* Let's at least start it. Let's watch the first couple. The 2:45-4:00, the 9:30-12:40 and then we might have to come back.
>
> *GRA:* Don't forget to mute yourself when you watch the video.
>
> *Instructor 3:* GRA, I'm clicking on the Drive link you sent but it just sends me to a verify your email address page and it is not going to the Drive at all.

To be able to resolve these issues the GRA would assist the instructor, which took time away from the OWG.

Because of space limitations, we are only reporting percentages on pedagogy and OWG logistics. Pedagogy was the largest topic of conversation that occurred across all OWGs (by week 4, 5, 8, 9, 10, respectively: 41.33%, 41.08%, 85.74%, 85.85%, and 59.50% and across all weeks, 59.15%). OWG logistics had the following breakdown: by week 4, 5, 8, 9, 10, respectively - 53.72%, 55.94%, 10.29%, 19.12%, and 22.50%, with a total of 36.98% across all weeks. Noteworthy is the difference in time spent discussing pedagogy and OWG logistics.

The objective of the OWG is to prepare instructors to teach inquiry-oriented instruction and thus the components were crucial for that discussion. Rarely were the components ever referenced by name, however, the practices that make up the components or a general sense of the components were discussed by the instructors. Generating was discussed 24.40% of the time, building 22.47%, shared 20.75%, and connecting 5.33%. The component Connecting was the least referenced component. While the week by week discussion varied, overall the remaining three components were roughly discussed the same amount of time.

Role of When Video is Watched

We note that during weeks 4 and 5 video clips were watched *during* the OWG and weeks 8, 9, and 10 they were watched *prior to* the OWG. Recall the inverse relationship between how often pedagogy and OWG logistics were discussed. When videos of instructors' classrooms were watched in the OWG (weeks 4 and 5), more OWG logistics were discussed than pedagogy. Yet, when video was watched prior to the OWG, logistics were discussed less and pedagogy more. Interestingly, when breaking down the pedagogy discussion into times when it was cross-coded with a focal instructional component, highlights something noteworthy (see figure 1). A large amount of the pedagogy discussion in weeks 8, 9, and 10, was not actually rooted in the focal instructional components. Participants noted in exit interviews they believe this was because the video was not fresh in their mind so the conversion could not be as deep.

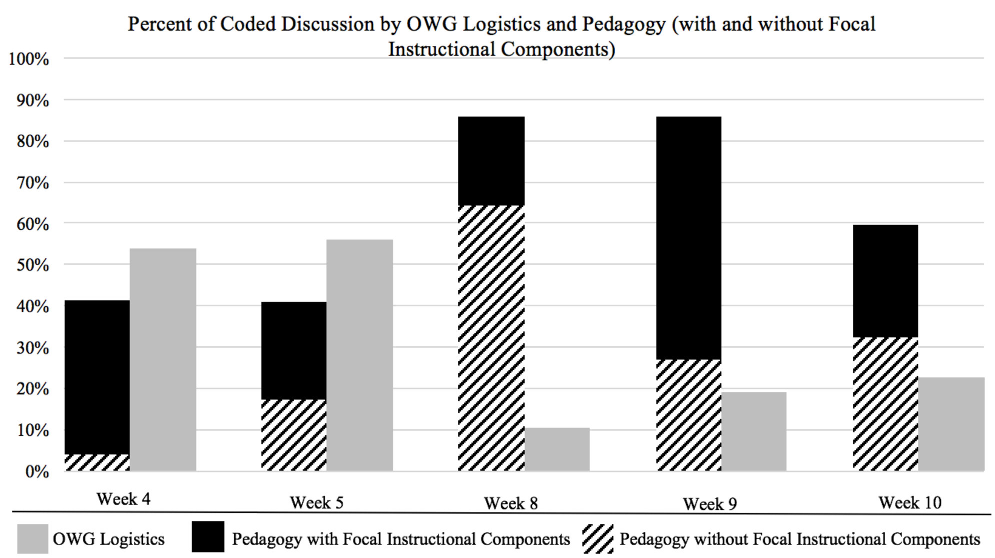

Figure 1. Percent of coded discussion by OWG logistics and pedagogy.

Conclusion

Overall, we have described the conversation around the use of video in faculty OWGs. As mentioned earlier, our research is part of a larger project, but the use of self-selected video and the discussion around it have provided us interesting new knowledge about what these conversations look like. We conclude this proposal with a brief interpretation of the results of our analysis and implications for future online faculty collaboration whose purpose is to support instructor change. The topics of conversation when the OWGs focused on the videos were heavily focused on the pedagogy during all the weeks of the OWGs. This is an important implication as faculty collaboration across universities is going to be increasingly more common. Traditionally, faculty collaboration has revolved around research and the development of new mathematics, but currently, faculty collaboration to discuss instruction is growing. Using the videos provided an object for pedagogy to revolve around.

Other conversation focused (in an interweaving way) on mathematical content, student thinking, and environment/norms. But we found that logistics were also common parts of the discussion. This category, along with orienting, had not been in our original code lists, but because of the online environment, they were important to document and interpret. We found that the orienting of other faculty participants to the classroom video was imperative to allow productive discussion to occur. Orienting needs to be encouraged, and different or more refined ways of orienting will be part of future work.

We particularly note the fine-grained analysis of the two methods of watching video, either during the actual OWG, or beforehand. Analysis showed that watching video during the OWG meant that technical support is needed to aid instructors in synchronously watching the videos, which in turn detracts from the amount of time that can be spent discussing the intended content (the focal instructional components). However, we also found that watching videos beforehand meant the discussion was not as rooted in the focal instructional components either because the video was not fresh in instructors' minds or they did not actually watch the videos. Further analysis is required to ascertain which method is concretely better, as our analysis revealed pros and cons for both approaches. Nevertheless, instructors noted they preferred to watch videos during the OWG in exit interviews.

As far as the focal instructional components that our project provided as a framework for thinking about inquiry-oriented instruction, we found that three of the components (generating ways of student reasoning, building on student thinking, and developing a shared understanding) were part of the conversation about an equal amount of time. The fourth component, connecting to formal notation, was present significantly less of the time. This is not surprising, as the content in differential equations involve much less formal structural development than other upper level undergraduate mathematics courses where our work is also focused.

The participants in the OWG were all from small universities where they were usually the only faculty member teaching Differential Equations and the only ones implementing this new kind of instruction. There is significant work going on across many universities in many projects that are attempting to improve STEM undergraduate instruction. We found that videos were a particularly powerful way to provide avenues for instructors to share their own classrooms in ways that were comfortable and affirming, reflect on their own authentic teaching and discuss pedagogy and students' mathematics.

Although the facilitator's role was not part of this proposal, it also has proven to be very important. Facilitators can learn from studying the research about OWGs that we are working on, to help better understand how to make the conversations most productive. Ultimately, the goal is to improve instruction in order to improve student outcomes. But taking this intermediate step of describing and analyzing one new and powerful tool, using video in OWGs, may help the mathematics education research community with the final goal.

Undergraduate Abstract Algebra: Is Teaching Different at 'Teaching' Colleges?

Rachel Elizabeth Keller, Virginia Tech
Estrella Johnson, Virginia Tech
Valerie Peterson, University of Portland
Tim Fukawa-Connelly, Temple University

Reforming the way undergraduate math is taught has been the target of significant research efforts for decades; however, lecture remains the predominant form of instruction. While interest has been primarily focused on entry-level courses in order to recruit and retain STEM-intending students, quality instruction in upper division courses is also important. In a national survey of abstract algebra instructors, we investigated typical teaching practices, beliefs, and constraints that influence pedagogical decisions, and similarities/differences between those who do/not lecture. Of particular interest was exploring whether instructors at Bachelor's-granting institutions have markedly different circumstances than their counterparts at Master's- and Doctoral-granting institutions and the effect (if any) this has on their pedagogical decisions.

Key words: Collegiate teaching practices, beliefs, abstract algebra

In STEM higher education, but specifically in mathematics, a well-established tradition of lecture still persists despite the growing volume of mathematics education research that urges teachers to move beyond this practice. The ineffectiveness of lecture has been consistently reported (Freeman, et al., 2014) and students have been pretty clear about their dislike of lecture-based courses. Eric Mazur, Harvard professor and active-learning proponent, suggests that change is coming: "Though it remains the dominant form of instruction in higher education…the lecture may be on its last legs" (Lambert, 2012). Data from the HERI report (Eagan, et al., 2014) confirm this trend, reporting an increase in student-centered teaching practices and a decrease in lecture over the past 25 years; listing the most recent figure (2014) hovering around 51% of faculty reporting that they lecture in "all" or "most" of their courses; however, when dis-aggregated by discipline, "the data continue to show that nearly two-thirds of faculty across STEM sub-fields utilize extensive lecturing in all or most of their courses" (Eagan, 2016). This is particularly problematic given that the President's Council of Advisors for Science and Technology found that fewer than 40% of students entering college in pursuit of a STEM degree complete that degree (PCAST, 2012, p. i). It appears that students are frustrated by "faculty modes of teaching that suggest [they] take little responsibility for student learning" (Seymour, 2006, p. 4), as students cite ineffective teaching methods and uninspiring atmospheres in introductory-level STEM courses as the primary reason for attrition (PCAST, 2012, p. i, p. 5).

The mathematical professional societies (AMATYC, AMS, ASA, MAA, and SIAM) have taken notice and issued a joint statement indicating that while they would refrain from specifying pedagogical practices, they "feel that active student engagement is necessary for a mastery of algebraic ideas" and that "problem-based, inquiry-based, and collaborative learning activities are appropriate means of maintaining student engagement" (CUPM, 2015). Despite this recommendation, lecture is still the norm – even in upper division mathematics courses, which tend to have fewer constraints and more flexibility in terms of content (e.g., these courses are typically not coordinated across multiple sections and have few subsequent courses). Keith Weber reports that "the advanced proof-oriented courses for mathematics majors are typically taught in a lecture format" (Lockwood, 2015) and in a recent study by (Fukawa-Connelly, Johnson & Keller, 2016), it was found that when considering abstract algebra specifically, lecture is overwhelmingly the dominant pedagogical technique both in terms of percentage of instructors using it and percentage of class time devoted to its use.

In our previous study, the target population was mathematics instructors teaching at Master's- and Doctoral-granting institutions; i.e., 'research' universities. The purpose of the present study is to extend this work by investigating the teaching habits, beliefs, and constraints of instructors at Bachelors-granting institutions, traditionally 'teaching' colleges, to see if any differences emerge. To that end, we investigate the following research question: Does the way that abstract algebra is taught vary by institution type and can those differences be explained?

Literature Review

The literature has cited many reasons why instructors choose to lecture, not least of these is the belief that lecture is the best method and/or necessary for content coverage (as discussed by Roth McDuffie, & Graeber, 2003; Wagner, Speer, & Rosa, 2007; Yoshinobu, 2014). While we do not wish to discount the enormous influence personal beliefs have on instructional decision-making, we must acknowledge that a bevy of other external circumstances can factor considerably when instructors plan their courses. Research has indicated that instructors are reluctant to change practice when serving an administration that provides neither pressure nor incentive to do so and, furthermore, that concerns about promotion and tenure inhibit change when the administration is not perceived to value experimentation in teaching (Roth McDuffie, & Graeber, 2003). Another important factor is departmental and university culture. According to Henderson & Dancy (2007), working with colleagues who either lack knowledge about or withhold support of pedagogical reform inhibits an instructor's willingness to modify current practice. Finally, departmental resources must be considered as a factor. Instructors who are not offered classroom assistance, release time to plan and prepare tasks and revise syllabi, or financial support for professional development are unlikely to abandon the traditional lecture style in light of the high "start-up costs" demanded by a change in pedagogy (Henderson, Beach, & Finkelstein, 2011; Wagner, Speer, & Rosa, 2007; Roth McDuffie, & Graeber, 2003).

In higher education, a distinction is drawn between what are colloquially referred to as 'research institutions' and 'teaching colleges'. The motivation for this study was rooted in the notion that the culture at teaching institutions might be better suited to adopt non-lecture practices based on the widely-held belief that lack of research demands at these universities affords the instructors time to hone their teaching and thoroughly develop their courses. Additionally, instructors surrounded by faculty and administrators who similarly value teaching might be more likely to have the necessary support for experimenting with new pedagogy. Our literature review showed support for this broad characterization. Differences between teaching and research institutions are real and cannot be attributed to merely academic folklore.

At both types of institutions there are expectations for quality teaching and scholarly research; however, the emphasis can and does vary widely. Professors at research universities are judged and rewarded based on their research; conversely, teaching (or comprehensive) universities "do not effectively accrue status through research" (Henderson, 2009, p. 11). Not surprisingly then, the vast majority of research is produced by faculty at research institutions. A 2003 study of research productivity across higher education found staggering differences in the publication rate of faculty at R1 institutions as compared with Bachelors-granting schools: a 2.04 publication/faculty ratio at the former as compared with a paltry .06 (weighted average across categories) for the latter (Toutkoushian, et al., p. 139). Karen Webber explains this discrepancy:

"especially at research universities, publications and extramurally-funded grants are central to the institutional image and pocketbook, and thus strongly affect individual promotion and tenure" (2011, p. 110).When the most important consideration in tenure decisions is research productivity, it stands to reason that, "teaching is, at best, a secondary obligation" (Vest, 1994). In a 1984 study, Katherine Kasten put forth hypothetical candidates for tenure review with vitaes reflecting varying degrees of research and teaching quality. The statistical analysis, confirmed by interview data, demonstrated that research is the most important consideration indicating that "excellent scholarship … counterbalances virtually anything else except dereliction of duty" and there exists a "threshold for research below which no degree of teaching…can provide compensation" (p. 506).

In comparison, at teaching institutions, the 'publish or perish' ethos has yet to establish a strong foothold. Henderson (2009) explains that while traditional research holds the highest status, "other forms of publication have always been given credit in the faculty reward system…department heads, deans, and provosts have always been happy when faculty members have published, no matter where or what they published" (p. 18). Scholarship is appreciated, but students and teaching are the central focus. At comprehensive universities, where the faculty is likely to be unionized (Henderson, 2009), the contract clearly defines faculty teaching loads and criteria for promotion. In one such example, the most recent collective bargaining agreement of the PA State System of Higher Education (composed of 14 teaching institutions) outlines the teaching load to be 24 credit hours in an academic year with a minimum requirement of 5 office hours per week, and allows for the assignment of up to three unique academic preps per term (APSCUF, p. 74). This document further lists the categories for performance review and evaluation as effective teaching, continuing scholarly growth, and service – in that order (p. 24). While the NCES (Cataldi, Bardburn, & Fahimi, 2004) has shown the average faculty workload is 53.4 hours/week – a figure that does not differ significantly when considered by institution type – but the sort of work activities that occupy that time do vary significantly. Instructors at Doctoral-granting institutions spend on average 25.3% of their time in research as compared with less than 1% (on average) across all other types of institutions.

We believe that these institutional differences may lead to differences in the students' educational experience. On the one hand, diminished research expectations coupled with heavy teaching assignments would tend to suggest that these instructors are more likely to reflect upon and experiment with their pedagogical practice as compared with their research university counterparts. On the other hand, comprehensive universities are more likely to have scarce financial resources in part due to their disproportionate receipt of grant monies, which could limit participation in the types of professional development opportunities that introduce new pedagogical techniques or disseminate curricular materials and are less likely to find the time needed to make instructional changes due to the increased course loads common at teaching institutions. Webber (2011) estimates that the time needed to prepare well for class may equate to three to five times the number of hours for each hour spent in the classroom (p. 113), representing a non-trivial increase in time commitment for each additional course an instructor is assigned. Furthermore, faculty who are somewhat distanced from the research community, whether due to interest or circumstance, are perhaps less likely to be up to date on the literature advocating for pedagogical change when this work is being done by instructors who are neither their colleagues nor, in some circumstances, their peers. The purpose of the present study is to investigate whether there is evidence to support these suppositions regarding inclination for pedagogical change in the specific context of abstract algebra.

Data and Methods

Survey Design

In the previous study, we developed a survey designed to solicit information about the teaching practices, beliefs, and situational context of abstract algebra instructors. This survey was informed in part by both Henderson and Dancy's physics-education survey (Henderson & Dancy, 2009) and the Characteristics of Successful Programs in College Calculus surveys[1]. Our survey had sections to assess each of the following types of information: basic demographics and course context, teaching practices, beliefs and influences (including perceived supports and constraints), and knowledge of and openness to non-lecture practices. In this study, we wished to obtain the same information from a different population for the purposes of comparison. For that reason, it was methodologically important that the items under investigation remain largely unmodified. We chose the subset of items we wanted to ask and kept the formatting the same as the previous survey. Due to space constraints, sample items are not here, but a version of the survey can be found at the following link: pcrg.gse.rutgers.edu/algebrasurvey.

Participants

In the previous research, the initial sample consisted of 200 institutions from which 126 completed surveys were received. In this follow-up, a random sample of 400 institutions was drawn from the IPEDS list, targeting specifically Bachelor's-granting schools. From this, we received 112 responses, 91 of which were completed. For the purposes of this paper, all data has been combined into one data set and then disaggregated by terminal degree for all future analysis; 117 Type B = Bachelor's, 59 Type M = Master's, and 108 Type P = PhD – these designations will be used hereafter.

Methods

We first calculated basic descriptive statistics appropriate for each item and compiled demographic information. Where indicated, percentages were tabulated on the aggregate and for each identified sub-group. Group measures were compared using inference testing procedures such as ANOVA, Chi-Square test, or the Kruskal-Wallis Test as determined by the type of data under investigation. When appropriate, the Holm-Bonferroni correction was applied to control for the family-wise error rate affiliated with multiple comparisons. Details as applicable to particular tests can be found in the Results section. In general, the objective was first to provide a characterization of the abstract algebra course (as reported by our participants), specifically determining who teaches it, what is being taught, and how it is being presented. The secondary analysis was designed to explain those findings based on instructors' beliefs, resources, and constraints.

Results

In response to our first research question, *Does the way that abstract algebra is taught vary by institution type?*, the results indicate that in many regards it does, but there are some key characteristics that appear to be universal. Instructors teaching abstract algebra are generally not new faculty; roughly 78% have been teaching for more than six years (i.e. post-tenure) and this does not vary significantly by institution type; however, the experience with teaching AA is quite varied. On the aggregate, there is nearly an even distribution of experience across the three levels

[1] See www.maa.org/cspcc for more information about the CSPCC project and a copy of the surveys.

(1-4 times, 5-8 times, 8+ times), though this does not persist (Kruskal-Wallis test: $\chi 2 = 6.667$, df $= 2$, $p = .036$) when the data are dis-aggregated as the modal class rises proportionately with the type of institution. At Type P institutions, the majority of faculty have taught the course upwards of 8 times, whereas at Type B institutions the majority of faculty have taught the course only 1-4 times. Across institutions the predominant course structure was an undergraduate (61%) course for math majors; other responses included mixed audience courses and graduate courses. Approximately 9% of respondents reported teaching a "groups only" or "rings only" course, but the majority covered both topics in a "groups first" format and this was consistent across institution type. For nearly everyone surveyed, their algebra course is not taught as a capstone course and has a proof-writing prerequisite, although there are distributional differences by type with Type P being least likely to require this prerequisite course (57% as compared with 79% for Type B and 82% for Type M). The most significant, although unsurprising, differences were found in terms of follow-on courses. Type B schools were much less likely to require a second course (6.9%) than Type M (14%) or Type P schools (18.3%).

Moving away from demographic characteristics, the analysis looked at more subjective and personal measures such as pedagogical style and teaching practices. Using the prompt, *Have you ever taught abstract algebra in a non-lecture format?*, we coded respondents as either self-identified lecturers (hereafter referred to as "Lecturers") for responding *No* or *I have in the past, but I currently lecture*; or as self-identified non-lecturers (hereafter referred to as "Non-lecturers") for responding *I currently do*. Our findings support the notion that lecture is still the predominant mode of instruction in upper-division mathematics courses with 83% of our participants identifying as Lecturers; this represented 78% of Type B, 79% of Type M, and 91% of Type P instructors. On the one hand, it appears that our suggestion that instructors at teaching institutions would be less likely to lecture is supported ($Z = 2.23$, $p = .026$); however, a lecture rate of 78% does not indicate that sweeping pedagogical reform has occurred.

In terms of teaching practices, again there were a few noticeable differences, but for the most part institution types were more alike than they were different. When asked to report frequency per term for the following activities: *having students present proofs or counterexamples to the class, having students develop their own definitions, having student develop their own conjectures, having students develop their own proofs,* and *leading discussions in which students discuss why the material is useful and/or interesting*, no significant differences in mean frequency were observed between institution types. Similarly, when asked to report frequency per class meeting for the following activities: *I pause and ask students if they have questions, I use visual and/or physical representations of groups and group elements, I use diagrams to illustrate ideas,* and *I include informal explanations of formal statements*, there were no significant differences in mean frequency observed between institution types. Only for two activities: *I have students engage in small-group discussions or problem-solving* ($F = 7.984$, $p < .001$) and *I have students ask each other questions* ($F = 4.119$, $p = .018$) were statistically significant differences found: Type B schools engage in these activities more often than Type P schools. (It is important to note that the average increase in mean frequency was approximately .3 which, given the scale used, translates into roughly one additional occurrence per class, or a difference of engaging in the activity once per class versus every other class.)

In addition to reporting on frequency of certain activities, instructors were also asked to comment on the average percentage of class time devoted to certain pedagogical practices on a scale ranging from 0 (never) to 4 (75-100%) of class time. These included: *showing students how to write specific proofs, having students work with one another in small groups, having students* *give presentations of completed work, having students work individually on problems/tasks, lecturing, holding a whole-class discussion,* and *having students explain their thinking*. On average, the approximate amount of class time devoted to these techniques was under 25%, across practices and institution type; the notable exception was *lecturing* which occupied, on average, more than 50% of class time. In support of our hypothesis, Type B/M schools tended to devote more time to student-centered pedagogical techniques with significant differences observed for *having students work in small groups* ($F = 12.075$, $p < .001$) and *lecturing* ($F = 12.493$, $p < .001$). Each time, the mean difference between Type B/M and Type P schools was .5 on average, roughly translating to about 12.5% of class time.

Having found evidence suggesting that instructors at Type B schools self-identify as Lecturers less often and that the percentage of class time engaged in lecture for those who do is less than their Type P counterparts, our secondary analysis was focused on trying to explain these differences in terms of beliefs and resources/constraints. The instructors were asked to indicate degree of belief on a 4-point scale (-2 = disagree, -1 = slightly disagree, 1 = slightly agree, 2 = agree) in the following statements regarding teaching: *I think lecture is the best way to teach, I think lecture is the only way to teach that allows me to cover the necessary content, I think there's enough time for all the content I need or want to teach, When I last taught algebra, I had enough time during class to help students understand difficult ideas,* and *When I last taught algebra, I felt pressured to go through material quickly to cover all the required topics*. The instructors were consistent in terms of pressure and time concerns and really only differed in terms of evaluating the appropriateness of lecture. Type P instructors were significantly more likely on average to indicate that lecture was the only way to cover the necessary content ($F = 4.688$, $p = .01$) reporting moderate agreement where the others reported disagreement. Belief that *lecture is the best way to teach* failed to be statistically significant[2], but instructors at Type P schools did hold this belief more strongly than those at Type M and Type B schools as was expected.

The instructors were also asked to indicate degree of belief on the same 4-point scale in statements regarding students. These included: *I think students learn better when they do mathematical work in class, I think students learn better when they struggle with the ideas prior to me explaining the material to them, I think that all students can learn advanced mathematics, I think all students can learn abstract algebra,* and *I think students learn better if I first explain the material to them and then they work to make sense of the ideas for themselves*. Interesting here was that Type P instructors were the most pessimistic about the ability of the students to learn either advanced mathematics in general or abstract algebra specifically (although these differences did not achieve statistical significance). Consistent with the reported lecture practices, Type B/M instructors held significantly stronger belief in the students' need to do mathematical work in class ($F = 5.568$, $p = .004$).

Looking at differences in professional activities, there was little that was unanticipated. When ranking interest on a 4-point scale ranging from 1 (very weak) to 4 (very strong), the following activities were considered: *Discussing/reading about how students learn key ideas in abstract algebra, teaching abstract algebra, teaching other advanced classes, doing research in abstract algebra,* and *doing/reading research that could be considered the scholarship of teaching and learning*. Type P instructors had greater interest in algebra research and less

[2] Based on reported means of 0.5 for Type P, 0.3 for Type M, and 0.0 for Type B schools. This resulted in an F value of 3.73 with $p = .026$ which failed to meet the more conservative $p < .0125$ threshold for the Holm-Bonferroni correction for multiple comparisons.

interest in education research (reading or doing) and teaching. Significant differences were only observed for the research items ($F = 7.295$, $p = .001$ for algebra research; $F = 4.407$, $p = .013$ for educational research). Probably the most surprising finding here is that all faculty rated interest in teaching nearly a full point higher on average than either type of research activity

Type P instructors were lecturing at significantly higher rates than Type B/M; however, the lecture rates for all three institution types was quite high. To investigate the propensity for pedagogical modification, the respondents were asked if they would consider teaching in a non-lecture format and were directed to specific follow-up items investigating their reasons why they would not or why they have not. Type P instructors were significantly less likely (48%) to consider not lecturing as compared with Type B/M (65%) instructors ($z = -2.196$, $p = .028$). Those unwilling to consider a change were most likely to cite concerns over content coverage or a belief that it would go poorly (in that order), and surprisingly, this was consistent across all institution types. A very small number of individuals (5) indicated that they would not have departmental support for such a change. For those willing to consider a change, the number one impediment was lack of time to redesign their course, independent of institution type. Secondary concerns were lack of materials and not knowing where to start. Interesting here is that there were 12 individuals who would like to switch but feel that they lack departmental support (6 of whom were Type P instructors).

Discussion

Overall, abstract algebra instruction looks fairly similar across institution types, there being many commonalities regarding course structure, class activities, and time use. Virtually all instructors who hold Ph.D.s in mathematics receive degrees from research universities where lecture is the dominant paradigm. It is perhaps to be expected, then, that their instructional decisions – influenced in part by their own experiences as students – might reflect the teaching culture in which they were raised. A difference appears among Type B faculty, though, who self-report as Lecturers at lower rates than Type P (78% versus 91%, respectively) and who spend less (12.5%) class time lecturing than do Type P instructors. Moreover, the fact that using small group discussions and asking students to inquire into one another's thinking occurs approximately twice as often in Type B classes than in Type P further indicates a distinction in the day-to-day experience of students in these classes. That a clear majority of Type B instructors still report conducting class primarily through lecture, however, indicates that reformers still have a long way to go in spreading student-centered practices in mathematics (at least in abstract algebra), specifically with regard to existing curricular materials.

The current numbers should not detract from what may be a promising outlook: 65% of Type B/M Lecturers reported that they would consider switching to non-lecture pedagogies (significantly more than the 48% of Lecturers at Type P schools). The remaining 35% of Lecturers were most likely to cite concerns over content coverage or their belief that it would go poorly (in that order). It is interesting therefore, that 81% of these same Lecturers also report feeling no departmental pressure to cover a fixed set of topics, making the issue of content coverage largely one of internal orientation. Future directions for this research include examination of the actual content coverage by topic and its variance by institution type, the possible influence possession of a growth/fixed mindset plays in pedagogical decision-making, and researching the potential effect of the interaction between institution type and pedagogical style on the distribution of class time

Mathematicians' Evaluations of the Language of Mathematical Proof Writing at the Undergraduate Level in Three Different Pedagogical Contexts

Kristen Lew
Arizona State University

Juan Pablo Mejía-Ramos
Rutgers University

This proposal discusses the extent to which mathematicians agree amongst themselves with regard to what are some of the linguistic conventions of mathematical proof writing. Data from a survey of 128 mathematicians are used to address this question. Participants were asked whether various excerpts highlighted in four partial proofs were unconventional in each of three different contexts: how proofs appear in undergraduate mathematics textbooks, what instructors write on the blackboard in undergraduate mathematics courses, and how students write proofs in these courses. These data point to a lack of agreement among mathematicians on the linguistic expectations of the proofs written by their students.

Key words: Mathematical language, Proof, Mathematics Textbooks, Mathematics Lectures

Research has shown that undergraduate mathematics students have difficulties when constructing (Weber, 2001), reading (Conradie & Frith, 2000), and validating (Selden & Selden, 2003) mathematical proofs. Among several different reasons for why undergraduates struggle with constructing mathematical proofs, Moore (1994) included students' unfamiliarity with the language of mathematical proof writing. However, there is a dearth of empirical and systematic research in the field of mathematics education on the language of mathematical proof writing at the advanced undergraduate level.

In particular, how advanced undergraduate mathematics students and mathematicians understand and use the technical language of mathematical proof writing is largely unknown. Author (Year) showed that the mathematicians and undergraduate students who participated in their study did not agree on the extent to which one should attend to English grammar, the introduction of new objects in a proof, and the context in which a proof was constructed when considering the exposition of said proof. While the interviews provided a clearer picture of how some mathematicians and students perceived the language of mathematical proof writing, the present study investigated how a larger sample of participants evaluated parts of the same proofs via an online survey.

This approach lends a quantitative perspective on how mathematicians and undergraduate mathematics students understand technical mathematical language. This work also further informs researchers' and instructors' understanding of both mathematicians' and students' expectations regarding the presentation of mathematical proofs at the undergraduate level. For the sake of brevity, this paper focuses solely on the results of the mathematicians' survey.

Related Literature and Theoretical Perspective

Prior Work on the Language of Mathematical Proof Writing

There is little systematic, empirical work on the language of mathematical proof writing. Konior (1993) studied over 700 mathematical proofs written in academic textbooks and mathematical monographs investigating the construction of mathematical proofs. He identified a common structure that framed the arguments of a proof by highlighting the plan of procedure and using cues to direct the reader through the proof. Burton and Morgan (2000) found that the norms suggested in professional writing guides (e.g. Gillman, 1987; Krantz, 1998) are sometimes broken by mathematicians, especially by those who were highly regarded in the field. Selden and Selden (2014) also described seven features of the style in which mathematicians write proofs (e.g. not including the statements of entire definitions within written proofs).While these studies begin to further the understanding of mathematical proof writing at the professional level, research on the language of proof writing at the undergraduate level is lacking.

As referenced above, a number of mathematicians (AMS, 1962; Halmos, 1970; Gillman, 1987; Krantz, 1997; Higham, 1998) have written texts describing how to properly and effectively use the language of mathematics for professional purposes such as published journal articles, dissertations, and books. Meanwhile, since the suggestions provided in these guides for mathematicians were written based on the authors' own assumptions and personal experiences, further work is necessary to investigate the extent to which these expectations of advanced mathematical proof writing are shared by the general population of mathematicians and how these conventions may apply to different contexts.

Linguistic Conventions of Proof Writing in Different Contexts

As a particular type of mathematical writing, we see mathematical proof as a particular genre of the language of mathematics. Mathematician Armand Borel (1983) equated mathematical proofs to the genre of poetry in natural language, saying, "our poems are written in a highly specialized language, the mathematical language […], unfortunately, these poems can only be understood in the original" (p .15). In this quote, Borel emphasized not only that the language of mathematics is distinct from the vernacular, but also that one *must* be knowledgeable in the language of mathematics in order to understand mathematical proofs. In this work, we assume that the genre of proof is a way of using mathematical language defined by both the formal properties and structures of language, as well as the communicative purposes of texts in particular contexts. This view of genre is consistent with the genre theory literature (Hyland, 2002). Our consideration of proofs in this light is in the pursuit of helping students to understand and follow the linguistic conventions of the genre, as work has done in other genres and discourses (Hyon, 1996).

In order to study the genre of mathematical proof writing, we sought to identify and validate the existence of linguistic conventions of mathematical proofs. We assume that conventions are rationally justifiable customs of practice to which members of that practice are expected to conform in the manner of Jackman (1998). Thus, we take linguistic conventions to be rationally justifiable customs of linguistic communication. Existing literature (AMS, 1962; Halmos, 1970; Gillman, 1987; Higham, 1998) has suggested possible conventions of writing mathematical proofs for professional contexts, such as correctly situating notation within a sentence according to proper grammar, and structuring the proof to guide a reader through the argument.

Meanwhile, it is important to consider how the context of the proof might affect how these conventions are followed as suggested by the mathematicians in Author's (2016) study. In particular, we investigate how mathematicians believe conventions of mathematical proof writing apply in the contexts of undergraduate textbooks, and in two classroom contexts: the way proofs are written on the board in class, and the ways in which proofs are written undergraduate students. The consideration of this variation of context within the genre of proof writing allows this work to highlight important similarities and differences in the contexts created by mathematical discourse, as Bondi (1999) had in her study of research papers, textbooks, and newspaper articles in the discourse of economics.

Researchers in higher education (Becher, 1987), linguistics (Hyland, 2004), and composition (Bizzell, 1982; Batholomae, 1985) have highlighted that different disciplines have characteristic discourse practices. Berkenkotter, Huckin, and Ackerman (1988) summarized the work of composition scholars Bizzell and Batholomae stating, "students entering academic disciplines must learn the genres and conventions that members of the disciplinary community employ. Without this knowledge, they contend, students remain locked outside of the community's discourse" (p. 10). We extend this necessity to acquire specialized literacy to undergraduate students of advanced mathematics, who—we argue—must understand the genres and conventions of mathematical discourse which includes the genre of mathematical proof in the different contexts that pervade their undergraduate study. Given the fundamental role of proof in mathematical practice (Thurston, 1994; Wu, 1996; Rav, 1999) and in light of Borel's (1983) quote above, understanding the language of mathematics in which proofs are written is of utmost importance for undergraduate students studying advanced mathematics.

In the present study, we investigate the conventions of mathematical proof writing from the perspective of mathematicians – the most prevalent instructors and examiners of undergraduate students' proof writing. As such, the present study investigates the following questions:

- To what extent do mathematicians agree among themselves on what the linguistic conventions of mathematical proof writing are in the three contexts of textbook proofs, blackboard proofs, and student-produced proofs?
  - Do conventions exist for the language of undergraduate mathematical proofs?
  - Does the context of said proofs affect what conventions are upheld in mathematical proof writing?

Methods

In order to evaluate how mathematicians perceive linguistic conventions in mathematical proofs, the survey adopted the methodology of breaching experiments in the style of Herbst (2010) and Herbst and Chazan (2003).The survey asked participants to make evaluations regarding the language used in several partial proofs, which were based on student work, but truncated to discourage participants from focusing on the logical validity of the purported proof being evaluated. Four of the seven partial proofs used in Author's (Year) study were included in the survey, each of the four proofs included in the survey presented three or four types of potential breaches of mathematical language.

These breaches were identified by Author (Year) as common, potentially unconventional uses of mathematical language found in student-produced proofs from 149 exams at the introduction to proof level. The breaches were categorized based on suggestions from the mathematical writing guides discussed above and their personal experiences with proof writing at the undergraduate level. One of the partial proofs and potential breaches included in the survey is illustrated below. Figure 1 shows the marked partial proof exhibiting the use of the unspecified variable, z, and the explanation for why someone might think it's unconventional, as presented in the survey. The explanations used in the survey are based on the mathematicians' discussions of the same potential breaches and proofs in Author (Year).

Each potential breach was presented on a separate page of the survey. On these pages, participants were provided a marked partial proof and an explanation of why a colleague might believe the corresponding proof excerpt had been written in an unconventional manner, as shown in Figure 1. Participants were then asked if they agreed that this proof excerpt was indeed unconventional for the stated reason and to what extent it affected the quality of the proof. These questions were asked for each of the contexts of a textbook proof, a blackboard proof, and a student-produced proof.

Marked Partial Proof Exhibiting the Potential Breach: Uses an Unspecified Variable	**Explanation of the Potential Breach**
Suppose $f : A \to B$, $g : B \to C$, $h : B \to C$, for sets A, B, and C. Prove: If f is onto B and $g \circ f = h \circ f$, then $g = h$. Suppose f is onto B and $g \circ f$. NTS: $g=h$ If f is onto B, $Rng(f)=B$ $\forall y \in B$, $\exists x \in A$ such that $f(x)=y$ let $(x, z) \in g \circ f$ such that $\exists y \in B$ $g(y)=z$	A mathematician suggested that this is unconventional mathematical writing because the variable *z* should be introduced prior to its use in the proof.

Figure 1. Example potential breach and explanation presented in the survey.

Participants were recruited from 25 of the top mathematics departments in the United States through email solicitation through their department secretaries. Mathematicians were sent a link that directed those who chose to participate in the study to the survey website. In total, 128 mathematicians (75 PhD students, 16 Postdoctoral fellows, and 37 faculty members) participated in the survey.

Analysis

The analysis for this study included investigating if the mathematicians answered the various aspects of the survey differently – in particular, whether they agreed or disagreed on the extent to which the potential breaches were unconventional in each of the three contexts (textbook proofs, blackboard proofs, and student-produced proofs).

Descriptive statistics were first considered to provide a holistic view of the data sets before conducting a number of statistical tests. Table 1 presents some of the findings from this study, indicating the proportion of the sample that agreed that the proof excerpt was unconventional for the reason provided, for each of the three contexts. To evaluate if the proportions of agreement indicated a high agreement within the samples, 75% and 25% of the sample were set to be the thresholds of a high agreement that a potential breach was unconventional and was not unconventional within the samples, respectively. Chi-squared tests for equality of proportions were conducted to check for proportions $p=0.75$ and $p=0.25$ with a level of significance of $\alpha=0.05/42$ (fourteen potential breaches in each of three categories). The results of these Chi-squared tests are indicated with ++ and - -, respectively. When considering this binomial data throughout this paper, the proportions of agreement were categorized in the following ways: high agreement that the use is unconventional (significantly different from and greater than 75%), high agreement that the use is not unconventional (significantly different from and less than 25%), or not shown to have high agreement within the sample.

Results

To what extent do mathematicians agree among themselves in these contexts?

Survey results suggest a lack of agreement amongst participants in whether the potential breaches are unconventional of mathematical language for the reasons provided. As can be seen in Table 1, the agreement percentages for fewer than half of all judgments made were significantly different from and above 75% or significantly different from and below 25%. However, both samples' responses also showed more internal agreement in the context of textbook proofs. Figure 2 shows the percentage of mathematicians who agreed that the potential breaches were unconventional in each of the three contexts. Lines connect the agreement percentages for evaluations in the same context and the shaded sections indicate the percentages significantly different and greater than 75% or significantly different and less than 25%. This section of the proposal discusses the types of potential breaches for which participants' responses showed high agreement and provides a post hoc analysis of the potential breaches for which the samples' responses did not show high agreement.

	Potential Breach of Mathematical Language	**Do you agree that this is an unconventional use of mathematical language for the reason provided? *(% Agree)***		
		Textbook Context	**Blackboard Context**	**Student Context**
Partial Proof 1	**Uses non-statement**	100% ++	100% ++	98% ++
	Uses an unspecified variable	59%	34%	37%
	Includes statements of definitions	41%	18%	12% --
	Lacks punctuation and capitalization	95% ++	34%	50%
Partial Proof 2	**Uses formal propositional language**	88% ++	74%	66%
	Uses unclear referent	93% ++	67%	70%
	Overuses variable names	98% ++	95% ++	93% ++
	Mixes mathematical notation and text	88% ++	28%	45%
Partial Proof 3	**Fails to make the proof structure explicit**	70%	29%	28%
	Uses mathematical symbols or notation as an incorrect part of speech	72%	19%	24%
	Uses informal language	77%	45%	48%
Partial Proof 4	**Fails to state assumptions of hypotheses**	64%	34%	40%
	Uses an unspecified variable with an existential quantifier	85% ++	55%	54%
	Lacks verbal connectives	97% ++	52%	72%

++ Significantly different from and greater than 75% of the sample, **--** Significantly different from and less than 25% of the sample (These tests were all evaluated with a level of significance α=0.05/42.)

Table 1. Mathematicians' responses indicating if they agree that the proof excerpt was unconventional for the reason provided in each context.

Types of potential breaches for which the participants' responses showed high agreement. Based on Figure 2, the mathematicians' responses showed that they found eight of the fourteen types of potential breaches to be unconventional in the context of a textbook proof for the reasons presented in the survey with high agreement. Moreover, there is high agreement among mathematicians that the proof excerpts exhibiting the use of non-statements or overuse of variable names are unconventional in each one of the three contexts. These findings provide further evidence that these eight potential breaches of the conventions of mathematical language are indeed unconventional in the context of textbook proofs for the reasons provided. The partial proofs that overused variable names or used non-statements were also seen by the mathematicians as unconventional in the two classroom contexts.

Finally, Figure 2 also shows the percent of mathematicians that agreed the inclusion of statements of definitions in a student-produced proof was unconventional is significantly different from and less than 25%. That is, there is a high agreement among the mathematicians that a proof excerpt including the statement of definitions is not unconventional in the context of a student-produced proof. Moreover, fewer than 42% of mathematicians agreed that the inclusion of statements of definitions was unconventional in any of the three contexts considered here. We note that this is in contrast to claims by Selden and Selden (2014) that mathematicians do not include the statements of entire definitions within written proofs. While the scope of the present study focuses on proofs at the undergraduate level, we note that two of the contexts (textbook proofs and blackboard proofs) are written by mathematicians. Thus, it may not be the case that the features of proof writing described by Selden and Selden (2014) extend to different contexts of proofs written by mathematicians or to the context of student-produced proofs.

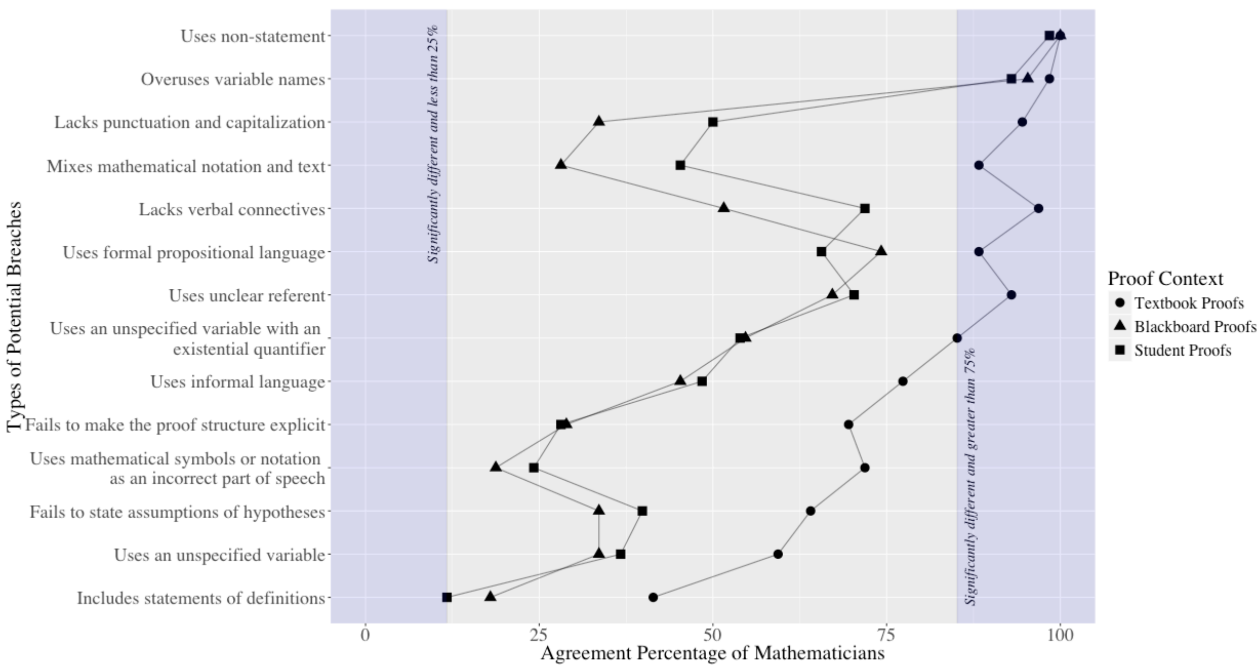

Figure 2. The mathematicians' agreement percentage for each potential breach in each context.

When the samples' responses did not show high agreement. For 29 of the 42 judgments made by mathematicians (fourteen potential breaches in each of three categories), percentages of agreement did not cross the thresholds for high agreement, i.e. percentages were not significantly different from and higher than 75% or significantly different from and lower than 25%. Figure 2 further shows that for five of the potential breaches, there was no high agreement among mathematicians *in any of the three contexts*, and that when we restrict the analysis to only the two classroom contexts (blackboard proofs and student-produced proofs), up to eleven of the fourteen types of potential breaches the results did not show high agreement. Finally, Figure 2 highlights that a number of these agreement percentages are close to 50%. In particular, eight of the 42 judgments had percentage agreements between 40% and 60%, including two judgments in the context of textbook proofs. These findings suggest that beyond failing to give confirmation that many of these potential breaches were indeed breaches of linguistic conventions in mathematical proof writing, that the disagreement among mathematicians may be higher when it comes to the classroom contexts, and that for some specific types of potential breaches the disagreement amongst mathematicians may be particularly extreme, even in the context of textbook proofs.

Moreover, it is clear that a larger percent of the mathematicians agreed that a potential breach was unconventional in the textbook context than when the same potential breach was assessed in either of the other contexts. In fact, Figure 2 suggests that for some of the types of potential breaches, the fewer mathematicians that agreed a proof excerpt was unconventional mathematical proof writing in the context of textbook proofs, the fewer that perceived that the same excerpt was unconventional in the classroom contexts.

Conclusion

The findings of this report highlight the existence of some potential breaches of mathematical language that mathematicians widely agree are unconventional in the context of textbook proofs. Specifically, mathematicians in our study widely agreed that including incomplete statements, overusing variable names for different mathematical objects, lacking proper punctuation and capitalization, carelessly mixing mathematical notation and text, failing to use connectives to bridge steps, using formal propositional language, using pronouns with unclear referents, and using an unspecified variable are all unconventional usage of mathematical language in textbook proofs. Moreover, mathematicians widely agreed on the specific rational justifications for why the proof excerpts breached linguistic conventions or mathematical proof writing on that context. On the other hand, mathematicians also widely agreed that one of the potential breaches studied (including full statements of definitions within proofs) was not unconventional in the context of student-produced proofs for the reasons provided, which suggests that Selden and Selden's (2014) claim that mathematicians do not include definitions in their proofs may not extend to other contexts and to mathematicians' expectation of how students write proofs.

Meanwhile this report also gives insight on how these mathematicians differed in their evaluation of the language of mathematical proof writing in the classroom contexts at the introduction to proof level. In particular, the results suggest that it is unclear what mathematicians expect a student-produced proof to look like. The mathematicians' responses did not indicate high agreement for twelve of the fourteen types of potential breaches in the student context, which may indicate the possibility that there is no shared understanding or expectation among mathematicians of how students should write proofs.

If it is indeed the case that there is not a consensus among mathematicians of how their students in introduction to proof courses should write their proofs, then how are instructors of these courses presenting proof writing to their students? Discussions amongst mathematicians, especially those who teach introduction to proof courses, concerning their expectations for language usage in the writing of proofs by their students would be a useful step towards a shared understanding of linguistic conventions of proof writing in the context of student-produced proofs. Further research is necessary to understand these varied expectations amongst mathematicians and how to address students' confusion when it comes to their professors' expectations of their proof writing. In turn, better understanding of mathematicians' expectations of their students' writing could enable the creation of interventions and curriculum to help undergraduate students in their transition to abstract and advanced mathematics courses.

An Unexpected Outcome: Students' Focus on Order in the Multiplication Principle

Elise Lockwood
Oregon State University

Branwen Schaub
Oregon State University

In an effort to better understand students' understanding of the multiplication principle, which is a fundamental aspect of combinatorial enumeration, we had two undergraduate students engage in reinvention of a statement of the principle during an eight-session teaching experiment. In this presentation, we report on the students' unexpected attention to the order in which they complete stages of counting process in a counting problem. We suggest that an early experience with a particular problem prompted them to think about order, and this way of thinking persisted throughout the experiment. The students' reasoning about order sheds light on ways in which students may think about order and about the nature of multiplication in counting. We conclude with potential implications and directions for further research.

Key Words: Combinatorics, Reinvention, Counting problems, Teaching experiment

Introduction and Motivation

The multiplication principle (MP), also known as "The Fundamental Principle of Counting" (e.g., Richmond & Richmond, 2009), is a foundational component of understanding of counting problems. The MP is the idea that for independent stages in a counting process, the number of options at each stage can be multiplied together to yield the total number of outcomes of the entire process (see Lockwood, Reed, & Caughman (in press) for a more in depth discussion of the MP; the statement by Tucker (2002) in Figure 1 is our preferred statement of the MP). This principle is often taught to students in discrete math classes and provides a basis for many counting formulas they are eventually taught.

In order to better understand student thinking about the MP, we had a pair of undergraduate students reinvent a statement in their own words over the course of eight hour-long interview sessions. While we have previously reported on this overall reinvention (Lockwood & Schaub, 2016), in this paper we focus on an unexpected feature of the MP to which the students attended. Specifically, the students' regularly and repeatedly expressed a desire to include in their statement a clause that the order of stages in a counting process does not matter. This was an unexpected focus that emerged during the teaching experiment. In this paper, we seek to address the following research question: *Why did the students in our study (unexpectedly) focus on order in their reasoning about and reinvention of the MP, and what does this suggest about the role of order in the MP?*

Background Review and Theoretical Perspective

Research about the MP in Combinatorics Education Literature

Previous work has demonstrated the importance the MP, and the lack of a well-developed understanding of the MP appears to be a significant problem and hurdle for students, particularly in terms of their ability to justify or explain formulas (e.g., Lockwood, Swinyard, & Caughman, 2015). We have found anecdotally that students can easily assume that they completely understand the MP in counting because multiplication is a familiar operation for them. As a result, they use the operation frequently but without careful analysis, and they tend not to realize when simple applications of the operation are problematic. Lockwood et al. (2015) had students reinvent basic counting formulas, and the students in that study did not appear to have a solid understanding of the MP. They worked with outcomes empirically but lacked the understanding of how those outcomes related to the underlying counting process involved with the MP. This work suggested the need for additional research that targets students' understanding of the MP as a fundamental counting process. In addition, Lockwood and Caughman (2016) wrote about students who struggled on a particular kind of problem (set partition problems), and the authors attributed the struggles in part to confusion about clauses about ordered stages in the MP.

Motivated by those two studies, Lockwood, et al. (in press) recently conducted a textbook analysis that examined statements of the MP in university combinatorics, discrete mathematics, and finite mathematics textbooks. This revealed a wide variety of statements of the MP (Figures 1 and 2 reveal two very different formulations of the MP). From this textbook analysis, Lockwood, et al. identified three key mathematical aspects to which many statements attended: *independence of options*, *dependence of option sets*, and *distinct composite outcomes*. We note that order is an implicit aspect of the MP – so implicit that it was not one of the features emphasized in the textbook analysis, in part because we assumed that students would already understand that they completed a counting process in some pre-determined order. Order is certainly an important component of the MP, but it varies in how explicitly it is addressed. For example, in Figure 1, Tucker (2002) explicitly describes "*m* successive (ordered) stages," while the order is implicit in the structure of k-tuples in Bona's (2007) statement in Figure 2.

> ***The Multiplication Principle****: Suppose a procedure can be broken down into m successive (ordered) stages, with r_1 different outcomes in the first stage, r_2 different outcomes in the second stage, ..., and r_m different outcomes in the mth stage. If the number of outcomes at each stage is independent of the choices in the previous stages, and if the composite outcomes are all distinct, then the total procedure has $r_1 \times r_2 \times \ldots \times r_m$ different composite outcomes.*

Figure 1 – Tucker's (2002) statement of the MP

> ***Generalized Product Principle:*** $|X_1| \times |X_2| \times \ldots \times |X_k|$ *Let $X_1, X_2, \ldots, X_k$ be finite sets. Then the number of k-tuples (x_1, x_2,..., x_k) satisfying $x_i \in X_i$ is .*

Figure 2 – Bona's (2007) statement of the MP

We also draw on Lockwood's (2013) model of combinatorial thinking, which emphasizes the relationships between counting processes, sets of outcomes, and formulas/expressions. We emphasize that a particular counting process can generate a set of outcomes with a certain structure, and different ways of structuring the set of outcomes may reflect different respective counting processes. In the following section we discuss the key issue of order in this paper.

Order in the Multiplication Principle

To appreciate this issue of order in the MP, we consider two problems. First, *"How many ways are there to flip a coin, roll a 6-sided die, and pick a card from a standard 52-card deck?"* In this problem, the outcome is simply a set of results of these three activities. If the problem said "first pick a card, then roll a die, then flip a coin" then the order is determined, but the problem does not specify this. However, when one goes to solve this problem, a natural approach might be to specify a process with a particular sequence of stages with a particular order. For instance, we might solve the problem by specifying we will first of pick a card, then roll a die, then flip a coin, but this is a different counting process than rolling a die, then flipping a coin, then picking a card. In the first case, the outcomes would be {card, number, coin} triples, where the first entry is a card, the second entry is from the set {1, 2, 3, 4, 5, 6} and the third entry is from the set {H, T}. The formula/expression to represent that counting process would be 52*6*2. On the other hand, a different process of first flipping a coin, then rolling a die, then picking a card still counts the same outcomes (and answers the counting problem), but the tuples are now slightly different – {H/T, number, card} triples with the final expression of 2*6*52. The answers are numerically the same, but in each case we specified a differently ordered process in order to solve the problem. Notably, though, either ordering represents a similar set of operations, and ultimately it would not matter much, in terms of effort or efficiency, which order of the stages we used.

As a point of contrast, consider a slightly more complicated problem, *"How many even five digit PIN numbers are there with no repeated digits (leading zeros allowed)?"* Here, again, we can specify a counting process. If we specify our stages as considering the options for each position from left to right (first to last), we can run into a problem at the last position, which needs to be an even number. The number of options we have for that last position depends on how many of the previous numbers were even. It seems like we will need a complex case breakdown to address this, until we realize that we have the flexibility to specify the order of the stages in our process. Let us, as the first stage in the process, consider options for the last position (there are 5 even numbers, 0, 2, 4, 6, 8). Then, once that is specified we can return to the first position (or any other position) and there will be 9 options (everything except the digit used last), then 8, then 7, then 6. The answer is thus 5*9*8*7*6. Now, mathematically we could re-write this as 9*8*7*6*5 as a numerically equivalent expression, but we lose the valuable information of the counting process with the specified order. In this problem, the ordered counting process is helpful. The point is that a person counting has flexibility with regard to what process is being implemented. A judicious ordering of stages facilitates an efficient solution.

In terms of how order plays into statements of the MP, the MP specifies how to use multiplication to count, once a particular course of action (or a particular order of stages in a counting process) has been determined. As a result, the statement need not explicitly include a clause that allows for any order of stages, even though it is true that often multiple orders of stages is allowable (such as on the 2*6*52 problem). Rather, the point of the statement is to speak to when multiplication applies once a counting process is specified. Interestingly, because multiplication, as an operation, is commutative, the issue of order in the MP raises questions about how multiplication as an operation differs from multiplication in the context of counting. We briefly explore the commutativity of multiplication and how it relates to multiplication in combinatorial enumeration in the Discussion and Conclusion section.

Methods

For data collection, we conducted a teaching experiment (Steffe & Thompson, 2000) in which a pair of undergraduate students solved counting problems over eight hour-long sessions. The students were enrolled in vector calculus in a large university in the western United States, and we selected them because they had not been explicitly taught about the MP in their university coursework. The interviews took place outside of class time over a period of four weeks. Broadly, the students solved a series of counting problems, and they were asked to write down and characterize when they were using multiplication as they solved these problems. They wrote down several iterations of statements of the MP, and throughout the study the interviewer selected tasks to highlight various aspects of the MP and regularly asked clarifying questions.

The students engaged in three kinds of activities during the teaching experiment: solving counting problems that involve multiplication, articulating and refining a statement of the MP and evaluating given textbook statements of the MP. Although there was some overlap of activities in each session, Table 1 gives the overall structure of the teaching experiment by outlining the session number (and total number of tasks in each session), a sample task given in that session, and the predominant activity that occurred in each session. When designing tasks for the teaching experiment, we drew on the three key mathematical ideas presented in the textbook analysis (Lockwood, et al., in press). That is, when preparing for and implementing the reinvention, we designed tasks with the aim of addressing those three key mathematical issues.

Session	Sample Tasks for Each Session	Goal of Session
1 – 2 (11 total tasks)	How many ways are there to place two different-colored rooks in a common row or column of an 8x8 chessboard?	Solving counting problems
3 – 5 (9 total tasks)	How many ways are there to flip a coin, roll a die, and select a card from a standard deck?	Articulating a statement of the MP
6 – 7 (9 total tasks)	How many 6-character license plates consisting of letters or numbers have no repeated character?	Refining their statement of the MP
8 (7 tasks)	Please read the following statement [such as Tucker's (2002) in Figure 1]. How is it similar to or different from your own statement?	Evaluating given textbook statements

Table 1 – Overall structure of the teaching experiment

For data analysis, we first videotaped and transcribed the interviews. For this paper we especially examined episodes in which the students talked about order in their statement of the MP. We developed and used a conceptual analysis of order in the MP, and we used that to better understand what the students might have been thinking about and emphasizing.

Results

In this Results section, we attempt to provide evidence for Pat and Caleb's (pseudonyms, both students are male) emphasis on order. In particular, we first present the students' work on a problem in which they first seemed to grapple with order. Then, we present three brief episodes that emphasize their repeated interest in order and highlight certain ways of thinking about order.

Students initially reason about order

During Sessions 1-2, the students were not yet articulating or refining statements of the MP but were solving initial counting problems involving multiplication. In Session 2 we gave them the problem, "*How many ways are there to place two different-colored rooks in a common row or column of an 8x8 chessboard?*" A possible solution to this problem involves thinking of 8 options for the first rook row, 8 options for the first rook column, 2 options for whether the second rook is in the adjoining row or column, and lastly 7 options for the second rook's specific square. Thus we have 8*8*2*7 = 896. The students gave the following answer, which explains a solution of 2*2*8*8*7:

Pat: *You'll have two selections for color… So then you'll choose color, you'll choose if you're doing rows, putting them in the same rows or columns, then you'll have eight selections* *for which row or column, and then you'll have eight selections for first placement, and then you'll have seven remaining options for the second placement.*

Here the students are inadvertently multiplying by an extra 2 for the first choice of rook color. Accounting for color is unnecessary, because placing a white rook in Square 1 and a black rook in Square 2 is the same as placing a black rook in Square 2 and then a white rook in Square 1. If we also multiply by 2 for the rook color, we count every possible placement of rooks twice.

We then discussed this issue for some time with the students. They realized that they were overcounting, but they also seemed attuned to order and the language of "first" and "second." We see Pat's exchange with the interviewer in the following conversation, and the underlined portion especially suggests that he was emphasizing that the order in which the rooks were placed should not be taken into consideration in the solution:

Pat: *You could put white here first or white here second, black here first or black here second, white here first or white here second, as long as it ends up there with the other one ending up somewhere, the first place.*

Int.: *Okay. So you're talking about, kind of, this first and second language.*

Pat: *Yeah, yeah. <u>So it doesn't matter which order they're placed, as long as they end up in the same position.</u>*

They went on to say that there was no "temporal" element to the process, all that matters is the final outcome of two rooks on a chessboard. We feel that as a result of this experience, the students were later reluctant about making any commitments about the specific order in which stages in the counting process must occur. We contend that was an important episode for the students, as this seemed to the impetus for their focus on order in the teaching experiment.

Students incorporate of clauses about order in their statements of the MP

We now offer data examples that exhibit how the students' interest in order arose in the context of their reinvention of a statement of the MP. These examples are meant to demonstrate the nature of the students' thinking about order as a component of the MP. As noted above, because this was an unexpected aspect of their work, by examining it we can better understand how students perceive order, hopefully ultimately leveraging insights about such thinking to help students develop productive ways of thinking about the MP.

The students had provided an initial statement (*Use multiplication in counting problems when…there is a certain statement shown to exist and what follows has to be true as well*), which we perceived as a first attempt that still needed significant refinement. We gave them more problems to investigate multiplication, and in Session 4, we gave the students the problem described above, *How many ways are there to flip a coin, roll a die, and select a card from a standard deck?* The students quickly gave the correct answer of 2*6*52, and we prompted them to try to explain their reasoning and potentially to connect their answer to their statement of the MP. The discussion that ensued suggested the students' view that time and order no longer mattered. We hypothesize that their ways of thinking were affected by the experience of overcounting in the rook problem.

Pat: *So I feel like, if there's no order in which the selections have to be made, I feel like there's multiplication.*

Int.: *Okay.*

Pat: *At least that's part of it. I feel like it's more complicated than that. <u>But I feel like as long as we're just selecting a coin toss, a dice roll, and a card, it's the same number of outcomes no matter how you do that</u>. And so if there's no order in which you have to* *make your selection, I feel like that makes all the movements possible, if you put it in order it will still be the same number of outcomes but you can do it however you want, and you'll have the same number. So regardless of how you say where to start, you'll get the same number of possible outcomes. <u>So it doesn't actually matter what order you do the selection that's, that would be mult... I don't know if that leads to multiplication or if it's just multiplication reflects that fact</u>.*

Caleb: Yeah. I think it might be more of the second one.

Pat: Yeah.

At the beginning of the statement (the first underlined portion), Pat articulates the idea that he will get the same number of outcomes no matter the order in which he does the three tasks. This is true, and for this problem in particular the order in which the three tasks are completed does not affect the total number of problems. However, note that in order actually to complete the multiplication and determine the solution, one must specify (and commit to) a particular order. That is, we could yield 2*6*52 or 6*52*2, or any other arrangement of the tasks, but in actually multiplying a specific sequence must be determined. In this particular problem, each ordering of the tasks yields essentially the same amount of work, and there is no clear benefit to doing tasks in any particular order. However, as we demonstrated with the PIN number problem above, sometimes it behooves a student to specify a particular order in which to complete stages of the counting process. So, Pat's observation about order on this problem is correct, but order does not always behave in this same way on other counting problems.

At the end of his statement (the second underlined portion), Pat reflects on whether the idea of order not mattering implies multiplication or if it is simply a reflection of multiplication. This is a noteworthy observation that highlights questions about the nature of multiplication and also the nature of a statement of the MP.

Questions about order came out again in Session 4 when the students try to articulate multiple pathways (options) into their statement of the MP. Here we see that they did not want to incorporate into their statement how they order the stages in the counting process.

Caleb: But it has, it's more than just that because that really only talks about one outcome and one pathway. It has to do with all these, like how many times you multiply too, and when the whole, <u>but I'm trying not to incorporate like how you order it</u>.

Int: Ok. Great. Hang on, so you're, real quick, so you're saying, so you're trying not to incorporate how you order it, and what do you mean by that?

Caleb: <u>So I'm not saying like one comes first and then you multiply another and then another. I'm trying to just say there's a total number of pathways and a total number of options</u>...

As a final example of their reasoning about order in the MP, we share an episode when we gave them the relatively straightforward problem of *How many ways are there to put four distinct people in a line?* The students were easily able to identify a counting process and solve the problem correctly (they said that they had four option for which person goes in the first spot, then three options for who goes in the second spot, and so on), but they were reluctant to acknowledge a specific order in which they solved the problem. We asked them to list out all 24 outcomes in a way that reflected their counting process, and they wrote an alphabetical list of the letters A, B, C, and D. Then, we asked them to list differently, in which the letter A was in the third position. To us, the two lists would reflect two different orders in which to complete the counting process, and we hoped it would help them realize that they could specify a certain order. As the exchange below shows, the alternative way of listing did not register for them, and in fact they saw no difference in the two orders that would produce two different lists.

Int.: *So then presumably you could also list out where C and D are in the third position right?*
Pat: *Yeah, you could.*
Int.: *I mean, you could get all 24. Does that seem like that matters at all to you, or is it just like –*
Caleb: *No, it means absolutely nothing.*

From these three examples, we suggest that the first problem involving rooks had a deep impact on the students' thinking about order in the MP. They were hesitant to enforce any sort of ordering on the problems, and they wanted to include a clause about order in their reinvented statement of the MP. Although in the end the students did create a cohesive and refined statement of the MP, this foray into order is to show an unexpected outcome of working on a reinvention of the MP, and it serves as a reminder that students often have robust and consistent ways of thinking that may differ from our (as researchers) initial expectations.

Discussion, Conclusions, and Implications

Perhaps because order is often treated implicitly in many textbook statements of the MP, it was not a feature that we expected students to discuss explicitly (as opposed to independence and overcounting, which we suspected would be key mathematical issues for students). However, order was one of the main issues to which Pat and Caleb students repeatedly returned, and this allows for a couple of important points of discussion.

First, our findings indicate that the notion that multiplication in counting involves ordered stages is not always natural for students to consider. And yet, our results suggest that it is important for students to think carefully about order and the role it plays in the MP. More specifically, the fact that counting processes specify an order emphasizes that we as counters can have flexibility, and we can choose to complete stages in a counting process in a way that will be effective or efficient (as the PIN number problem suggests). This is an issue that we feel should be emphasized among students as they learn to count

The results also highlight a potential distinction between multiplication as an operation (which is commutative over the nonnegative integers) and multiplication in a combinatorial context. The fact that different orders of stages might result in a better solution to a counting problem suggests that commutativity of multiplication may not be a key feature of multiplication we want to emphasize in combinatorial contexts.

We acknowledge that since this is just one set of students, we cannot say for certain how other students will treat the same issue. And, we believe that this is likely a remnant of their work on one particular problem (rooks on a chessboard), and that the experience of solving that problem had a lasting impression on them. However, the fact that order was such an important feature of Pat and Caleb's work suggests to us that it represents a strongly held mathematical idea, and we conjecture that other students might also think similarly about order in the MP.

In further research we would like to do more teaching experiments that acknowledge student thinking about order in a more purposeful way. Due to the unexpected nature of this issue, we would like to create more problems and questions to help students become attuned to order in future teaching sessions. We strongly believe that having a well-defined understanding of order within the MP is a key mathematical aspect of understanding the when and why one can use multiplication when solving counting problems.

Computational Thinking in and for Undergraduate Mathematics: Perspectives of a Mathematician

Ami Mamolo
University of Ontario Institute of Technology

Miroslav Lovric
McMaster University

We report on a mathematician's perceptions and awarenesses related to incorporating problem-based activities requiring computational thinking into an upper level undergraduate mathematics course. Computational thinking is understood as the thinking, strategies, and approaches for problem solving that parallel the design of computational algorithms which can be followed and executed by a computer. Data from this case study is qualitative in nature, and seeks to present an in-depth account of one professor's experiences developing and teaching computational thinking in and for mathematics. Analyses highlight the similarities and differences amongst the values and opportunities perceived for computational thinking versus other more ubiquitous mathematical approaches, as well as the perceived tensions and challenges in trying to foster such values and opportunities.

Key words: Computational Thinking; Undergraduate Mathematics; Awarenesses; Disciplinary Goals; Mathematics Professor

This study reports on the case of a mathematician's aims and objectives when incorporating a focus on computational thinking in an upper level undergraduate course focused on problem solving, simulations, and mathematical investigation. Computational thinking can be loosely defined as the thinking involved in, and related to, computer programming. This can include screen-based programming, paper-based or embodied pseudo-coding, as well as other approaches to problem solving that parallel the design of computational algorithms which could be followed by a computer (Aho, 2012; Wing 2006). While the idea of using computer programming in mathematics is not new (e.g., Feurzeig, et al., 1969; Howson & Kahane, 1986; King et al., 2001; Marshall et al., 2014a; Papert, 1980), research has been primarily focused on elementary or secondary school learning (e.g., Floyd et al., 2015; Gadanidis, 2014, 2015; Sneider et al., 2014) with recent attention turning towards ways computer programming can be used in undergraduate mathematics (Muller, et al., 2009; Marshall & Buteau, 2014). However, purposes and best practices for computational thinking in undergraduate mathematics learning are far from well understood.

This research is part of a broader research program that aims to address the what, why, and how of computational thinking in and for undergraduate mathematics learning. In this paper, we focus specifically on the experiences and perceptions of a mathematician in his design and implementation of a mathematics course that sought to incorporate computational thinking as a key practice. In particular, we address the following research questions:

1. What does a mathematician teaching an undergraduate level problem solving course describe as the values and opportunities for student learning when incorporating computational thinking in and for mathematics?
2. What challenges and tensions were experienced from a teaching perspective?

We use a case study approach and qualitative analysis, which are suitable for collecting and interpreting in-depth stories of teaching and learning (e.g., Stake, 2000; Yin, 1994). We use Mason's (1998) framework of levels of awareness to analyze both the disciplinary and pedagogical values associated with computational thinking in and for mathematics, as well as our participant's perceptions of opportunities, challenges, and tensions.

Background

Research has highlighted an extensive set of skills and competencies that may be developed by incorporating computational thinking in mathematics learning. These include, but are not limited to: self-motivation to do and explore mathematics; experimentation; development of mathematical intuitions and approaches; critical reflection; working with abstraction and different representations (Howson & Kahane, 1986; King et al., 2001; Marshall & Buteau, 2014; Marshall et al., 2014). Addressing mathematics problems through the use of computer programming has also been described as transformative to learning (Papert, 1980), fostering learner-driven active engagement, as well as resilience and creativity in the face of new and challenging problems.

Parallels between learning computer programming in general, and developing computational thinking for mathematics in particular, have been noted. Wing (2008) observes that: "In computing, we abstract notions beyond the physical dimensions of time and space. Our abstractions are extremely general because they are symbolic, where numeric abstractions are just a special case" (p.3717). In considering higher levels of mathematics, abstractions become more complex than simply numeric abstractions and research has suggested that the more condensed an abstract object is, the more challenging it is to reason with (e.g., Hazzan, 1999). For example, operating on a set of numbers is seen as a more abstract, and more complex, endeavor than operating on a single number. As such, computer programming may offer a sort of scaffold in fostering abstract reasoning by increasing students' experiences with abstraction while providing tangible and immediate feedback on how such abstractions may be operated upon.

Weintrop et al. (2016) developed their taxonomy for computational thinking in mathematics and science by analyzing characteristic practices that were seen as the most important in meeting both the needs of students and the disciplinary practices of mathematics and science professionals. They cite their work as contributing a set of actionable guidelines for bringing computational thinking into mathematics and science classrooms quickly and effectively that can "serve as resource to address "what" and "how" questions that accompany the creation of new educational materials" (p.129). Their taxonomy is depicted in Figure 1, with some elaboration of practices below.

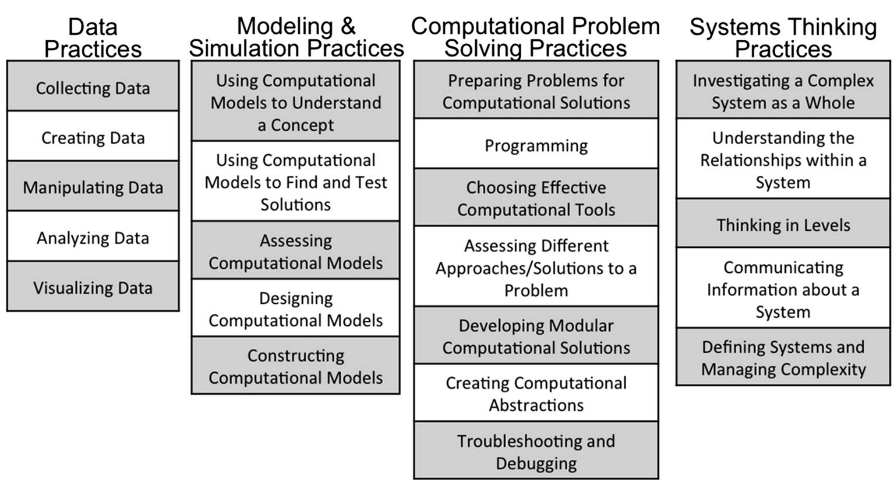

Figure 1: Computational thinking in mathematics and science taxonomy (Weintrop et al., 2016, p. 135)

As the professor participating in our study focused his course on problem solving and simulations, we take a moment to explicate some of the facets in the two corresponding dimensions of the taxonomy. *Modeling and Simulation Practices* focus on skills in using, analyzing, designing, and constructing computational models. Models may be used "to test many different solutions quickly, easily, and inexpensively" (p.137), and understanding how the model relates to the phenomenon being represented can help students articulate the similarities and differences between the two. Noticing similarities and differences is part and parcel to rich mathematical thinking (Mason, et al., 1982), and in the context of computational thinking can be fostered by questions such as "what assumptions have the creators of the model made about the world and how do those assumptions affect its behavior?" and "what layers of abstraction have been built into the model itself and how do these abstractions shape the fidelity of the model?" (Weintrop, et al, 2016, p.137). *Computational Problem Solving Practices* include interpreting and preparing problems for modeling, choosing between and assessing different tools and approaches, developing solutions, and debugging or revising. Students must be aware of which problems can be effectively addressed through computational solutions as well as how to reframe a problem so that "existing computational tools – be they physical devices or software packages – can be utilized" (p.138). Choosing amongst possible strategies, tools, or solutions, and developing modular approaches can foster critical mathematical thinking and logical deduction, while equipping students with a set of approaches that can be applied to larger, more complex problems. Of interest in this research study is whether and which practices emphasized in the taxonomy are recognized, valued, and incorporated by the professor teaching a problem-based mathematics course, and which practices may be seen as more challenging to incorporate.

Theoretical Framework

Mason's (1998) article discusses the necessary levels of awareness which distinguish between a novice, an expert, and a teacher in the discipline of mathematics. These levels of awareness are linked to the structure of attention, which "encompasses the locus, focus, and form of attention moment by moment" (p.250). Through shifts of attention, awareness is broadened and an individual may move from novice, to expert, to teacher through his or her attention and sensitivity toward different aspects of the discipline. Mason (1998, p.256) identifies and develops three forms of awareness:

- *Awareness-in-action*: this is the awareness which focuses attention on what to do in the moment. It is "highly personal and context specific" (p.256) and enables us to act, to know what to do in response to some stimulus. Awareness-in-action includes the "power to select, distinguish, demarcate, discern, detect differences; … to see (construct) something as an example of something else… to abstract… to connect… to express… [and] to decide" (p.257).
- *Awareness-in-discipline*: this awareness is awakened when one becomes aware of his or her awareness-in-action. In other words, it is an awareness "which enables articulation and formalisation of awarenesses-in-action" (p.256). Awareness-in-discipline is broadened by the ability to formalize algebra and geometry, to appreciate how and why we act in the moment, to enact the "habits of thought, forms of fruitful questions, and methods of resolution of those questions" (p.259) applicable to the discipline of mathematics.
- *Awareness-in-counsel*: this is the awareness required of teachers. It is an awareness of awareness-in-discipline; the "self-awareness required in order to be sensitive to

> what others require in order to build their own awareness-in-action and –in-discipline" (p.256). Awareness-in-counsel "provides access to sensitivities which enable us to be distanced from the act of directing the actions of others, in order to provoke them into becoming aware of their own awarenesses" (p.261).

In Mason's perspective (and we agree), teaching is not about telling students what to do, but rather it involves eliciting and fostering their ability to decide for themselves what to do. In the context of undergraduate mathematics education, an instructor's awareness-in-counsel is evidenced in his or her choices (and the expressed reasons behind these choices) of what content, practices, habits of minds to emphasize, as well as in the features of the problems or tasks chosen to elicit and support the shifts of attention that will help novice become expert.

As an analytic lens, we use the construct of awareness to interpret and analyse a mathematician's decisions and reflections regarding the values, opportunities, challenges, and tensions of teaching a problem-solving mathematics course with a focus on computational thinking. We focus in particular on our participant's awarenesses related to the taxonomy of computational thinking and practices developed by Weintrop et al. (2016) as they are associated with, or different from, mathematical thinking and practices more generally. In particular, we examine what our participant identified as valuable ways of knowing and practicing mathematics with computational applications, what opportunities were envisioned or provided, what challenges emerged, and what tensions were felt in terms of realizing those values and opportunities in the face of the emergent teaching and learning challenges.

Methodology

Our participant was an experienced and well-received mathematics instructor, whom we shall refer to as Dr. Y. Dr. Y has taught at the undergraduate level for over 25 years, and this was his third time teaching a course which emphasized computational thinking for mathematics problem solving. Since this research focuses on an in-depth qualitative analysis of an individual's experiences and decisions regarding teaching and learning, a case study approach (e.g., Stake, 2000; Yin, 1994) is appropriate. Data include field notes taken during the course by one of the researchers, personal reflections and instructional materials provided by Dr. Y, as well as unstructured interviews conducted at the completion of the course.

The course taught by Dr. Y was an undergraduate third year problem solving course for mathematics majors. The main objectives of the course included enriching students' existing content-based knowledge and enhancing their problem solving strategies and thinking. Classes were conducted in 50-minute blocks, and students spent the majority of class time working on problems, which they could choose to do individually or in small groups. The problems were chosen to elicit or provide different perspectives on material that was covered in other courses, as well as to stimulate reflection on various new and familiar ways of engaging in solving problems. Students were expected to discuss and justify their solutions with their peers and their instructor, and were required to present solutions to the class at various times throughout the semester. Weekly assignments were assessed, as well as two in-class tests and a final exam. As part of his description of the course, Dr. Y emphasized (and this was confirmed via field notes) that very little of class time was spent on lecturing. Dr. Y reported that lecturing was "done only to introduce a problem or a set of related problems, and provide context and motivation. Students realize that the problems are not in any way 'randomly' selected, but instead are tied to their previous knowledge and experiences."

Students in the course were described as "mathematically mature" – each had taken several second year courses, with experience working with theorems and proofs, and had "developed a critical attitude toward the level of rigour required of a proof". However, students' computer programming background varied widely: some had no programming experience beyond using one-line commands in Maple of Matlab, while others had taken computer science courses and / or had written programs in several languages. Dr. Y indicated that as of Fall 2016 this would change, as students will be required to complete a new programming requirement by the end of their second year. In this problem solving course, student learning objectives included "practicing math the way math researchers do" and "learning to write programs in Python and use them to investigate problems in math". At the time of this research, Dr. Y indicated that approximately 40% of class time and assessment was devoted to computational thinking, with an emphasis on the "basic building blocks" of coding such as conditional statements and loops. Detailed course objectives were co-constructed throughout the course as students discovered and developed an extensive list of strategies for problem solving.

Results and Analyses

We organize this section around our two research questions, addressing respectively:

1. Values and opportunities: we examine Dr. Y's perceptions via his choices in pedagogical structures, such as features and affordances of exemplar tasks, as well as his expressed motivations and intentions for course activities and objectives;
2. Challenges and tensions: we rely on field notes, reflections, and interview data to analyse Dr. Y's experiences enacting his teaching agenda within institutional constraints and in response to student feedback.

Values and opportunities

As previously mentioned, Dr. Y spent minimal class time lecturing students and the value he placed on providing opportunities for students to "discover" and "develop" were made explicit in course objectives. Exemplifying his *awareness-in-counsel*, he sought to foster students' powers in selecting and distinguishing problem-solving strategies (*awareness-in-action*) and to compel them to formalize this awareness via their articulation of (e.g.) which kinds of problems could be reformulated in such a way as to be solvable with programming (*awareness-in-discipline*). To this end, students encountered a variety of problems and tasks which required reformulation, and in the cases where the problems could be fruitfully solved through programming, students were required to use, assess, and design computational models for solving – features of the *modeling & simulation practices* described by Weintrop et al. (2016). One of the early examples of a programming activity to which students were exposed introduced the concept of a two-dimensional random walk and required students to construct a program which simulated N steps of the walk (start at the origin, and with equal chance move up, down, left, or right).

Dr. Y described some of his reasons for using this problem:

> "The problem itself is not so difficult. Most students have little or no problems writing and running the code. However, testing the code is a challenge, because there is a new element in it – randomness. Students are familiar with testing a 'deterministic' program, where they could predict the answer, run the program and see whether or not their answer agrees with the computer's answer. But how does one test a program whose output is based on randomness? This is more difficult. Visualization helps, trial and error, tinkering with the code… Eventually students have to figure out the distance between the initial and terminal points of a random walk with N steps, and then compute the average distance as the random walk is repeated many times. Now they can compare the average distance they obtained to a theoretical result, thus having a way of checking that their code is correct."

In this excerpt, we identify several points of interest. First we note Dr. Y's use of a "not so difficult" problem that increased in complexity through the practice of testing and verifying the code. Following Papert's (1980) lead, such a "low-floor / high-ceiling" approach requires minimal prerequisite knowledge yet offers opportunities to investigate more complex ideas, practices, and relationships. Referring to Weintrop et al.'s (2016) taxonomy, we note opportunities for students to develop *computational problem solving practices*, such as preparing problems for computational solutions ("writing and running the code"), assessing different approaches / solutions ("testing the code"), and troubleshooting and debugging ("tinkering with the code"). We interpret the selection of this problem as an instantiation of Dr. Y's *awareness-in-counsel*, namely, the sensitivities required to direct novice students' attention toward complex computational practices required for disciplinary expertise. A second point of interest is Dr. Y's acknowledgement of the complexities associated with random systems, and the role of visualization in helping to attain a theoretical result. Randomness can be challenging for mathematics learners to address, and novice strategies for dealing with randomness have included various ways of reducing its level of abstraction (e.g., Chernoff & Mamolo, 2015). By contextualizing questions related to randomness within computational thinking, students may be provided with scaffolding for developing abstract reasoning – the tangible feedback given by the program they construct, test and adapt offers insight that may not be readily perceived in other contexts. Similarly, the insights gained through the practice of visualization have been linked to conceptual development in higher mathematics (e.g., Tall, 2007), as well as achievement and understanding (e.g., Koehdinger, 1992). A final point we note is the connection, within this task, of mathematical disciplinary practices and content and computational practices. The computational practices support mathematical ones and facilitate the development of mathematical content, while the act of verifying that students' code is correct highlights an important difference between the two disciplines and their practices – specifically, as Dr. Y put it, that "providing evidence that a computer code is correct is different than a formal math proof!"

Challenges and Tensions

With respect to institutional constraints, some challenges were already mentioned – the diversity in students' prior programming experience, the scheduling of three short classes per week, as well as the size of the course. The course runs with 30-40 students in a regular classroom (rather than a computer lab), and students are required to bring their own portable devices in order to engage with class activities – while most students brought notebook computers, some tried to work on their phones and others had no devices. A few of the observed challenges included syntactical differences in Python depending on what operating system was in use – for instance, the tab function will work for indenting in iOS but yields an error in Windows. While not a major concern, such discrepancies needed to be negotiated during students' peer-peer interactions and work. A more significant issue that emerged occurred when students either did not own, or did not bring, their own portable computer. This led to group work that positioned some students at the periphery, while others were central to the activity. Dr. Y expressed frustration at this imbalance, and noted that "students who watched someone else type and work on screen seemed to learn less, and were less confident in their coding." This was a particular challenge during problem-solving activities wherein students would go straight to on-screen programming solutions, without preliminary discussion or paper-work, making it difficult for other students (and the instructor) to follow their thinking. Dr. Y also noted that the 50-minute classes were not ideal for his pedagogical approach. The time limit constrained the types of problems selected for the course, stemmed peer-peer discussions, and inconvenienced students – Dr. Y remarked: "just as students get in the ‘zone’ [problem-solving zone] tackling some rich mathematics, the class ends and they’re off to biology or physics or something completely different.” Watson (2008) has touted the importance of extended experiences with mathematics, noting that it is more difficult to learn the subject when attention is constantly shifting from one task to another. We see this as particularly relevant for computational thinking in mathematics problem solving, as the added need to reformulate a question in programming terms and to coordinate theoretical and computational solutions may require additional time, especially for inexperienced learners. In reflecting on these issues, Dr. Y’s attention seemed to shift from acknowledging the constraints to posing questions around how to better navigate them, suggesting a broadening of his *awareness-in-counsel*. He raised questions around how to construct appropriate activities that include programming and which could be meaningfully tackled given the aforementioned constraints of time, class-size, and student access to computing devices.

A notable tension that emerged for Dr. Y concerned the use of group work and how this impacted ways in which he was able to fairly assess students. He noted that previous offerings of the course had relied primarily on take-home assignments that could be completed in groups, but were to be submitted individually. Dr. Y noted “in a problem-solving course, it makes sense to assess problem-solving and it’s difficult to do that in a midterm or exam.” However, concerns emerged: “most students were handing in perfect, or near-perfect, solutions, often very similar to their peers’ solutions, and yet different from the kinds of work they were producing and presenting in class. It was obvious that they did not take the course requirements seriously.” In addition, Dr. Y identified challenges in assessing programming-based problem solving as “when students work on-screen, usually overwriting the code, it’s hard to follow their thinking.” As a result, Dr. Y introduced a significant in-class assessment component comprised of tests and exam, and accounting for 80% of the course grade. Dr. Y lamented, “I’m not sure what else to do.”

Concluding Remarks

Despite the tensions and challenges which emerged, Dr. Y’s perceptions of the role of computational thinking in and for undergraduate mathematics were positive. Dr. Y reflected:

> “Very often, when we teach math, we ‘forget’ how results, theorems, or definitions have been arrived at. We present a proof, but rarely talk about how it was constructed, and in particular, we don’t talk about failed attempts! By attempting to solve a problem, students experience some of that essential process of creating mathematics. By writing a computer program, they can engage in rich mathematics, develop important habits of mind, and produce something tangible in the end”

Dr. Y plans to increase the emphasis on computational thinking in future instances of the course, and we plan to extend this research following him through changes inspired by the shifts of attention and broadening of awarenesses that occurred during the course of this study. With a growing emphasis on computational applications of mathematics, both in industry and education, there is a need to better understand the role that mathematics courses can play in fostering computational thinking. Attention toward how the broad array of computational practices for mathematics may be developed is needed, particularly for those practices which closely relate to the mathematical habits of mind necessary for disciplinary expertise. Yadav et al. (2014) noted that fewer than 15% of the pre-service teachers surveyed recognized critical thinking as part of computational thinking, and fewer than 10% viewed computational thinking as helpful in understanding the “why” behind problems, suggesting work is needed to raise awareness of what is computational thinking (in and of itself, as well as in connection to mathematics) and what are fruitful learning experiences for students.

"Explanatory" Talk in Mathematics Research Papers

Juan Pablo Mejía-Ramos
Rutgers University

Matthew Inglis
Loughborough University

In this paper we explore the ways in which mathematicians talk about explanation in their research papers. We analyze the use of the words explain/explanation (and various related words) in a large corpus of text containing research papers in both mathematics and physical sciences. We found that mathematicians do not frequently use this family of words and that their use is considerably more prevalent in physics papers than in mathematics papers. In particular, we found that physicists talk about explaining why disproportionately more often than mathematicians. We discuss some possible accounts for these differences.

Key words: corpus linguistics, mathematical language, mathematical explanation.

The notion of explanation in mathematics has received a lot of attention in both mathematics education and the philosophy of mathematics. In mathematics education, scholars have been particularly interested in proofs that explain mathematical theorems (i.e. proofs that provide an insight into why a mathematical claim is true) and their role in the mathematics classroom (e.g. Hanna, 1990). Philosophers of mathematics have discussed at length possible equivalents for mathematics of existing philosophical theories of scientific explanation (e.g. Steiner, 1978). Some of these discussions bring to bear the extent to which explanation is relevant to the actual practice of mathematicians and often cite individual mathematicians' views on mathematical explanation (more often than not that mathematician seems to be Henri Poincaré, Paul Halmos, or William Thurston). In this report we explore the extent to which mathematicians talk about explanation in their research papers, and the ways in which they do so.

Literature review

In an influential paper in mathematics education, de Villiers (1990) argued that proof serves several different roles in mathematics, that proof is not only used in mathematics as a way to verify results, to provide conviction of the truth of those results (see also Bell, 1976). One of those other functions of proof was to *explain* mathematical results, to provide an insight or understanding into why these results were true, as opposed to just evidence in support of that result. Hanna (1990) made a similar distinction in the context of the teaching and learning of mathematics, discussing the idea that certain proofs fulfilled this explanatory function better than others, to the point that among the set of all proofs one could identify proofs that explain why a theorem is true, while others simply demonstrate that a theorem is true. Mathematics educators have generally suggested that in the mathematics classroom, mathematical explanation should be an important, if not the primary role of proof (de Villiers, 1990; Hanna, 1990; Hersh, 1993).

This distinction between proofs that explain and proofs that demonstrate has a longer history in the philosophy of mathematics. Steiner (1978) put forward a model of mathematical explanation, arguing that a mathematical proof could be better defined in terms of what he called *a characterizing property* of a concept in the theorem, as opposed to other alternative defining characteristics such as the abstractness or the generality of the proof. Steiner's top-down approach to modeling mathematical explanation by providing a general definition of explanatory proof (and thus creating an absolute distinction between explanatory and non-explanatory proofs) has been criticized by other philosophers of mathematics. In particular, Hafner and Mancosu (2005) argued that ascribing explanatoriness to specific proofs should be done based on practicing mathematicians' evaluations, not philosophers' own intuitions (such as Steiner's). The extent to which practicing mathematicians not only agree with philosophers' characterization of mathematical explanation, but simply talk about explanation in their practice plays an important role in the general argument for the *existence* of explanation in mathematics (which not all philosophers believe). As such, it is not uncommon for a discussion of mathematical explanation to mention how much mathematicians talk about it. For example, Steiner claimed that "mathematicians routinely distinguish proofs that merely demonstrate from proofs which explain" (p.135), and Hafner and Mancosu (2005) supported their claim that mathematicians seek and value explanation in mathematics by presenting several examples of what they called *"explanatory" talk* in mathematical practice: passages of research mathematics papers in which the authors explicitly discuss the role of explanation in their own work. However, we do not currently have empirical evidence, other than these small selections of introspective accounts, about the extent to which talk about mathematical explanation is part of mathematical discourse. We believe one of the reasons this has not been studied at a larger scale may be methodological: a researcher would have to be able to process and analyze a large number of mathematical research papers or conversations among mathematicians.

One method of studying mathematical discourse at such a scale is to use the techniques of corpus linguistics, a branch of linguistics that statistically investigates large collections of naturally occurring text, known as corpora. Methods developed by corpus linguists can be used to investigate many different types of linguistic questions. Here, we report a study that employs some of these techniques to address the following questions: to what extent do mathematicians discuss explanation in their research papers, how does it compare to the extent to which they discuss other important related notions (such as *showing* or *proving* given mathematical results), and how does it compare to discussions about explanation in other types of scientific discourse?

Theoretical perspective

Discussions about mathematical explanation tend to differentiate between explanations of other mathematics (i.e. mathematics X explains mathematics Y, or X is an explanatory proof of theorem Y), and explanations of physical phenomena (i.e. mathematics X explains physical phenomenon Y). Colyvan (2011) refers to these two types of explanation as *intra-mathematical* and *extra-mathematical*, respectively. Here we focus on intra-mathematical explanations.

Hafner and Mancosu (2005) further differentiated between two uses of intra-mathematical explanations: those that are "instructions" on how to master the tools of the trade (as in explaining how to employ a certain mathematical technique), and those that "call for an account of the mathematical facts themselves, the reason why" (p. 217). While Hafner and Mancosu considered the latter to be a "deeper" use of mathematical explanation, which is also the focus of the larger philosophical discussion around explanatory proofs, others have emphasized the importance of the former type of explanation in mathematical practice. For instance, Rav (1999) insisted that one of the main reasons mathematicians read proofs is because of all the mathematical know-how embedded in them, emphasizing the mathematical methodologies and problem solving strategies/techniques contained in proofs. According to Rav, "proofs are for the mathematician what experimental procedures are for the experimental scientist: in studying them one learns of new ideas, new concepts, new strategies—devices which can be assimilated for one's own research and be further developed." (p. 20) Indeed, there is empirical evidence (from both small scale interview studies and large scale surveys) that mathematicians maintain that one of the main reasons they read proofs is to gain insights into how they can solve problems that they are working on (Weber & Mejía-Ramos, 2011, Mejía-Ramos & Weber, 2014).

An interesting question related to the specific ways in which mathematicians talk about explanation in their papers, relates to these two types of *"explanatory" talk*: to what extent do mathematicians discuss explanations of why a certain mathematical statement is true, compared to their talk about explanations of how to do something in mathematics?

Methods

One of the main ways in which mathematicians around the world communicate about mathematics is through research papers stored in the ArXiv. The ArXiv is an online repository of electronic preprints of scientific papers in the fields of mathematics, physics, astronomy, computer science, quantitative biology, quantitative finance, and statistics. These papers constitute a large corpus of scientific text that can be used to analyze mathematical discourse.

We downloaded the bulk source files (mostly TeX/LaTeX) and converted the source code to plain text, which we could then analyze using standard software packages for corpus analysis. We then sorted these articles based on their primary and secondary subject classification (Alcock et al., 2017, discussed the details about the processing of these source files). All analyses reported here are based on a proper subset of this corpus, containing all mathematics and physics articles (based on their primary subject classification) uploaded in the first four months of 2009. This left us with 6988 mathematics papers (30,892,695 words) and 14861 physics papers (58,859,660 words).

Results

Frequency of explicit *"explanatory" talk* in mathematics papers

Table 1 shows the frequencies of all words linguistically related to the word *explain* (henceforth *explain-words*) in our corpus of 6988 mathematics papers. Explain-words showed up 4871 times in this set of papers, or approximately once every 1.4 papers. While this certainly provides an existence proof of explicit *"explanatory" talk* in this corpus, it is not very surprising (it would very rare if no word based on the word explain showed up in these many mathematics papers). In order to get a sense of the extent to which these frequencies were high or low in this type of mathematical discourse, we compared them against the frequencies of words related to other important mathematical activities.

Tables 2 presents the frequencies of words linguistically related to the notions of showing, solving, and proving, which were chosen based on their relevance in mathematical explanation. Measured against these other frequencies, mathematicians used explain-words rather infrequently. Indeed, mathematicians used explain-words in their papers approximately 11 times less frequently than show-words or solve-words and nearly 23 times less often than prove-words.

One possibility is that explain-words are simply not used much in this kind of scientific discourse in general. Thus, even though the importance of scientific explanation is so obvious that it does not need to be justified by looking at *"explanatory" talk* in science, it could be the case that this type of talk is not that common in scientific research papers either. In order to test this hypothesis we studied the use of explain-words in the 14861 physics papers in our corpus (Table 3). Explain-words showed up 21305 times in this set of papers, approximately once every 0.7 papers, or twice as often as they showed up in the mathematics papers. Thus, based on the comparison of the use of explain-words in mathematics and physics papers, it seems that mathematicians discussed explanations more infrequently than physicists.

Table 3. Frequency of words related to *explanation* appearing in the physics papers

Finally, the search for explain-words may be thought of as requiring an extremely explicit discussion of explanation, one that would leave unnoticed a significant amount of the *"explanatory" talk* in these papers. Hafner and Mancosu (2005) offered a list of eight expressions that they had found to be commonly used in the mathematics and philosophy of mathematics literature to describe the search for explanations. Table 4 presents these expressions along with the specific concordance search we made to investigate their prevalence in both the mathematics and physics papers, and the frequencies with which these alternative expressions appeared. We note that the total number of occurrences of these expressions is only about 10% of the total amount of explain-words in each set of papers (with disproportionately more occurrences of these expressions in the physics papers than the mathematics ones) and thus this analysis does not affect the finding made by only investigating the use of explain-words.

Alternative expression	Concordance search	Mathematics	Physics
"the deep reasons"	deep* reason*	5	16
"an understanding of the essence"	understand* the essence	0	5
"a better understanding"	better understand*	161	767
"a satisfying reason"	satisfy* reason	0	0
"the reason why"	reason* why	312	924
"the true reason"	true reason	3	1
"an account of the fact"	an account of the fact	0	0
"the causes of"	cause* of	16	609
	Total	497	2322

Table 4. Frequencies of alternative expressions of related to *"explanatory" talk*

Explaining why vs. explaining how

In order to investigate mathematicians' discussion of *explanations of why* a certain mathematical statement is true (Hafner and Mancosu's "deep" explanation), in comparison to their talk about *explanations of how* to do something in mathematics (related to Rav's notion of mathematical know-how), we created a concordance of the corpus of papers and identified every instance an explain-word had been immediately followed by the words why or how (e.g.

unexplained why, explanation how). We did this by searching the concordance for *expla* why and *expla* how, and checking that all results were indeed uses of explain-words. We then repeated the process with the corpus of physics papers. As, shown in Table 5, there is a clear difference between the ways that explain-words show up in the mathematics and the physics research papers.

	Mathematics	Physics
expla why	247	952
expla how	458	353
Total	705	1305

Table 5. Frequencies of explain-words immediately followed by the words *why* or *how* in the mathematics and physics research papers

We note that when taken together the total of *expla*-why and *expla*-how expressions were roughly as common in math papers as they were in physics papers, with approximately one of these expressions showing up every 10-11 papers in the corresponding set, and also a relatively small subset of the wider use of explain-words (roughly 14% and 6% of explain-word usage in mathematics and physics, respectively). However, the distribution of these two different types of expressions in the two sets of papers was significantly different (Fisher's exact test, $p < .001$), with mathematicians using nearly twice as many *expla*-how expressions than *expla*-why expressions, and physicists on the other hand using a little under three times as many *expla*-why expressions than *expla*-how expressions.

Discussion

Our analysis of *"explanatory" talk* in a large sample of mathematics papers does not offer support for a claim often made in the philosophy of mathematics: that this type of talk is prevalent in mathematical discourse. When compared to explicit discussion of other related mathematical practices (showing results, solving problems, and proving theorems), mathematicians do not seem to discuss explanation nearly as much. Furthermore, when compared to another scientific discourse, we found that mathematical discourse contains only a fraction of *"explanatory" talk* as research papers in physics. Indeed, we believe these findings suggest that the prevalence of *"explanatory" talk* in mathematical discourse has been widely exaggerated.

Furthermore, by analyzing the frequency with which variations of the expressions *explain why* and *explain how* occur in mathematics and physics research papers, we found that, to the extent to which they engage in *"explanatory" talk*, mathematicians seem to be much more interested in discussing explanations of how to do something in mathematics, than in explanations of why things are the way they are in mathematics. In physics we found the situation to be the opposite. This is particularly interesting given mathematics educators' and philosophers' of mathematics preoccupation with the type of intra-mathematical explanations of the form X explains why Y (where X and Y are mathematical assertions), and particularly with the notion of explanatory proofs (in which proof X explains why theorem Y is true). This focus may have been inherited from the more traditional study of the notion of scientific explanation, which is not only naturally concerned with this type of explanations (the desire to explain the real world is full of why-questions), but according to our findings may also be more commonly discussed in scientific discourse in terms of answers to why-questions. However, our findings suggest that this focus may also be misguided for those interested in studying the notion of mathematical explanation as it more commonly occurs in the discourse of professional mathematicians. Indeed, as suggested by Rav (1999), it seems that when it comes to proofs and explanations, mathematicians are primarily interested in learning how to solve other problems, possibly over learning the reasons why some mathematical results hold true.

Now, one must be careful about several inferential jumps made in this kind of analysis. First, while the ArXiv may well be the largest, most widely used repository of this type of preprints and postprints in the world, we have analyzed a very specific type of mathematical discourse, leaving open the possibility that studies of mathematical discourse in others settings (conversational or other digital communications) could lead to contrasting findings. Second, we have analyzed these research papers for a limited type of *"explanatory" talk*, one required to contain explain-words or a limited number of alternative, related expressions. While this was an obvious place to start to investigate *"explanatory" talk* in mathematical discourse, it is certainly possible that the analysis of other expressions related to mathematical explanation may skew our results. These limitations of the present study indicate clear avenues for future empirical research on mathematical explanation.

Managing Tensions Within a Coordinated Inquiry-Based Learning Linear Algebra Course: The Role of Worksheets

Vilma Mesa, Mollee Shultz, Ashley Jackson

How do nine instructors teaching a linear algebra course at a research university manage tensions that emerge because of the requirement of teaching the course with an Inquiry-Based Learning approach within a coordinated system? Using Herbst's practical rationality framework (Chazan, Herbst, & Clark, 2016; Herbst & Chazan, 2011) we identify features of the course organization that contributed to tensions between professional obligations that were resolved via the production of worksheets that teachers gave to the students. We noted differences in how these tensions were handled, and provide some evidence that such differences might be related to the research orientation the instructors brought and to their status in the institution. We formulate some hypotheses that can shed light on how to assist in changing post-secondary instructional practices.

Key words: Linear algebra, Inquiry-Based Learning, Professional Obligations

Objectives

Promoting change in instructional practices in undergraduate mathematics education has been an important concern for over three decades. The calculus reform from the 80s and 90s resulted in key changes to the calculus curriculum, more prominently by bringing more contextualized and representation-rich problems that could capitalize on new hand held technologies (Douglas, 1986; Ganter, 1999; Harver, 1998). Federal support for calculus innovation through grants by the National Science Foundation increased as these were seen as a vehicle for making science, technology, engineering, and mathematics (STEM) fields more appealing to students. The need for instructional change was fueled by reports that mathematics teaching was one of the main reasons why students left STEM fields (Seymour, 1995, 2002; Seymour & Hewitt, 1997). Women in particular indicated feeling unwelcome in science and mathematics courses.

Changing instructional practices is a difficult enterprise, however, as documented by decades of research in teacher training in the K-12 system and as noted by Henderson, Beach, and Finkelstein's (2011) seminal literature review on change strategies in undergraduate STEM education. Henderson and colleagues noted that part of the problem relies on the change strategy that institutions use. They note that "developing and testing 'best practice' curricular materials and then making these materials available to other faculty" (p. 952) is ineffective in generating the anticipated change that would happen because of the availability of new materials and documents. They also noted that the second typical approach, "'top-down' policy-making meant to influence instructional practices" (p. 952) is equally ineffective as it generates arguments that usually threaten and affect collegiality so necessary for departments to function well. They note instead that the most effective strategies are aligned with or seek to change the beliefs of the individuals by involving them over a long-term process that promotes an understanding a college or university as a complex system, thus making the changes to be fully compatible with the given environment.

What happens when such approach to change is implemented in a department? This study contributes to answering that question by documenting the tensions that emerged as a department chose to implement inquiry-based learning methods (IBL) of instruction in a linear algebra course that involved about 300 students and 11 instructors. IBL is an approach that "invites students to work out ill-structured but meaningful problems… [and] construct, analyze, and critique arguments… present and discuss solutions alone at the board or via structured small-group work, while instructors guide and monitor this process" (Laursen, Hassi, Kogan, & Weston, 2014, p. 407). We followed the implementation with two goals in mind: first, to understand how the faculty operationalized teaching with inquiry-based learning methods and second, to document and understand how they managed the need to cover the prescribed content allowing at the same time free exploration of the ideas to comply with the spirit of IBL. Having information about what happens when a department seeks to institute teaching changes in a key mathematics course such as linear algebra is informative for departments interested in pursuing similar moves. This study primarily contributes to the literature on teaching change in undergraduate settings.

Theoretical framework

We assume that teaching and learning are phenomena that occur among people enacting different roles—those of teacher or students—aided by particular resources, and constrained by specific institutional requirements. We are neither concerned with the knowledge, beliefs, or attitudes of the individual teacher who enacts a particular instructional approach nor with the knowledge, beliefs, or attitudes of the students of those teachers. Rather, we seek to understand how the people in these roles navigate their obligations as teachers and students to ensure that the purposes for which they are gathered together are fulfilled.

Herbst and colleages (Chazan, Herbst, & Clark, 2016; Herbst & Chazan, 2011), using the notion of *practical rationality*, have proposed that teachers respond to four distinct professional obligations while teaching and that some of these create tensions that put teachers in a double-bind as they make decisions in the classroom. In this study we attended to the disciplinary and the institutional obligations. The disciplinary obligation refers to the expectation that teachers will represent the knowledge and practice of mathematics appropriately (e.g., precise ideas, correct language). This may include the responsibility of checking the mathematical quality of tasks, textbooks, or other resources provided to students. The institutional obligation refers to the expectation that teachers will fulfill their role as a part of larger organizations (e.g. the department, university, etc.). It involves following regimes such as official pedagogies, policies, and assessment that exist independently of teachers' individual preferences. Thus the obligation to a given course's curriculum is a manifestation of the institutional obligation, while the disciplinary obligation can "oversee[s] and question[s] the quality of the representation of the discipline offered by the curriculum" (p. 1067). We describe key tensions within the IBL linear algebra course as a clash between these two obligations precisely because of the need to teach the course using IBL.

Methods

This qualitative study took place in a coordinated linear algebra course of 11 sections taught at a research university. Two major goals for the course are stated in the syllabus as: "to learn linear algebra and to learn how to write a rigorous mathematical proof. Students should leave this course prepared to use linear algebra as well as to succeed in further theoretical courses in mathematics." The syllabus also states that the course is difficult and names two alternative courses offered to those interested in the "computational side of linear algebra."

Participants in the study were all the nine faculty members who taught the course in Fall 2015 at this university. The participants included four post-doctoral fellows, four tenured faculty, and one tier-three lecturer. Instructors were further classified as applied or non-applied mathematicians based on their background and current research interests. There were four applied (Bethany, Ed, Henry, and Miles[1]), four non-applied (Laura, Lewis, Thomas, and Ulrich), and one self-described non-applied mathematician with research interests in applied fields. Three of the instructors (Bethany, Ed, and Henry) had taught the course in the year immediately before the semester in which we collected the data and had developed enough material for the course; three instructors (Ed, Laura, and Lewis) taught the course in the semester following the data collection term (See Table 1).

Table 1: Characteristics of study participants.

Participant	Status	Research	Terms teaching Linear Algebra with IBL
Bethany	Post-doc	Applied	Winter 2015, Fall 2015
Ed	Post-doc	Applied	Winter 2015, Fall 2015, Winter 2016
Henry	Clinical faculty	Applied	Winter 2015, Fall 2015
Laura	Tenured faculty	Non applied	Fall 2015, Winter 2016
Lewis	Tenured faculty	Non applied	Fall 2015
Miles	Post-doc	Applied	Fall 2015, Winter 2016
Monica	Tenured faculty	Both	Fall 2015
Thomas	Tenured faculty	Non applied	Fall 2015
Ulrich	Post-doc	Non applied	Fall 2015

We collected several types of data: interviews with instructors, field notes from about half of the course planning meetings, observations and focus groups with students, instructor and student surveys on instructional practices, bi-weekly logs about the course from some of the faculty, and various documents: the textbook, the pacing chart, worksheets, quizzes, syllabus, and exams. We analyzed the interviews thematically by question, seeking to identify threads that were relevant to the institutional and disciplinary obligations that instructors responded to. We performed an analysis of the textbook to identify the elements that were more prominently discussed during planning meetings contrasting its content with the content present in a non-IBL textbook. We created a matrix with initial assertions, identifying the faculty to which the assertion applied to and the different sources that corroborated the assertion, in this way engaging in a cross-case analysis and triangulation of the data sources.

In order to corroborate our interpretations, we sent a summary of our findings to our participants so that they could verify or rectify what we have found. Three of eight participants (Bethany, Henry, and Laura) responded making specific suggestions about the textbook analysis (part of a longer version of this paper) and corrected some factual information regarding the context of the course. Given their comments and who responded we have reason to believe that our interpretations accurately reflect the situation that we are about to describe.

There are two limitations to our study. First, we are still in the process of collecting student performance data. As of now, we have data from focus groups on student perceptions of how IBL supported their learning, but we do not have access to student final grades in the course or in subsequent courses. Thus, although we could talk about impact of the change we are in no position to do so. Additionally, this study seeks only to document processes of change not the impact of the change on students. The students were quite satisfied with the learning they were experiencing, but self-report data is hardly sufficient as a tool to convince administration of the appropriateness of a programmatic instructional change. In a subsequent phase we plan to perform a historical analysis of data to study impact of the implementation

[1] Names are pseudonyms.

of IBL. Second, the first and third authors were involved as evaluators in a training grant that involved the participating faculty. The goal of the grant was to increase the number of undergraduate students in the lower division courses experiencing IBL. As evaluators, their role was to document how the IBL training strategies were deployed and to assess which ones were perceived by the faculty as beneficial in helping them understand how to teach with IBL. As such, some of the data collected sought to providing feedback to faculty rather than provide data for our research questions. For that reason, data related to faculty feedback (observations and focus groups) play a secondary, albeit important role, that of triangulation, in this analysis.

Results

The department had put in place a number of mechanisms to ensure that all the students in the 11 sections of the course were exposed to similar content and experiences. These mechanisms came in the form of the pacing chart, that indicated the sections of the textbook to cover each day; the textbook itself that students had to use to do their daily reading quiz and that instructors should use to design worksheets; the homework, which was the same for all students in the course; and the exams (two midterms and a final) which were also common and graded with a common rubric. Two tensions emerged from the need to fulfill the obligations while adhering to those mechanisms._The first tension expressed itself through complaints regarding the presentation of content in the textbook required by the department that differed from what some faculty thought should be the definitions that should be used, an evidence of their allegiance, or obligation towards upholding the knowledge in the discipline. This tension is especially interesting to observe in an IBL setting because instructors distribute supplementary material in the form of worksheets where they can choose to support or deviate from the textbook.

The second tension emerged from the two explicitly stated goals of the course, "to learn linear algebra and to learn how to write a rigorous mathematical proof" and what instructors saw was the best way to approach the linear algebra content, either by exemplifying notions through concrete examples that then get formalized or by starting with definitions that are then exemplified with concrete examples. We saw the faculty resolving this tension in their worksheet production by either emphasizing applications of concepts or by increasing the level of abstraction and development of mathematical theory. We believe that their choices were related to their research interests. We expand on the first tension here.

According to Henry, the selection of Brestcher as the textbook for the course was predicated on the desire to choose a book that helped develop intuition. This was the book he felt students could best learn from. Henry chose the textbook after reviewing various options and, after having given it "a try," found it sufficiently readable and usable by the students. His perception was that the problems were "decent" and sufficient for helping students develop the needed intuitive understanding of linear algebra ideas, despite its shortcomings regarding the definitions used for linear independence and linear transformations, and the particular ordering of the chapters. During the first semester in which all the sections used IBL with Bretscher the faculty heatedly discussed these shortcomings during the weekly course planning meetings.

Confirming those discussions, the interviews with faculty suggested that nearly all instructors (7 out of 9) recognized problems with the mathematics in the required textbook (e.g., "This book is almost like not having a book. It has good problems and historical treatment, but doesn't have the definitions that mathematicians use," Thomas). Instructors with applied backgrounds handled this problem differently than instructors with non-applied background. The former group sought to maintain consistency of content and pacing across the different sections of the course, making an effort to align the content with the required readings. For example, Bethany, a professor with an applied background, said,

> A lot of it came down to how much we should rely on the book versus how much you should rely on what you think is convention. From my perspective, this is the book that students read, and we should try our best to provide them a consistent picture. I'll sacrifice nonstandard definitions for the sake of that consistency.

Similarly, Ed said that once the textbook is chosen, he sticks to it even if it is not ideal. He figured he could be creative with the worksheets and be more rigorous if he wanted to. He also said that Bretscher's definitions (e.g., linear transformations) were good for conceptual understanding but not for theory. Henry, who choose the textbook for the course, was also an applied mathematician. In contrast, faculty with a non-applied background prioritized mathematical development. Lewis did not require students to read the book because he was unhappy with the sequence of topics: "The book was awful on many counts, even their definitions were suspect." Monica, while unhappy with the textbook, did not deviate from it. She said, "Certain things were in the wrong order," for example, the way the book introduced vector spaces. She liked the use of examples to develop students' intuition, "...but then the book stays with the example of $\mathbf{R}^n$ and if that's the first time you hear about a vector space, which is really an abstract concept, …it does harm [if] that's all we know." Like Ed, she found the worksheets to be a place that she could supplement the book. She tried to build an abstract conception of vector spaces and general structures in class and in the worksheets and also through lectures in parallel to the textbook's examples in $\mathbf{R}^n$.

Henry and Lewis wrote the original worksheets that were used by most of the instructors: Bethany, Ed, and Miles used and revised Henry's worksheets while Thomas and Laura used or referred to Lewis'. We noted that the first group includes all instructors with applied background, while the second group includes faculty with non-applied background. Henry's worksheet (Figure 1) from the section on subspaces of $\mathbf{R}^n$, bases, and linear independence (section 3.2) contains exercises that use of the term *redundant*, a term introduced by Bretscher (2013, p.125) to create an intuitive build-up to linear independence. However, the worksheet also contains a problem that walks students through a proof using the standard definition of linear independence.[2] Lewis's worksheet (Figure 2) on linear transformations (sections 2.1 and 2.2) begins, "Our definition will be a bit different than the one in the book but you will see that it is equivalent to the definition in the book." His worksheet on linear independence, bases, spanning sets, and basis (section 3.2) begins with the standard definition of *linear independence*, *span*, and a *basis*, and briefly mentions *redundant* in his "Something to think about" section at the end of the worksheet. Thus, Henry started with the book's definition and related it to the standard definition, while Lewis started with the standard definitions and related them back to the textbook.

[2] A subset S of a vector space V is called **linearly dependent** if there exists a finite number of distinct vectors $u_1, \ldots, u_n$ in S and scalars $a_1, \ldots, a_n$, not all zero, such that $a_1u_1 + a_2u_2 + \cdots + a_nu_n = 0$. In this case we also say that the vectors of S are linearly dependent. A subset S of a vector space V that is not linearly dependent is called **linearly independent**. As before, we also say that the vectors of S are linearly independent (Friedberg, Insel, & Spence, 2002, p. 36-37).

3. More fun with linear independence!

   (a) Are the vectors $\vec{v}_1 = \begin{bmatrix}1 & 0 & 0 & -2\end{bmatrix}^T$ and $\vec{v}_2 = \begin{bmatrix}1 & 1 & 0 & 0\end{bmatrix}^T$ linearly independent? Why or why not?

   (b) Now, consider the five vectors $\vec{v}_1 = \begin{bmatrix}1 & 0 & 0 & -2\end{bmatrix}^T$ and $\vec{v}_2 = \begin{bmatrix}1 & 1 & 0 & 0\end{bmatrix}^T$, $\vec{v}_3 = \begin{bmatrix}-1 & 0 & 1 & 0\end{bmatrix}^T$, $\vec{v}_4 = \begin{bmatrix}-2 & 2 & 3 & 4\end{bmatrix}^T$ and $\vec{v}_5 = \begin{bmatrix}0 & 0 & 0 & 1\end{bmatrix}^T$. Which is the first redundant vector? Write it as a linear combination of the preceding vectors.

   (c) Write a nontrivial linear relation among $\vec{v}_1$, $\vec{v}_2$, $\vec{v}_3$, $\vec{v}_4$, and $\vec{v}_5$. *(Hint: your work in (b) has the outside chance of being useful.)*

4. Wasn't that fun? What fun thing should we do next? Let's suppose we have a set of vectors $\vec{v}_1, \vec{v}_2, \ldots, \vec{v}_m$.

   (a) If $m = 5$ and we know that we have the linear relation

   $$-\vec{v}_1 + 2\,\vec{v}_2 + 3\,\vec{v}_3 - \vec{v}_4 + 0\,\vec{v}_5 = 0,$$

   explain why $\{\vec{v}_1, \ldots, \vec{v}_5\}$ are linearly dependent (by identifying a redundant vector in the set).

   (b) Explain why the existence of a nontrivial linear relation $c_1\vec{v}_1 + \ldots + c_m\vec{v}_m = 0$ (nontrivial means that at least one $c_i \neq 0$), shows that there is a redundant vector, and hence that $\{\vec{v}_1, \ldots, \vec{v}_m\}$ are linearly dependent.

   (c) Conversely, if $\vec{v}_i$ is a redundant vector in the set $\{\vec{v}_1, \ldots, \vec{v}_m\}$, show that there is a nontrivial relation among the vectors in this set.

Figure 1. *Sample of Henry's worksheet from the section on subspaces.*

A *basis* of V is a collection of elements that is both *linearly independent* and a *spanning set.*

1. Decide if the following collection of vectors are a basis for $\mathbf{R}^3$. If not, say what property or properties fail.

   (a)
   $$\vec{v}_1 = \begin{bmatrix}1\\0\\1\end{bmatrix}, \quad \vec{v}_2 = \begin{bmatrix}0\\1\\1\end{bmatrix}.$$

   (b)
   $$\vec{v}_1 = \begin{bmatrix}1\\0\\1\end{bmatrix}, \quad \vec{v}_2 = \begin{bmatrix}0\\1\\1\end{bmatrix}, \quad \vec{v}_3 = \begin{bmatrix}2\\1\\3\end{bmatrix}.$$

   (c)
   $$\vec{v}_1 = \begin{bmatrix}1\\0\\1\end{bmatrix}, \quad \vec{v}_2 = \begin{bmatrix}0\\1\\1\end{bmatrix}, \quad \vec{v}_3 = \begin{bmatrix}2\\1\\2\end{bmatrix}.$$

   (d)
   $$\vec{v}_1 = \begin{bmatrix}1\\0\\1\end{bmatrix}, \quad \vec{v}_2 = \begin{bmatrix}0\\1\\1\end{bmatrix}, \quad \vec{v}_3 = \begin{bmatrix}2\\1\\2\end{bmatrix}, \vec{v}_4 = \begin{bmatrix}0\\1\\-1\end{bmatrix}$$

2. Let V be the set of vectors $\begin{bmatrix}x_1\\x_2\\x_3\end{bmatrix}$ in $\mathbf{R}^3$ satisfying the relation

   $$x_1 + 2x_2 - 4x_3 = 0.$$

   (a) Prove that V is a subspace of $\mathbf{R}^3$.
   (b) Find a basis for V.

Something to think about

Vector $\vec{v}$ in Bretscher's book was overheard saying "I hate being a redundant vector. If I was the zero vector, that would be okay. But if I'm redundant just because others were ahead of me in the line, then that's not fair!" Do you sympathize with vector $\vec{v}$?

Figure 2. *Sample of Lewis' worksheet from the section on subspaces.*

These examples illustrate the tension between the obligation to comply with the institutional requirement of using a textbook that will be consistently used across all sections of the course, and the disciplinary obligation to represent accurate mathematics when the goal is to foster proving and illustrate how instructors managed them through the writing of the worksheets, suggesting a possible explanation rooted on the research background of the instructors. This is speculative, as other factors (e.g., institutional status) might have played a role as well.

Discussion and Implications

The instructors were able to use the worksheets as a place to manage the tensions that arose from their institutional and disciplinary obligations. The instructors who were unhappy with the content of the textbook were able to provide supplementary material to their students that, in their opinion, displayed the mathematics more appropriately. In particular, we found instances where instructors preferred different yet equivalent definitions, and used the worksheets to connect them to the curriculum.

All the instructors expressed deep commitments to their students, which indicates that these decisions reflected their interest in student success. Research on how courses are designed can help the research community build knowledge on what speaks to faculty teaching students in STEM environments. The preliminary evidence from this investigation suggests that the tensions that can emerge as mathematics departments seek to increase the number of students experiencing new ways of teaching can be navigated via a coordination system that allows faculty some space for exerting their professional commitments.

Function Sameness to “Function” Meaning

Alison Mirin
Arizona State University

Exploring students’ conceptions of sameness is an avenue for exploring their understandings of the objects being compared. More specifically, finding what students think it means for functions to be identical can help us figure out what students think it means for something to be a function, since identity within a category (in this case the category of function) is inextricably tied to the defining aspect of that category. This paper has three primary aims: to illustrate the importance of using students’ assessments of sameness as a means to discover their concept images, to describe a particular student’s concept image of function and of function sameness, and to suggest that the math education research community develop a more refined understanding of a “process”(cf., Breidenbach, Dubinsky, Hawks, & Nichols, 1992) conception of function.

Key words: equivalence, function, concept image, sameness

I designed this study on function sameness with the following research question in mind:

(1) Which function representations do students view as representing identical functions?

However, my research motivations go beyond the stated research question at the service of the larger question:

(2) What do students think “function” means*?*

Questions 1 and 2 are inextricably linked. Finding what students think it means for functions to be the same can help us figure out what students think it means for something to be a function, since identity is inextricably tied to what something *is.* This paper uses a case study to illustrate the importance of using (1) to answer (2) and to suggest that the math education research community investigate what students with a process conception of function (cf., Breidenbach, Dubinsky, Hawks, & Nichols, 1992) view as representing the same process.

It was natural to adopt Tall & Vinner’s (1981) usage of *concept image* and *concept definition*, since these constructs capture the essence of my research question. Someone’s concept definition is the definition that he would give in words to that particular concept or string of words. A person’s concept image is anything he associates with a particular concept or string of words, including mental pictures, computational processes, and properties. I will use the term “concept image” interchangeably with “understanding,” “conception,” and “meaning.” We can reframe (1) as “what is a student’s concept image of sameness of function?” and (2) as “what is a student’s concept image of function?”.

As mathematicians, we view functions f and g to be *the same function* if and only if f and g have the same domain and $f(x)=g(x)$ for all values of x in the domain. A student, on the other hand, might have a different conception of function sameness. To a student, “f and g are the same function” might not mean the same thing as “$f=g$”; this would be unsurprising in light of the research that shows that students often view “=” as a command to calculate (Powell, 2012). I investigate what a student thinks it means for two representations of functions to be of the same function, disentangled from her assessment of whether or not “equals” means “the same as” in the case of function. In other words, I investigate a student's concept image of "function sameness," *not* her concept image of "function equality".

Research shows that many students have a weak conception of function (Bardini, Pierce, Vincent, & King, 2014; Breidenbach et al., 1992; Clement, 2001; DeMarois & Tall, 1996; Musgrave & Thompson, 2014; Oehrtman, Carlson & Thompson, 2008; Sfard, 1992; D. Tall & Bakar, 1992; Thompson, 1994; Vinner, 1983). For example, Clement (2001) shows that a high percentage of precalculus students fail at completing basic tasks in assessing whether particular relations are functions and impose incorrect conditions on what it means to be a function. In particular, several students classified a non-continuous relation (that happened to be a function) as a non-function on the grounds that it was non-continuous, even though when giving their concept definition of function, they did not mention continuity. The method that Clement (2001) uses to assess students' concept images is a common way of investigating students' concept image of "function"; several other researchers (e.g., Bardini et al., 2014; Breidenbach et al., 1992; Clement, 2001; Tall & Bakar, 1992; Sfard, 1992; Vinner, 1983; Vinner & Dreyfus, 1989) assess what students consider to be instances and non-instances of function. This method (of having students assess instances and non-instances of function) is useful because it helps researchers see beyond simply the student's stated definition of function.

Subject and Methods

I asked students to identify pairs of representations of functions as representing the same function or not. By finding what criteria students use to decide whether two functions are identical, we can begin to discern what students take functions to be, since the identity criteria for a class of things defines what those things are. Consider sets: if someone says that $\{2,3\}$ is not the same set as $\{3,2\}$, then we can infer that this person believes that a set is something more than simply a collection of objects. In the case of function, a student may hint that he thinks a function is simply an equation by indicating that different equations automatically indicate different functions. For example, Sfard (1988) describes how some students revealed their views of functions as computational processes when they refused to view the functions f and g defined on the natural numbers by $f(x)=x^2$ and $g(0)=0$, $g(x+1)=g(x)+2x+1$ as the same function, despite acknowledging that they output the same values.

The goal of my study, which takes the form of an hourlong semi-structured clinical interview, is to model the student's concept image of function sameness through a series of tasks and accompanying questions, with an eye toward assessing the student's concept image of function. The majority of the interview protocol consists of function comparison questions: the student is given two different descriptions or representations of possibly different functions and must determine if indeed these representations describe the same function. Four subjects were enrolled in the study, but here I discuss only one, Jane. At the time of interview, Jane was a senior microbiology major earning an A or a B in an upper-division transition-to-proof course.

Jane's Concept Images

Jane began the interview with a mathematically correct concept definition of function sameness, but she soon began to think that more conditions are necessary. Throughout the interview she talked about two possibilities for sameness: her original, mathematically correct notion, which she called "equivalence,"[1] and then something she considered an additional possible criterion for sameness that would create a narrower definition. Jane clarified that equivalence was necessary for sameness but perhaps not sufficient. She said that there is another possible criterion for sameness, which she described as sameness of mathematical processes. So, Jane considered two possible characterizations of sameness of functions: sameness as equivalence, and sameness of mathematical processes together with equivalence. Her notion of mathematical process sameness as a criterion for function sameness fits with her concept image of "function," which I will describe in detail later.

Jane's Concept Image of "Equivalence"

As early as Task 2, Jane coined her term "equivalence" and stated that it was necessary, but perhaps not sufficient, for sameness of functions:

Excerpt 1: Task 2: What does it mean for f and g to be the same function? I: Interviewer; J: Jane

I	What does it mean for f and g to be the same function?
J	I don't know if a math function being the same is the same as it being equivalent...what I mean by equivalent is that if every x I put in through this function gives me the same y as every x that I put in...like… if x-sub-1 corresponds to y-sub-1 here...if I can put x-sub 1 into either of these equations and always get the same y, I would say they are equivalent. I don't know if in math terms if they would be the same

As the interview progressed, it became clearer that Jane's notion of "equivalence" of functions was the mathematically correct conception of equality of functions. She continued to express that equivalence was necessary for sameness, articulating that the functions must have the same domain and must output the same value anytime they are given the same input. Whenever she could use equivalence to show that two functions were not the same, she did. For example, she argued that the functions defined by $f_1(x) = x^2/x$ $f_2(x) = x$ are not equivalent and hence not identical by virtue of having different domains, and she argued similarly for functions represented graphically (where one function was a subset of the other). Moreover, when asked to give examples of functions that are not the same and prove that they are not the same, she described pairs of functions that differ on particular values. Jane stressed that she knew that the functions were not the same due to differing on a particular input value. She used the language "input" and "output" and avoided "independent variable" and "dependent variable". For example, she described the function defined by $f(x+1) = (x+1)^2$ as at least equivalent to $g(x) = x^2$ because "the $g(5)$ here it's still like, if you are gonna graph it and you get to 5, either way you are still going to get (5,25), so ... if you could always put the same input in and get the same output. If there's the same relationship between the points, I would say they are equivalent."

Jane's Concept Image of Sameness of Mathematical Process

[1] I use "equivalence" to refer to what Jane calls "equivalence," which is (in the case of function) what mathematicians would call "sameness".

As mentioned earlier, Jane thought that it was possible that there was more to sameness than "equivalence". In several instances in the interview, she described why two equivalent functions would not be the same, if in fact equivalence is not sufficient for sameness. She referred to this extra criterion as "the same mathematical process" and designated examples and non-examples of this criterion. In the remainder of this paper I discuss Jane's notion of sameness under her hypothetical assumption that equivalence is not a sufficient criterion, and thus hone in on her notion of "same mathematical process".

At several points during the interview, Jane revealed her notion of "same mathematical process." She said that the functions in Task 6 ($h_1(x) = |x|$ and $h_2(x) = \sqrt{x^2}$) are equivalent but not the same, but that the functions in Task 8 ($f(x) = 5$ and $h(x) = 1(0x + 5) + 5 - 5$) *are* the same (and thus also equivalent). She argued that the functions h_1 and h_2 were different by virtue of doing different "mathematical things," despite being what she calls "equivalent".

Excerpt 2: Task 6: $h_1(x) = |x|$ and $h_2(x) = \sqrt{x^2}$. Are h_1 and h_2 the same function? Why or why not? I: Interviewer; J: Jane

I	What part of sameness is it lacking?
J	Um, like, it's not mathematically, like, I don't know if mathematically it's doing the same thing.
I	What do you mean?
J	Like, whereas this just takes the magnitude of it, this does a mathematical thing to it which comes up with the same answer.

Yet, she argued that the functions f and h in Task 8 were "doing the same thing," and further hinted that transformability may be a relevant property for determining sameness. She described a process of simplification and contrasted it with a situation in which standard algebraic transformation procedures would not apply.

Excerpt 3: Task 8: Are $f(x) = 5$ and $g(x) = 0x + 5$ the same function? Are $f(x) = 5$ and $h(x) = 1(0x + 5) + 5 - 5$ the same function? I: interviewer; J: Jane

J	You just have to simplify to like what does this mean or what's the simplest terms we can put this function in. (...) But I feel like there's some function where like, oh the sum from like k=1 to infinity of 2k+1 is equal to like, (n+1) squared or something... these are like mathematically different things you do to the numbers, it makes them equivalent, like at any k value ...or n value...those things are equivalent. So for me that's equivalence. But for me this [points at $g(x) = 0x + 5$] is about the same thing, because you just simplify it and you get $f(x) = 5$.
I	What about this one? [points at $h(x) = 1(0x + 5) + 5 - 5$]
J	Well for me, this now, it's like you have your 5 and your negative 5 and those just cancel, and you multiply the 1 across and you still get 0x+5 which is just 0 times whatever value this is so always 0 so always just 5. So like, I just feel like you can just simplify it, and if you can just simplify it, then it's the same.

I	Would you not say you could simplify this infinite sum to the formula $(n+1)^2$?
J	Yeah I guess you probably could...it just feels different to me….because like this (sum) is a different sort of structure...it's like hey if we are taking all of these values and adding them up...you know...we get some value, and this (formula) is like what's the value you put this one number in. **This (sum) is still an input-output deal but like, it's like a mathematically different process to get the output** but here [points to $f(x) = 5$ and $h(x) = 1(0x+5)+5-5$]...these feel like the same process.

When Jane compared a piecewise function with a non-piecewise function, she yet again emphasized that, although the functions are equivalent, they differ because "you're using a different tool to get to a place".

All the examples that Jane described as equivalent but not the same were not transformable via typical algebraic manipulations. However, this isn't to say that transformability alone is sufficient for sameness in her eyes; she immediately identified the functions $f_1(x) = \frac{x^2}{x}$ and $f_2(x) = x$ as being non-equivalent, and thus not the same, due to having different domains. Moreover, Jane described $g(x) = x^2$ and $f(x+1) = (x+1)^2$ as the same function, acknowledging that not only are they equivalent, but also the same, with the explanation that "they are taking an input, and, um, making...mathematically doing the same thing to give an output. So in my mind those are the same function". In light of this example, it seems that Jane believes that for functions to be the same, they must have some degree of similarity in what it is that they do to their input. For her, transformability via familiar algebraic procedures ("simplification") indicates a sufficient degree of sameness of process.

Jane's Concept Image of Function

When we consider Jane's concept definition of function, her inclination to consider the sameness of process makes more sense:

Excerpt 4: Task 1: What is a function?

J	Well, the sort of grade school way we get is like, a little box. We have an x go in, and a y go out. You have an input, **do something to it** and get a y out. Um, I uh, I don't know uh...so uh...**you could have maybe different functions that could all allow you to put an x in and get that same y** I	And those would be different functions?
J	They could all be different functions.

She describes this function machine and that it does something. If a function does something, how it does it seems to matter. For her, it seems that doing something to its input is not simply a matter of mapping to a particular value, but mapping to a particular value via a particular process - this makes sense in light of her saying "different tool to get to a place" (mentioned earlier).

In Excerpt 4 she also seems to say that different functions can have the same inputs and outputs (second bolded portion), indicating that the process the function performs is an essential aspect of the function. Further, Jane's assessment of $f(x+1)=(x+1)^2$ and $g(x)=x^2$ as defining the same function illustrates her view that a function performs some process on its inputs. For her it is clear that "squaring" is a process regardless of what you name the input. However, taking the absolute value is a different process than squaring and then taking the positive square root (Excerpt 2).

In summary, if we view Jane's concept image of function as a process that accepts particular inputs and then gives outputs according to that process, then it makes sense that for her, sameness of functions involves having the same inputs and the same outputs for each input (equivalence) and *also* having the same process.

Classifying Jane's Function Concept in the Action-Process-Object Framework

Breidenbach et al. (1992) use the term "action conception" to refer to a conception about functions as methods to use to produce a result. Thompson (1994) describes the student as viewing the function as a "recipe" for calculation. Breidenbach et al. (1992) describes the student as having a process conception of function when the student views all of the steps of computation together as a process, where a process is "when the total action can take place entirely in the mind of the subject without necessarily running through all the specific steps" (p. 249). In other words, when a student is thinking of a process, she is not thinking of a step-by-step computation, but is instead thinking of the transformation as a whole. When a student sees a function as an object (e.g. a set of ordered pairs) and manipulates it as such, then she has an object or structural conception. Sfard (1992) additionally describes a *pseudostructural* conception of function as viewing a function as its representation, such as conflating a function with its equation or an image of its graph.

Jane definitely does *not* have an action conception of function. She does not seem to need to plug in specific values. She discusses the processes that functions perform without actually carrying out these processes herself (e.g., when she is comparing sameness of processes). When asked "What is a function?", she does not give any of the descriptions that Breidenbach et al. (1992) associate with an action conception. It is evident that Jane does not have a pseudostructural understanding of function either; this is especially evident when we consider that she allows the use of different variable names and inputs to define the same function.

Instead, it appears as if Jane has a process conception of function. Her description is similar to one of the descriptions Breidenbach et al. (1992) associated with a process conception: "a function is some sort of input being processed, a way to give some sort of output" (p. 252). Additionally, she has the ability to discuss the general notion of a function's output without having to compute it herself.

Discussion

Jane considered transformable equations as representing the same process. Why this is the case is not clear, but one hypothesis is that through schooling, she reflexively "simplifies" any expression that she sees. She may think of, say, multiplying by 2, adding 3, and then subtracting 3 to be the same thing as simply multiplying by 2, just more complicatedly expressed.

If (to a student) a function is a process, then sameness of functions reduces to sameness of processes. A different student also considered transformability to be sufficient for sameness of process, but gave a different answer to Task 6: he argued that taking the absolute value is just an abbreviation of the process of squaring and then taking the radical. His rationale was that taking the absolute value is not a "mathematical process" and just a shorthand way of telling a function to square and then take a radical. Further investigation is required to see the rationale that students give for transformability and sameness of processes, possibly leading to a more refined notion of "process conception".

There is potentially interesting research that can be done regarding the historical community's notion of sameness of processes. Sfard (1992) discusses how, like with functions, the mathematical community considered fractions as representing a division or measuring process rather than numbers. Did mathematicians have anything to say about the similarity between the processes 1/2 and 2/4? Was there a sense in which the historical community considered them to be representing the same process?

Using the notion of sameness of representations is useful in other mathematical education research settings. I am currently working on a project in which I ask students about the derivatives of the functions defined by $f(x) = x^3$ if $x \neq 2$, $f(x) = 8$ if $x = 2$, and $g(x) = x^3$. Some students claimed that f and g are the same function with identical graphs but different derivatives, leading me to wonder what these students think it is that they are differentiating (an equation?).[2] Another student (Jane, in fact) claimed that despite the functions f and g having the same graphs, they could not be the same function, since (according to her) she could use the power rule to find $g'(2)$ but could not for $f'(2)$.

One of the goals of another research project I am involved in is to see what students think a "graph" is (and in particular, if students conflate "graph" in the sense of "set of ordered pairs" with "displayed graph" or "image of graph"). We used the notion of sameness to further this investigation by asking students to assess whether certain pairs of displayed graphs are indeed the same graph. For example, we asked students if an image of $y = x^2$ with same-scale axes is a different graph than the image of $y = x^2$ with axes of different scale in order to learn if the student thought that a graph is defined by more than its ordered pairs.

The notion of sameness can potentially be useful in exploring students' understanding of structures. Consider asking students about the groups Z_2 and $Z/2Z$. These are different groups (Z_2's elements are integers, $Z/2Z$'s elements are equivalence classes of integers). However, if a student thinks that they are the *same* group, then we know that the student might *not* think of a group as a set together with an operation (if he did, then different sets would imply different groups!). Similarly, we could learn about a student's understanding of equivalence classes by asking him if [4], as a member of Z/2Z, is the same as [10].

[2] Harel and Kaput (1991) describe a similar phenomenon.

Students' Quantitative Reasoning in a Revenue Maximization Context

Thembinkosi P. Mkhatshwa
Miami University

Helen M. Doerr
Syracuse University

The purpose of this study was to investigate students' quantitative reasoning when solving a multivariable problem in a revenue maximization context. We conducted task-based interviews with 12 pairs of business calculus students. Analysis of verbal responses and work written by the students revealed that in reasoning about the relationships among the quantities (sales, discount, and total revenue) in the problem, nearly all the pairs of students created new quantities. The creation of these quantities helped the students to reason about the effect of the discount on sales and total revenue. An important finding of this study is that the students took different approaches to the meaning of the discount and only five pairs of the students interpreted the discount as intended in the design of the problem. Directions for future research are discussed.

Key words: quantitative reasoning, optimization problems, business calculus

This study used Thompson's (1993) definition of quantitative reasoning: analyzing a problem situation in terms of the quantities and relationships among the quantities involved in the situation. According to Thompson, what is important in quantitative reasoning is not assigning numeric measures to quantities but rather reasoning about the relationships between or among quantities. Quantitative reasoning, as used in this study, refers to how students described and represented relationships between or among quantities and how they created and used new quantities to solve the problem they were given. The term quantity has been defined and used in similar ways by several researchers (e.g., Ärlebäck, Doerr, & O'Neil, 2013; Moore & Carlson, 2012; Thompson, 2011). This study used the definition of quantity proposed by Thompson (1990): "a quantity is a quality of something that one has conceived as admitting some measurement process" (p. 5). Examples of quantities in this study include sales, discount, and total revenue.

Much research has investigated students' reasoning about quantities in physical contexts such as in kinematics (e.g., Beichner, 1994; Bingolbali & Monaghan, 2008; Monk, 1992), heat and energy (e.g., Prince, Vigeant, & Nottis, 2012), temperature (e.g., Carlson, Jacobs, Coe, Larsen, & Hsu, 2002), and volume (e.g., Monk & Nemirovsky, 1994). However, we know very little about how students make sense of quantities in an economic context and how they reason about those quantities, which is the motivation of this study. This study examined business calculus students' quantitative reasoning when solving an optimization problem that is situated in the context of revenue maximization. The following research question guided this study: What do business calculus students' responses to optimization problems involving multiple covariates that are situated in the economic context of revenue maximization reveal about their quantitative reasoning?

Literature Review

Research on students' quantitative reasoning at the undergraduate level is scarce: much of the existing research that has looked at students' quantitative reasoning is at the elementary and the secondary levels (e.g., Lobato & Siebert, 2002; Thompson, 1993; Yerushalmy, 1997). A few studies (e.g., Moore, 2014; Moore & Carlson, 2012) have looked at students' quantitative reasoning at the undergraduate level. Yerushalmy (1997) studied six Israeli secondary school students' reasoning while modeling a multivariable situation. The researcher investigated how the students related three quantities (cost, number of days, and number of kilometers driven) as well as how they described the various representations they used to relate the quantities. Over a period of four one-hour meetings, the students worked in two groups to determine the total cost of renting a car from a rental car company that charges its customers "1000 shekels for a day and an additional 5 shekels per kilometer" (p. 435). Yerushalmy reported that to represent the relationship among total cost, the number of days a car is driven, and the number of number of kilometers a car is driven, the students used real-valued algebraic functions of two variables, three-column tables, and a three dimensional graph. Yerushalmy argued that even though a majority of the students had difficulty using correct mathematical notation to represent the relationship algebraically, the use of three-column tables helped some of the students to correctly determine an algebraic equation relating the three quantities. Only one student attempted to represent the relationship in a three dimensional plane by combining a pair of two dimensional planes (total cost versus number of days a car is rented and total cost versus number of kilometers a car is driven). The findings of this study suggest that representing relationships among several quantities using algebraic equations and graphs in the context of renting a car is particularly difficult for students.

Moore and Carlson (2012) examined how nine students, drawn from three sections of a precalculus course at a large public university, engaged in quantitative reasoning while reasoning about the volume of a box. The box was "formed by cutting equal-sized squares from each corner" (p. 51) of an 11 inch by 13 inch sheet of paper and folding the sides up. Each of these students participated in a task-based interview where they were asked to "write a formula that predicts the volume of the box from the length of the side of the cutout" (p. 51). Moore and Carlson found that, at first, a majority of the students did not recognize that the length and width of the box co-varied with the length of each square that was cut out from the sheet of paper. Consequently, the students conceived of the box as having a static base with dimensions 13 inches (length) by 11 inches (width) instead of a dynamic base with dimensions (13-2x) inches by (11-2x) where x is the length of each square that is cut out from the sheet of paper. The students were eventually successful in creating a correct formula for the volume of the box. Moore and Carlson argued that "it was only after the students imagined the process of making the box and considered how the relevant quantities of the situation changed in tandem that they created a correct volume formula" (p. 57). Similar results were reported by Lobato and Siebert (2002) in the context of a wheelchair ramp. In general, the findings of Moore and Carlson (2012) and those of Lobato and Siebert (2002) show that covariational reasoning (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002) is an essential understanding that students need if they are to be successful in relating co-varying quantities using algebraic equations. In the study reported in this paper, we examined how undergraduate students reasoned about relationships among co-varying quantities in a revenue maximization context.

Theoretical framework

This study draws on the theory of quantitative reasoning, an evolving theory in mathematics education whose origin can be traced to the early work of Thompson (1990). Thompson (2011) described three tenets that are central to the theory of quantitative reasoning. These tenets are: a quantity, quantification, and a quantitative operation. According to Thompson (1990), "a quantity is a quality of something that one has conceived as admitting some measurement process" (p. 5). Thompson added that a quantity is a mental construction. Thompson (1993) distinguished between a quantity and a numerical value: a quantity has a unit of measurement and a numerical value does not. Thompson (1993) added that “quantities, when measured, have numerical values, but we need not measure them or know their measures to reason about them” (pp. 165-166). For example, we can think of Company A’s profit for a given trading period, Company B’s profit for the same trading period, and the amount by which Company A’s profit is bigger (or smaller) than Company B’s profit, without having to know the actual numerical values of the profit. According to Thompson (2011), quantification “is the process of conceptualizing an object and an attribute of it so that the attribute has a unit of measure, and the attribute’s measure entails a proportional relationship (linear, bi-linear, or multi-linear) with its unit” (p. 37). In a sense, the process of quantification entails assigning numerical values to the attributes of an object. A quantitative operation is the process of forming a new quantity from other quantities (Thompson, 1994b). Thompson (1993) stated that “comparing two quantities with the intent to find the excess of one against the other” (p. 166) is a specific example of a quantitative operation formed by comparing two quantities additively. In economics, for example, comparing (by way of finding the difference) total revenue and total cost with the intent to find the excess (profit or loss) of total revenue against total cost is a quantitative operation known as a quantitative difference.

The design of our study was influenced by the theory of quantitative reasoning in three phases, namely task design, data collection, and data analysis. Drawing on the theory of quantitative reasoning as a theoretical framework for our study, we designed the mathematical task (shown in the methods section) that provided students with opportunities to reason about relationships between or among quantities. This task provided opportunities for students to reason about relationships among sales (number of computers sold), sales discount, and the total revenue generated when a business sells computers to a school. Our interview protocol allowed us to engage students in reasoning about relationships among quantities during the data collection process. Finally, a major part of the data analysis phase focused on looking for evidence for when students created new quantities (performing quantitative operations), how they used these quantities to reason about relationships between or among quantities, and whether or not these quantities helped the students to solve the problem posed in the task.

Methods

This qualitative study used task-based interviews (Goldin, 2000) with 12 pairs of business calculus students. There were four tasks in total (Mkhatshwa, 2016). In this paper, we report on how the students reasoned quantitatively about one of the tasks, adapted from Hughes-Hallet et al. (2002):

> The Smith family runs an electronics business in Southern California. The family is considering signing a contract to supply a small junior high school with laptops, the exact number to be determined by the principal of the school later. For any supply of up to 300 laptops, the price per laptop will be $900.
>
> For any supply of more than 300 laptops, the school will receive a $2.50 discount per computer (on the whole order) for every additional computer over 300 supplied.
>
> The Smith family would like you to advise them whether or not to sign the contract. They want to make sure that they make the most amount of revenue possible from this contract. What advice can you give to the Smith family on whether or not to sign the contract and why?

This task was designed to examine students' reasoning about the relationship among three quantities, namely sales (the number of computers ordered by a small junior high school), the discount offered on orders of over 300 computers, and the total revenue that is generated by the sales when the discount is taken into consideration. The discount was intended to be applied on the whole order for any order of more than 300 computers. For example, the selling price for each computer in an order of 301 computers would be $897.50, the selling price for each computer in an order of 302 computers would be $895.00, and so on. This means that the amount of the discount on every computer varies with the number of computers ordered. As we will show in our results below, half of the pairs of students did not interpret the discount as intended in the design of the task.

Setting and participants

This study was conducted at a research university in the north-eastern part of the United States. The study participants were 24 undergraduate students who had recently completed a business calculus course. Twenty-two of these students were business majors (e.g., management, marketing, accounting) while the other two students were considering majoring in business-related programs. Twelve students took business calculus in the spring semester of 2015 and the other twelve students took it in the fall semester of 2015. In addition to taking business calculus: (1) ten students had taken AP economics (AP microeconomics and AP macroeconomics) in high school, (2) twelve students had taken a high school course (AP or non-AP) in calculus, and (3) twenty-one students had taken at least one college-level economics or business class (e.g., intermediate microeconomics, managerial accounting) prior to participating in this study. At the time of conducting the study, fifteen of the study participants were sophomores and nine participants were freshmen.

Data Analysis

Data analysis was done in two stages. In the first stage, we used a priori codes. We carefully read through each interview transcript and coded instances where students reasoned about: (1) new quantities (e.g., diminishing marginal returns), (2) relationships between or among quantities (e.g., revenue decreases as more computers are sold at a discounted price), and (3) representations of relationships among quantities (e.g., using graphs and algebraic equations). In the second stage, we looked for patterns in students' responses to the task. These patterns include common understandings or difficulties in students' reasoning about the effect of the discount on sales and total revenue. The common understandings or difficulties in students' reasoning found in the second stage of our analysis provided answers to our research question.

Results

Our analysis of the data revealed that eleven pairs of students created new quantities (e.g., the rate at which the revenue is increasing, the accumulation of the discount, and the point of diminishing marginal returns) which they used to reason about relationships among sales, the discount, and the total revenue generated. Of these eleven pairs of students, six pairs of students reasoned with the context of the task but not as intended in the design of the task. Instead, these six pairs of students applied the discount only to the additional number of computers over 300 ordered and created a new quantity, the rate at which the revenue is increasing. This quantity was then used to reason about the relationship among sales (number of computers sold), the discount, and the total revenue generated. Another five pairs of students reasoned with the discount as intended in the context of the task: they applied the discount to the whole order. These students created a new quantity, the accumulation of the discount, which they used to reason about the relationship among sales, the discount, and the total revenue generated. Abby and Shawna are the only pair of students who did not create any new quantity in this task. These students indicated that they needed to have the demand and supply equations (which were not given in the task) in order to solve the problem posed in the task.

Applying the discount only to the additional computers over 300 ordered

Kierra and Isaac are representative of the six pairs of students who applied the discount only to the additional computers over 300 ordered. These students created a new quantity (the rate at which the revenue is increasing) which they used to reason about the relationship among the quantities: sales, the discount, and the total revenue generated. Kierra and Isaac are the only pair of students (out of the six pairs of students) who created a graph (Figure 1) to show the relationship among these quantities. By applying the discount only to the additional computers over 300 ordered, Kierra and Isaac came to the conclusion that the relationship between the revenue and sales is such that the revenue will continue to increase as more computers are sold beyond 300. In the following excerpt, which occurred at the beginning of working on the task, Kierra and Isaac reasoned about the relationship between the number of computers that are sold and the total revenue.

Isaac: Well I think it’s, I think, I kind of picture it as almost like a graph

Researcher: How would it look like as a graph?

Kierra: Like it would, for the first 300 [computers] it [revenue] would go up at the same rate like at one rate of $900 and then like once it hits that 300, like 301, it slightly changes the slope of the line of going up of each laptop by $897.50 so I guess like, there is never gonna be a time when like they will be losing money. They will just be like slightly gaining money, nine hundred minus $2.50

Researcher: You said something about the slope changing at like 300, right?

Isaac: Yeah, because like anything above 300 is when they give that discount of $2.50

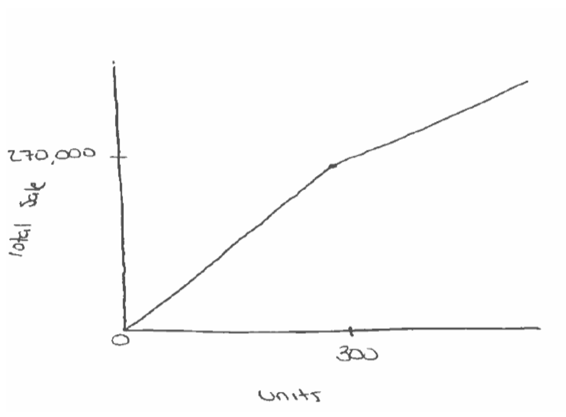

Figure 1. Isaac's graph of the relationship among the number of computers sold, the revenue, and the discount.

Kierra mentally created a new quantity (the rate at which the revenue is going up) when she stated that the revenue “would go up at the same rate like one rate of $900.” Her statement that “there is never gonna be a time when like they will be losing money” suggests that she viewed the application of the discount on orders of more than 300 computers as insignificant in that the revenue continues to increase no matter the size of the order. Kierra and Isaac recognized that graphically, the effect of applying the discount will be a slight change in the slope of the graph of the total revenue function after 300 computers as shown in Figure 1. When asked to elaborate on how the slope would change, Isaac created Figure 1. He also stated that the revenue "will go up like a steep rate" as more computers are sold up to 300, which suggests that he also created a new quantity, the rate at which the revenue will go up. Isaac continued to reason about this new quantity when he indicated that "the slope would be less steep" when he referred to how the revenue continues to increase as more computers are sold over 300 in Figure 1. At the end, Kierra and Isaac advised the Smith family to sign the contract for any number of computers ordered by the school, which was reasonable advice based on their understanding of how the discount is applied.

Applying the discount to the whole order

Yuri and Kyle are representative of the other five pairs of students who reasoned about the context of the task as intended, where the discount is applied to all of the computers ordered. This pair of students created a new quantity, the accumulation of the discount, when reasoning about the relationship among sales, the discount, and total revenue generated. In addition to verbalizing the relationship among sales, the discount, and the total revenue generated, Yuri used an algebraic equation shown in Figure 2 to represent this relationship and Kyle used a graphing calculator to graph Yuri's revenue equation. Kyle's graph was a concave down parabola.

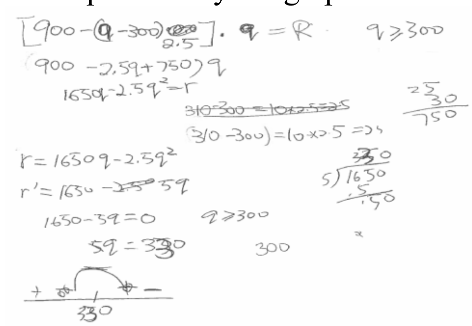

Figure 2. Yuri's algebraic representation of the relationship between the revenue and the number of computers sold.

Yuri and Kyle described the discount as "cumulative." They explained what a cumulative discount is by giving examples. Kyle indicated that "if you buy three hundred and two you get five dollars off each computer." Yuri added that "if you sold three hundred and ten computers, you get twenty-five dollars discount per computer you sell." Yuri and Kyle's understanding of the discount as cumulative suggests that these students mentally constructed the accumulation of the discount as a new quantity. With the understanding of the discount as cumulative, Yuri and Kyle calculated the total revenue from selling 310, 350, and 400 computers respectively. They found that the revenue from selling 310 computers is the same as the revenue from selling 350 computers and that the revenue from selling 400 computers is less than the revenue from selling 310 computers. Yuri and Kyle then advised the Smith family to consider the size of the order placed by the school prior to signing the contract. They indicated that an order of "315 computers" will generate more revenue "than if they sold 415 computers." This suggests that Yuri and Kyle recognized that, in the long run, the accumulation of the discount will cease to increase the Smith family's revenue and will, instead, result in loss of revenue.

After doing the work shown in Figure 2, Yuri concluded by saying that the Smith family business should sign the contract if the school orders at most 330 computers. He, however, did not talk much about the details of his work in Figure 13 such as when and why he took the derivative of the revenue function denoted by the letter r in Figure 2. Kyle also concluded by advising the Smith family to sign the contract when the school orders 330 computers "since that's the most money they can make on this deal [contract]." When asked how he arrived at this conclusion, he said [referring to the graph of the Yuri's revenue function which he graphed on his calculator], "I did second calc max to find the maximum and the max quantity is three hundred and thirty for a revenue of two hundred and seventy-two, two hundred and fifty." That is, Kyle used a graphing calculator to determine the revenue-maximizing quantity of 330 computers.

Discussion and Conclusions

This study examined undergraduate students' reasoning about the relationship among several quantities, namely sales (number of computers ordered), the discount offered, and the total revenue generated. An important finding of this study is that in reasoning about this relationship, the students took different approaches to the meaning of the discount and created new quantities. Six pairs of students did not interpret the discount as intended in the design of the task. These students applied the discount only to the additional computers sold over 300 and created a new quantity, the rate at which the revenue is increasing. Five other pairs of students interpreted the discount as intended in the design of the task. They applied the discount to the whole order and created a new quantity, the accumulation of the discount. The creation of these new quantities helped the students to make sense of the relationship among the quantities in the task especially the effect of the discount on number of computers sold and the total revenue generated in addition to helping them answer the problem posed in the task which is advising the Smith family business whether or not to sign the contract. Other research (e.g., Lobato &, 2002; Moore & Carlson, 2012) has shown that when engaged in reasoning about relationships among three quantities, students tend to talk about two quantities explicitly while treating the third quantity as an implicit quantity. Consistent with findings of this research, the students in our study tended to talk, explicitly, about the relationship between the number of computers sold and the total revenue generated while treating the discount as an implicit quantity. Previous research (Yerushalmy, 1997) has reported on students' use of graphs and algebraic equations when representing relationships among several variables. In our study, only one pair of students (Isaac and Kierra) used a graph and only one student (Yuri) used an algebraic equation to represent the relationship among the three quantities in the task they were given. It might be important for future research to examine the opportunities for students to learn to reason about economic quantities such as sales discount presented in business calculus textbooks and classroom instruction.

Preservice Secondary Teachers' Abilities to Transfer from Graphical to Algebraic Representations of Functions

University of West Georgia
Kyunghee Moon

In this study, I examined 14 preservice secondary teachers' abilities to transfer graphical to algebraic representations of functions. The analysis showed that the vast majority of the participants had problems in noticing critical behaviors of function graphs and in using them to construct algebraic forms. About half or fewer of the participants noticed qualities such as x-intercepts, vertical asymptotes, slant asymptotes, and concavity/extrema, with only a few of them successfully using such qualities in constructing algebraic forms. Only a few noticed and used qualities such as horizontal asymptotes, point discontinuities, domain, and end behaviors in constructing algebraic forms. It is advisable that the teaching of the function concept incorporate transformational activities beyond algebraic to graphical transformations and focus more on the critical characteristics of functions.

Keywords: Function, Concept image, Graph, Preservice secondary teacher

Introduction

Understanding concepts in multiple representations is critical in mathematics (Hiebert & Carpenter, 1992). Yet making connections among representations is not trivial. One should not only know how to transform within the same and across different forms of representations (Dufour-Janvier, Bednatz, & Belanger, 1987; Even, 1998), but also understand subconcepts and translate the meanings among multiple representations (Hitt, 1998; Lesh, Post, & Behr, 1987; Markovits et al., 1986).

There are many studies that deal with individuals' conceptions of functions related to graphical representations of functions. Several of these studies report that students and teachers tend to associate functions only with equations or with graphs of continuous functions (Carlson, 1998; Hitt, 1998). However less frequently reported is research that concerns whether individuals can indeed relate function graphs to function equations. As such, in this study I investigate individuals' abilities to transfer function representations that are related to equations. Such information would be beneficial not only to the understanding of individuals' cognitive structure on the function concept but also to the teaching of the function concept. This study answers the research question: "What do preservice teachers notice and use when transferring from graphical to algebraic representations of functions?"

Background

Theoretical Framework

The overarching framework of this study is the construct of concept image—"the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes" (Tall & Vinner, 1981, p. 152). The construct of concept image has been widely used to understand students' cognitive structures of the function concept in association with the formal concept definition of function—"a relation between two sets *A* and *B* in which each element of *A* is related to precisely one element in *B"* (p. 154). Due to the nature of this study, however, I focus on the characteristics of functions that are essential to the conversions between graphical and algebraic representations of functions, especially fractional functions $f(x)/g(x)$ with $f(x)$ and $g(x)$ polynomial or radical functions. Fractional functions embed many of the important characteristics of functions. As such, students' mathematical behaviors with fractional functions provide a good portrait of their understanding of function characteristics in general.

In typical college algebra or precalculus textbooks, where manual representations of rather elaborate graphs of functions are handled with no aid of the calculus concepts, a graph of a function equation $y = f(x)$ is sketched through the concepts such as domain/range, zero, and limit. The domain/range determine where the graph lies; zeros determine where the graph crosses the x axis, with $f(0)$ determining where the graph crosses the y axis; and limits determine to which lines the graph is tangent—that is, the vertical/horizontal/slant asymptotes—as well as whether the graph has point discontinuities (holes) and what the end behaviors of the graph are like. Yet understanding functions and their graphs in relation to the above concepts is not trivial for many individuals. Included below are some studies that concern individuals' understanding of characteristics of functions.

Literature Review

In general, many individuals have a limited concept image of functions. They associate functions to single equations or continuous functions and lack understanding of important characteristics of functions (Breidenbach et al., 1992; Even, 1998; Hitt, 1998).

For the concepts of domain and range, studies show that students do not hold the concepts in their cognitive structure nor do they use it appropriately in problem solving. A college student in Aspinwall, Shaw, and Presmeg and Nenduradu 's study (1997) showed a discrepancy between her image of second-degree polynomials and the domain of second-degree polynomial functions. The student thought that second-degree polynomials had vertical asymptotes, but at the same time she thought that the domain was all real numbers. Hitt (1998) also showed that many beginning secondary teachers could not articulate whether or not a curve represented by an algebraic form—circle or ellipse—was a function. The teachers also did not identify subconcepts of functions, such as domain and range, in graphical representations of functions. Williams' study (1998) also showed that for the vast majority of 28 calculus students, the concept of domain and range was not present in their concept map of functions.

For the concept of limit, most studies deal with students' understanding of limit in association with the formal concept definition of limit. Only a limited number of studies concern individuals' understandings of the limit concept related to graphs of functions—asymptotes, holes, and end behaviors. Even' study (1998) showed that a prospective teacher had difficulty telling whether a discontinuous graph with holes was a function or not. Lauten, Graham, and Ferrini-Mundy (1994) showed that constructing a function that satisfies some conditions might not be easy for college students. When a student, Amy, was asked to provide an example of a function that satisfied given conditions of f(1) = 2, f(3) = 6, and f(5) = 9, Amy only attempted to find a single equation that met the conditions. Failing the attempt, she then moved to a graphical representation and provided a continuous curve by connecting three points she plotted. She also failed to distinguish between the roles of x and y when describing limits, making it difficult for her to see a function value as a vertical distance. Amy also did not use a calculator as a toolkit. She had minimal use of a calculator, mainly using it to find values through the trace keys when problems were accompanied with graphs. She however did not use a calculator independently to explore ideas before answering questions.

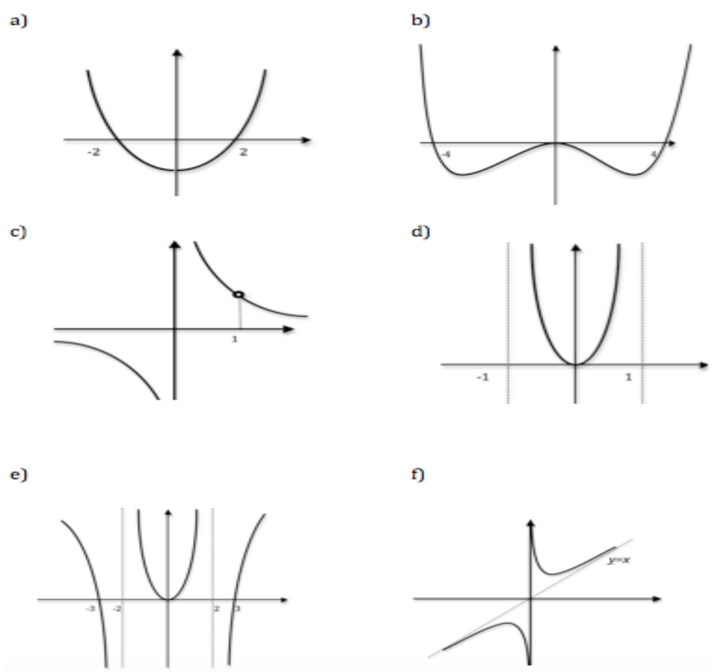
When the graphing technology is used properly, however, students could develop a sound understanding of the characteristics of functions related to the limit concept. Students in Yerusalemy (1997) graphed rational functions using computer software programs and constructed the definitions of asymptotes based on the graphs. They also created equations that have graphs lying between the rational function $f(x) = (x^2 - 1)/(x^2 + 1)$ and its horizontal asymptote and investigated how asymptotes could be evaluated from the symbolic manipulation of algebraic equations.

Methodology

The participants of this study were 14 undergraduate mathematics majors in the secondary teaching track at a medium-sized state university in the Southeast. The levels of participants' mathematics backgrounds varied—three taking Precalculus, one taking Calculus I, and the other ten taking Calculus II or above. The participants were individually interviewed twice, for about one-and-a-half hours each time, in the form of semi-structured clinical interviews. The interviews were recorded with a video camera and were transcribed. Their written responses were also collected.

The interview item relevant to this study is Q1 below from the second interview, which required graphical to algebraic representational transfers for 6 graphs that could be associated with fractional functions. Preservice teachers were asked to "think aloud" during the interviews.

Q1: For each of the graphs below, give an example of a function equation that can match the given graph:



For analysis, I used an open coding strategy (Strauss, 1987). I coded the characteristics and graphical behaviors of functions that participants noticed and used in the representational transfer as well as their understandings and difficulties shown in the transfers.

Results

Analysis showed that the preservice teachers had difficulty in constructing algebraic equations that could yield given graphs of functions. Most of them solely depended on their memory and randomly guessed the corresponding equations, or did not even attempt to guess, without careful inspections of graphs. Even in the cases in which they noticed certain characteristics or behaviors of graphs, they were incapable of constructing algebraic equations that could embed such qualities. Except for Graph (a) in which 9 out of 14 participants came up with a reasonable form of a parabolic equation, they struggled for all the other graphs. With Graph (b), which could be represented as a higher-order polynomial function, only 3 provided a correct algebraic form. For the other 4 graphs, which could not be represented as polynomial functions, only one teacher or none of the teachers was able to construct a correct equation (see Table 1).

Table 1 Correct algebraic representation of graph

	Graph (a)	Graph (b)	Graph (c)	Graph (d)	Graph (e)	Graph (f)
The number of participants who provided a correct equation	9	3	1	0	1	1

Note: Both $y = x^2 - 2$, which was based on the y-intercept, and $y = x^2 - 4$, which was based on the x-intercepts, were accepted as correct answers for Graph (a).

Preservice teachers' ability to notice critical characteristics or behaviors of graphs was also very limited. Although many of them mentioned x-intercept/zeros (7), vertical asymptote (10), and slant asymptote (8) at least once, only a few of them mentioned horizontal asymptote (3), hole/point discontinuity (2), concavity/maximum/minimum (4), and domain (2). None of them mentioned the end behaviors of the function graph, which involved the limit concept (see Table 2).

Their noticing of the characteristics or behaviors of graphs also did not lead to their using of the information in the graphical to algebraic transfer. They were able to use qualities such as x and y intercepts and concavity/extrema when constructing corresponding algebraic forms if they noticed the qualities. However, they could not embed graphical behaviors related to the concepts of limit and domain when constructing in algebraic forms even if they noticed them. The details follow.

For the concept of the y-intercepts, 5 teachers noticed it in Graph (a) and 3 of them used it to construct algebraic form with success. The other two mentioned that they needed to shift the graph of $y = x^2$ to have the y-intercept of -2 (which they thought was the value of the y coordinate of the y-intercept), but did not know how to modify the equation $y = x^2$ to have its graph translated by 2 to the negative direction of y. For the concept of the x-intercepts, 6 teachers successfully used it at least once to construct an algebraic form for Graphs (a), (b), (d), and (e).

Three used it only for the Graph (a), two used it for the Graphs (a) and (b), and one used it for Graphs (a), (b), and (e). Out of reach for most preservice teachers was the Factor theorem—for a polynomial $y = p(x)$, $p(c) = 0$ if, and only if, $x – c$ divides $p(x)$—in relation to the graphs. Although they knew that the x-intercept of $(c, 0)$ of the graph of $y = p(x)$ would satisfy $p(c) = 0$, they could not use the Factor theorem to write $p(x)$ as $(x – c)$ times something. Instead, they performed a trial and error method to construct a form that would yield $p(c) = 0$. For example, for the Graph (a), they acknowledged that (2, 0) and (-2, 0) were the x-intercepts. However instead of creating the quadratic form $(x - 2)(x + 2)$ by using the Factor theorem, they manipulated $x^2 + constant$ repeatedly until they came up with the form $y = x^2 – 4$, which yielded the two zeros, 2 and -2. Many of them showed the same trait for the Graphs (b) and (e), with some of them failing to provide a correct form by doing so.

Table 2 Characteristics or behaviors noticed or used at least once

	Noticed	Used With Success
The y-intercept	5	3
The x-intercept or zero	8	6
Vertical asymptotes	11	6
Horizontal asymptotes	3	0
Slant asymptotes	8	1
Hole (point discontinuity)	3	2
End behaviors, excluding horizontal and slant asymptotes	0	0
Concavity/maximum/minimum	5	5
Domain	2	1

Note: It is possible that an individual creates an incorrect equation even if she uses one or more characteristics in a correct way, if she fails to use other characteristics correctly.

Preservice teachers also struggled to notice the graphical behaviors related to the concept of limit—vertical/horizontal/slant asymptotes, holes, and end behaviors—and/or to use them to construct algebraic equations. For the vertical asymptotes, although 11 teachers noticed vertical asymptotes in at least one of the Graphs (c), (d), (e), and (f), only 6 of them were successfully able to use them at least once to construct an algebraic form. Their performance was also inconsistent, indicating that they did not have a firm understanding of the idea that a vertical asymptote of a graph was related to a zero of the denominator of $p(x)/q(x)$. Five of them successfully used the vertical asymptotes to construct an equation for the Graph (e), 3 for the Graph (d), and 1 for the Graph (f).

In the case of the horizontal asymptotes, only 3 of them noticed it in the Graph (c). However, even those three teachers did not use the information to construct an algebraic form. One teacher came up with the equation $y = 1/x$ by simply by using the vertical asymptote, without checking whether the equation had a horizontal asymptote of the x-axis; another teacher came up with the equation $y = \log(x)$; and the other teacher did not provide any algebraic form.

Three teachers noticed the characteristic of point discontinuities, with only one of them successfully using it to construct an algebraic form. This teacher did not mention vertical/horizontal asymptotes when he came up with his first equation $y = 1/x$ from his memory. He then noticed the hole and changed the equation to $y = (x - 1) / x(x - 1)$ by incorporating the hole at (1, 1). For the other two teachers, one came up with $y = 1/(x - 1)$ as the answer without noticing the hole and the other came up with none. As for the slant asymptote, although 8 teachers noticed it in Graph (f), only one teacher was able to use it to construct an equation. This one teacher came up with a correct equation $y = (x^2 + 1) / x$, but his understanding of asymptotes was somewhat shaky. He mentioned that a rational function, $p(x)/q(x)$, would have a horizontal asymptote of $x = 0$ if deg $(q(x))$ > deg $(p(x))$; a horizontal asymptote of x = the leading coefficient of $p(x)$/ the leading coefficient of $q(x)$, if deg $(q(x))$ = deg $(p(x))$; and a slant asymptote if deg $(p(x))$ = deg $(q(x)) + 1$. Yet he came up with the equation $y = x / (x^2 - 1)$ for the Graph (d) by focusing on the zero and the vertical asymptotes, without realizing that his equation, $y = x / (x^2 - 1)$, would yield a horizontal asymptote of $y = 0$, which the given graph did not have. He also said, "my problem is I don't know how to get a slant asymptote," after constructing a correct equation $y = (x^2 + 1) / x$ for the Graph (f). For the end behaviors of graphs, none of the teachers mentioned end behaviors of graphs that were not related to horizontal or slant asymptotes.

For the concavity/extrema/increase/decrease, of the 5 preservice teachers who noticed the characteristics, 4 used the information correctly to determine the degree of polynomial as 4. However, only 3 of them were able to use the information in conjunction with the zeros of the function to come up with a correct function equation.

For the concept of domain, preservice teachers in general did not pay attention to or use the concept of domain when constructing a function equation. For the Graph (d), for example, although many of them noticed that there were two asymptotes in the graph, only two of them specifically mentioned the graph was lying on the interval, (-1, 1). Further, those two teachers did not know how to use the domain information together with other characteristics of the function. One teacher came up with an algebraic equation of $y = x^2$ with $x \in (-1, 1)$ even after she mentioned the graph had two vertical asymptotes of $x = 1$ and $x = -1$, influenced by the look of the graph that was similar to a parabola. The other simply guessed that the equation $y = csc\ (x)$, would be an algebraic form for the graph by thinking that the interval of (-1, 1) was somehow related to trigonometric functions. Four preservice teachers, including one of the two above, came up with a variation of $y = x^2$ as an answer for the Graph (d). Three teachers came up with $y = x / (x^2 - 1)$ or $y = x^2 / (x^2 - 1)$ by reflecting the vertical asymptotes with or without considering the parabola figure in the graph.

Discussion and Conclusions

Prior research showed that many post-secondary students including secondary preservice teachers have misconceptions of functions and have a concept image of functions as continuous functions or associate them only with equations (Carlson, 1998; Even, 1998). However, there is little information about whether individuals indeed understand functions that are associated with equations. Here in this study, I attempted to answer part of this question and investigated preservice secondary teachers' abilities to transfer graphical to algebraic representations. In particular, I focused on what behaviors of function graphs they noticed and used when transferring graphs to equations.

The results showed that most teachers held only a few characteristics of functions in their concept image of function and had difficulty noticing and using them when transferring graphs to algebraic equations. Many preservice teachers noticed and used the concepts of x and y-intercepts and vertical asymptotes, but most of them could not make use of the Factor theorem efficiently to construct an equation. Although they knew that $f(a) = 0$ if $(a, 0)$ was an x-intercept of the graph of $y = f(x)$, they did not see $(x - c)$ as a divisor of $f(x)$ and write $f(x)$ as $(x - c)$ times something.

Preservice teachers also had problems in noticing and using other concepts. For the concept of domain, as with the beginning secondary teachers in Hitt's (1998) or Williams' study (1998) who did not hold the concept of domain in their concept map of functions, preservice teachers did not consider the domains of functions when constructing function equations. Even in the case in which they acknowledged the domain of a function, they did not know how to construct an equation with that domain. As with a college student in Aspinwall, Shaw, and Presmeg's study (1997) who had a conflicting understanding that second-degree polynomials had vertical asymptotes and at the same time the domain of all real numbers, one preservice teacher in this study also showed a discrepancy in dealing with a parabola-like graph. Although she noticed that the graph was defined on (-1, 1) with the vertical asymptotes of $x = 1$ and $x = -1$, she constructed the equation $y = x^2$ with $x \in (-1, 1)$.

For the concept of point discontinuities, Even's study (1998) showed an example of a teacher who could not tell whether a discontinuous graph with holes was a function or not. In this study, only three out of 14 teachers noticed a hole in a graph, and of those, only one of them was able to embed the information when constructing an equation. It was also noticeable that none of the teachers mentioned the end behaviors of function, which is part of the limit concept, and only one teacher who noticed a slant asymptote was able to construct an equation with the slant asymptote.

In light of the findings of this study, the teaching of critical concepts of functions might have to be handled with more care. In addition to the traditional, algebraic to graphical transfer activities that have been primarily used in classrooms, other activities that focus on the same concepts from different angles might have to be considered. The transformational activities such as those included in this study are an example. Instruction using graphic utilities such as Yerusalemy's (1997), which was effective for the understanding of vertical asymptotes of rational functions, is another. As shown in Lauten, Graham, and Ferrini-Mundy (1994), students show different understandings of the function and limit concepts in different representational contexts, and further, the use of technology does not guarantee students' understandings of the function characteristics. Only with well-designed activities that could offer students opportunities to explore critical ideas of the various function concepts is there a great possibility for students' better understanding of functions.

Preservice Secondary Teachers' Abilities to Use Representations and Realistic Tasks

University of West Georgia
Kyunghee Moon

This study reports three preservice secondary teachers' abilities and tendencies to use representations in problem solving as well as their abilities to use realistic tasks after taking mathematics content and methods courses that emphasized the roles of representations and realistic tasks. Qualitative analyses showed that the preservice teachers developed beliefs that representations and realistic tasks are important components of secondary education and used motivational tasks in their instruction. However, they used the tasks mainly as the application of learned facts rather than as the departure of students' construction of mathematical ideas. They also showed tendencies to use algebraic approaches in problem solving for grade 5-12 level tasks and had difficulties connecting algebraic and geometric representations when solving high school level algebra problems.

Keywords: Representations, Teacher Education, Mathematical Tasks, Problem Solving

Objectives

The importance of representations in mathematical teaching and learning has been emphasized in many studies (Brenner et al., 1997; Hiebert et al., 1997; Leinhardt, Zaslavsky & Stein, 1990; Thomson, 1994ab). Yet studies have suggested that many teachers have less than optimal understanding of the roles of representations and have difficulties using them in their instruction and in their own problem solving. Nevertheless, not much is known about how and in what ways teachers, especially secondary teachers, develop conceptions or knowledge of representations. This study addresses this under-documented area. It examines in what ways a series of mathematics and mathematics education courses that emphasized the roles of representations and tasks helped preservice secondary teachers to develop their mathematical knowledge for teaching. In particular, this study answers the following two research questions: (RQ 1) How were preservice secondary teachers' tendencies and abilities to solve problems using representations after taking courses that emphasized the roles of representations and tasks? (RQ 2) How were preservice secondary teachers' abilities to use tasks in instruction after taking courses that emphasized the roles of representations and tasks?

Framework and Literature Review

This study was conducted under the premises that knowledge and external representations are closely related and that mathematics is a human activity—"the activity of mathematicians that involves solving problems, looking for problems, and mathematizing subject matter" (Gravemeijer, 2008, p. 285). According to Hiebert and Carpenter (1992), "mathematics is understood if its mental representation is part of a network of representations. The degree of understanding is determined by the number and the strength of the connections" (p. 67). When internal representations are connected, the connections produce networks of knowledge, which are structured hierarchically or as a spider's web. These internal representations and their connections, however, cannot be observed. Under the assumption that there is a relationship between external and internal representations, learners' knowledge is often viewed through their abilities to use and connect external representations.

On the other hand, representations play a central role in the Realistic Mathematics Education (RME). In RME, mathematics is viewed as an organizing activity that makes sense of the world, and learners are viewed as mathematicians who act as the reinventors of mathematics. By constructing, connecting, and evolving representations while being actively engaged in "realistic" contexts, learners construct or reconstruct mathematical ideas (Gravemeijer, 2008). As such, realistic tasks play a critical role in RME. Realistic tasks in RME are different from traditional word problems in that tasks serve as the start of knowledge construction instead of as the application of learned facts at the end of instruction. Realistic tasks have representations built-in, are truly problematic so that students have motivations to solve them, and are open enough so students can take various paths to solving the problems (Fosnot & Jacob, 2010; Gravemeijer, 2008).

In this study, I use the lenses of representation and realistic task—the lens of representation for teachers' problem solving tendencies and abilities, and the lens of realistic task for task design and implementation—to examine teachers' knowledge. As the participants in this study took various courses, designed following some principles of RME, where representations and realistic tasks were particularly emphasized, these lenses served as appropriate analytic tools to look into their knowledge.

I here begin with a brief literature review that regards secondary teachers' tendencies and abilities to use representations in problem solving, as well as their conceptions about representations. The literature on teachers' conceptions of or tendencies and abilities to use realistic tasks that is consistent with the RME description is rare at the secondary level, and I include two studies that show the effects of RME with Dutch secondary teachers.

Teachers' Conception, Use, and Understanding of Representations

Studies have shown that many secondary teachers hold less than optimal conceptions or knowledge of representations in teaching and learning. They focus mostly on symbolic representations in teaching (Cunningham, 2005); they tend to use algebraic approaches in their own problem solving and favor students' algebraic approaches over other approaches (Nathan & Petrosino, 2003); and they view non-symbolic representations as informal objects, not necessarily as mathematics itself (Stylianou, 2010). In Moyer's study (2001), even after an intervention that emphasized the role of manipulatives and technology in instruction, many in-service middle grade teachers used manipulatives mainly in teacher-directed ways in their instruction and viewed the use of manipulatives as playing, exploring, or changing of pace, but not necessarily as making sense of mathematical concepts or ideas.

Many studies have also shown teachers' lack of abilities to connect representations in problem solving. Hitt (1998) showed that many beginning secondary teachers were unable to articulate whether a curve represented by an algebraic form—circle or ellipse—was a function or not. Even (1998) showed that secondary teachers have difficulties in determining the number of zeros of an algebraic equation, $y=ax^2+bx+c$, due to their inability to connect the equation to its graph. In Presmeg and Nenduradu (2005), a teacher used mostly tabular/numerical representations in solving problems. Even for a problem in which he used a graphical representation, he came up with a line graph in spite of his table showing a quadratic pattern.

Teachers' Conceptions of Realistic Tasks

In the Netherlands, the RME theory has been used in teacher education programs to prepare preservice teachers, and there have been some reports attesting to positive effects from the programs. According to Korthagen and Kessels (1999), a national evaluation study of all Dutch education programs showed that preservice secondary teachers who were trained within the RME framework had higher ratings than their counterparts. Wobbles, Korthagen, and Broekman (1997) also showed that a group of preservice teachers trained in RME not only was much more in favor of RME principles than was a random group of experienced inservice teachers, but also characterized their teacher education program favorably—as using mathematics in contexts, having an inquiry approach, using mathematics as an activity, and using different explanations. However, when asked about important characteristics of "high school" mathematics education, only a few of the 10 preservice teachers mentioned that using mathematics in "realistic" contexts or mathematics as an activity are important characteristics.

As evidenced by research above, there is much to be done about secondary teachers' conceptions of the roles of representations and realistic tasks and their abilities to use multiple representations in problem solving. Yet research documenting the kinds of interventions implemented and the effects of such interventions is very limited. This study concerns this under-documented area. The details of this study follow.

Methodology

Research Contexts

The subjects of this study are three preservice secondary mathematics teachers—Jennifer, Kristal, and Shane (pseudonyms)—who took four mathematics content and methods courses. As undergraduates, the teachers majored in mathematics with an emphasis in secondary teaching and minored in mathematics education. In their junior year, they participated in the mathematics content courses, Math A and B (pseudonyms). After completing their undergraduate degrees, they entered a teacher education program, offered at the same university, to obtain secondary teaching credentials in mathematics. During the teacher education program, they had two mathematics education courses, ED A and B (pseudonyms). The three participants were specifically chosen for this study because they were the only teachers in the secondary teaching cohort who had taken Math A and B and Ed A and B.

The Math A and B courses had two main goals: helping future teachers reconceptualize the key concepts of grade 5-12 mathematics through the analysis of student work and tasks, and providing them with opportunities to construct mathematical ideas themselves through the problem solving of college level mathematics. Throughout the courses, the roles of representations and tasks in teaching and learning were emphasized through reading, discussion, problem solving, and task analysis by using *Young Mathematicians at Work: Constructing Fractions Decimals and Percents* (Fosnot & Dolk, 2002), *Making Sense: Teaching and Learning Mathematics with Understanding* (Hiebert et al., 1997), and the *Contexts for Learning* series. College level tasks based on historical contexts, such as Euclid, Archimedes, and Omar Khayyam as well as the tasks based on literature, such as Thompson (1994a) and Carlson et. al (2004), were also used so that preservice teachers themselves would experience construction of mathematical ideas. Most of the tasks used in the courses were realistic and naturally embedded representations. It is noteworthy, however, that much of the materials used in the courses were either at the grade 5-8 level or at the college level, due to their focus on student mathematics thinking at the grade 5-12 level and a lack of professional materials at the high school level that followed principles similar to RME.

The two graduate mathematics educations courses, Ed A and B (offered in the fall and winter quarters, respectively) focused mainly on grade 5-12 mathematics. The main activities for the courses were problem solving and discussion of articles regarding many issues in mathematics teaching and leaning. The two major components of the courses were *Young mathematicians at work, Constructing algebra* (Fosnot & Jacob, 2010) and the *Cookie*s unit from a reform based high school curriculum, *Interactive Mathematics Program*. Much of the class hours were spent on solving algebra problems and discussing students' construction of ideas in algebra. As a final portfolio, they submitted 15-20 pages of writing on the *Cookies* unit in which they explained how the unit brought out mathematical ideas—such as equivalence, inequality, variation, the Cartesian connection, and optimization—in relation to representations—such as the number line model and the Cartesian coordinate plane.

Data and Analysis

Two different types of data were used for analysis: two individual interviews and the Performance Assessment for California Teachers (PACT) teaching events. The first interview lasted about an hour and was conducted after the participants finished the Ed A course. The second interview lasted about 2 hours and was conducted while they were taking the Ed B course. Interview questions included items that could measure participants' problem solving tendencies and abilities, their conceptions of representations, and their student teaching experience and PACT. Both interviews were recorded with a video camera and were transcribed. Participants' written responses on the interviews were also collected. The PACT teaching event was collected at the end of their teacher education program.

There were 7 interview questions that regarded the first research question—"How were preservice secondary teachers' tendencies and abilities to solve problems using representations after taking courses that emphasized the roles of representations and tasks?" The questions were similar or identical to items in the MKT survey (Hill et al., 2008) or tasks in Dufour-Janvier, Bednarz, and Belanger (1987), Even (1998), and Knuth (2000). For the grade 5-8 level, included were three problems related to a division of fractions, $2/3 \div 1/6$; a multiplication of decimals, $1.5 \times .7$; and an algebraic expression, $(x+2)(x+3)$. For the high school level, included were four problems related to the number of solutions of $x^4 = x + 2$; the number of solutions of $\sqrt{x} = x - 2$; the solutions of an equation, $?x + 3y = -2$, with a graph of the equation provided; and the signs of a, b, and c in $y = ax^2+bx+c$, with a graph of the function provided. For analysis, I coded the kinds of approaches the participants used in problem solving and the correctness of their work.

For the second research question—"How were preservice secondary teachers' abilities to use tasks in instruction after taking courses that emphasized the roles of representations and tasks?", PACT events as well as interview items that were relevant to task design and implementation were analyzed. Two interview items asked the participants to generate a task and to explain how they would implement the task for students who had little instruction on the mathematical topics of linear functions and of quadratic functions. Three interview items asked them to explain the roles of representations, the roles of realistic tasks, and their experiences in student teaching. The PACT event was a collection of instructional materials—video clips of teaching segments, students' work samples, daily reflections on instruction, and commentaries—from a week-long learning segment of instruction during their student teaching. As such, it showed participants' abilities to design and implement tasks in instruction. Among multiple tasks included in the PACT event, I selected major tasks for which the preservice teachers spent 30 minutes or longer of instructional time. Because an implementation of realistic tasks normally requires a considerable amount of time, those tasks had a better chance to show participants' abilities to use representations and realistic tasks. Jessica and Kristal had two tasks and Shane had one task that met the selection criteria.

For the analysis of data related to the second research question, I modified the Context Scale of the Assessment of Facilitation of Mathematizing (AFM; Fosnot, Dolk, Zolkower, & Seignoret, 2006). The AFM Context Scale was a measuring tool, examining teachers' abilities to use contexts in teaching on three levels based on teachers' use of representations and tasks. Rather than classifying the tasks into three levels as in the AFM Scale, I classified the participants' tasks into two levels. The discriminating factor between the two levels was how they used tasks in instruction: If a task was used as an application of learned facts, it was rated Level 1; if a task was used as a departure of students' construction of mathematical ideas, it was rated Level 2.

Results

Tendencies and Abilities to Use Representations in Problem Solving

Analysis showed that despite taking the courses that focused on multiple representations and the connections among representations, preservice teachers showed tendencies to use traditional, algebraic approaches in problem solving for both grade 5-8 and high school level problems when they were not prompted to use visual/geometric representations. In addition, when they were prompted to use visual/geometric representations, they were more successful on the grade 5-8 level problems than on the high school level problems.

As for their tendencies to use visual/graphical representations, for each of the three grade 5-8 level problems, only one participant used a visual representation to answer the question when not prompted to do so. Kristal used an area model to explain why $(x+2)(x+3)$ is equivalent to x^2+5x+6, and Jennifer and Shane used the FOIL method to explain it. The same trait was shown for the questions regarding the division of fractions, $2/3 \div 1/6$, and the multiplication of decimals, 1.5 x .7. Shane used number line models to explain both operations, but Jennifer and Kristal used the invert and multiply method for the fraction problem and the multiplication algorithm for the decimal problem. Their tendencies to use algebraic approaches on the three high school level algebra problems were higher than those on the grade 5-8 level problems. Except for the case where Shane used a graph to answer one of the three problems, all three participants used algebraic approaches to answer the high school level questions. All three used algebraic approaches and successfully found a solution of ?$x + 3y = -2$; Jessica and Shane used algebraic approaches and successfully determined the number of solutions of $\sqrt{x} = x - 2$; Jessica and Kristal used algebraic approaches, but failed to determine the number of solutions of the equation, $x^4=-x+2$.

Despite having tendencies to use traditional, algebraic approaches for the grade 5-8 level problems, when they were prompted to use visual/geometric representations, they came up with representations to explain the grade 5-8 level problems. All three participants used area models to explain 1.5 x .7 and $(x+2)(x+3) = x^2+5x+6$, and Kristal and Shane used a number line model and an area model to explain $2/3 \div 1/6$. However, they were less successful in solving high school level problems using geometric representations, even with prompts. Although all three participants provided a solution successfully by examining the graph of ?$x + 3y = -2$, when prompted, they could not determine the number of solutions of $\sqrt{x} = x - 2$ or of $x^4=-x+2$ by using graphs. A major obstacle for them was that they did not know where to start. Kristal and Jessica said that with no y present in the equations, they did not know what graphs had to be considered. Yet when they were told that graphs of $y=x^4$ and $y=-x+2$ could be considered, they sketched the graphs and explained using graphs that there were two real solutions of $x^4=-x+2$. In the question where they had to determine the signs of a, b, and c in $y = ax^2+bx+c$, using the given graph, none of them could determine the sign of b successfully. They could determine the sign of a from the concave down shape of the parabola graph, but they were unable to use the location of the vertex to determine the sign of b.

It was noteworthy that they were unable to associate graphs to the equations, $x^4=-x+2$ and $\sqrt{x} = x - 2$, after taking many courses that emphasized the connections among representations. It was also noteworthy that their positive conceptions of representations did not help them to solve the problems. They said in an interview: “Graphs are important since they are used in all sorts of things. But if you don’t understand what graphs mean, then the graph has no meanings and it can’t serve its purpose”; “a teacher’s knowing many ways of representing is important because students learn differently”; and “representing in many ways is important because there would be some students who might not understand in one representation.” However when they were given tasks in which they had to solve by connecting representations, they were unable to do so.

Knowledge of Tasks

Their abilities to design and use realistic tasks shown in the two interviews were quite satisfactory, with all of them rated Level 2. For the linear function topic, Jennifer used a money context that showed a constant rate of change of 5; Kristal used a paper-cutting context which led to the linear function $y=2x$; and Shane used a context involving two different constant rates of change of jumps. All of them also explained that they were using the contexts as the start of the construction of the ideas such as slope, rate of change, and the initial value, by connecting tables and graphs to the problem contexts. For the quadratic function topic, Jennifer used a square number sequence context of 1,4,9, … and emphasized that the differences in the steps formed a linear function; Kristal used $y=x^2$ by connecting it to the linear function $y=x$ and $y=x^2 + c$ graphs; and Shane used a tile context in which the nth step included n^2 number of tiles. All of them explained that they were using the tasks as a departure of a meaning-making process, focusing on the development of concepts such as the rate of change of a quadratic function as a linear function or its connection to linear function by connecting tables, graphs, and problem contexts.

The tasks in their PACT events were rated lower than those on the linear and quadratic function concepts. Jennifer had two word problem tasks on linear functions, rated Level 2, which were similar to the tasks she provided in an interview. Kristal had two hands-on activities on linear inequality, rated Level 1, which she used as a practice of learned rules. Shane had a hands-on task on parallelogram, rated Level 1, which was basically a parallelogram constructing activity using the conditions of parallelogram learned in previous classes. Jennifer was the only one who used tasks as the departure of meaning-making process, and Kristal and Shane used the tasks as applications of learned facts.

Some factors that contributed to the lower ratings on PACT tasks were their students’ academic levels (or their beliefs about how students with lower academic abilities should be taught) and their lack of understanding about realistic tasks. In Kristal’s case, for example, although she believed that students in general needed to be given opportunities to construct ideas themselves, she learned from her teaching that her low academic level students could not learn mathematics in that way. She thus adjusted her teaching style, following behaviorism principles, and used mostly skill-based or low-level tasks in her instruction. Another contributing factor was their lack of understanding of "realistic" tasks. All three described realistic tasks as "real-life," "hands on," "fun," "interesting," "something that made them engaged," "making them want to learn math," and "incorporate something hands-on." But none of them mentioned that the use of tasks as the starting point of constructing mathematical ideas was important in task implementation. As such, when they were asked in interviews to design tasks on the topics with which they were familiar through the intervention courses, such as linear function and quadratic function, they came up with tasks that were similar to the tasks used in the courses and explained in the ways that they would use the tasks as the departure of understanding. But when they were given a topic with which they were unfamiliar, such as parallelogram in Shane's case, they focused on the fun, hands-on, interesting, and real-life part of tasks rather than on the use of tasks as the departure of construction of ideas.

Discussion and Conclusions

This study examined three preservice secondary teachers' problem solving tendencies and abilities to use representations as well as their abilities to use tasks in instruction after taking a series of mathematics and mathematics education courses that focused on representations and realistic tasks. The results of this study are bi-fold. As for their abilities and tendencies to use representations, on the positive side, they were able to solve problems or to explain ideas using representations other than symbolic for the grade 5-8 level problems when they were prompted to do. On the negative side, however, they could not solve high school level problems by connecting algebraic and geometric representations as in the teachers in Gagatsis and Shiakalli (2004) and Presmeg and Nenduradu (2005), even when they were prompted to do so. Algebra problems requiring the connections between symbolic and graphical representations, such as those in Dufour-Janvier et al. (1987) and Even (1998), were very challenging to them. Furthermore, when they were not prompted to use visual/geometric representations or approaches, they still showed tendencies to use algebraic or traditional approaches as in teachers in Nathan and Petrosino (2003).

As for their use of tasks in instruction, on the positive side, they developed beliefs that realistic tasks or multiple representations are important parts of learning. Unlike the grade 5-8 teachers in Moyer (2002) and Stylianout (2010) or in Wobbles, Korthagen, and Broekman (1997), the preservice secondary teachers in this study believed that it was important to understand mathematical ideas in many representational contexts, that students' construction of ideas was an important characteristic of secondary mathematics, and that realistic tasks were important. They also designed many tasks that embedded multiple representations that could potentially help students construct critical ideas. Yet on the negative side, they understood realistic tasks as tasks that were related to real-life, fun, and interesting, but not as tasks that were used as the departure of construction of ideas.

This study suggests that preparing secondary teachers should be done with special care. Teachers need to be provided with opportunities to design or modify tasks using traditional mathematics curriculum or ill-designed tasks. As shown in this study, it is difficult for them to design and implement tasks that can lead to students' construction of ideas on unfamiliar topics, if they learn the importance of tasks only with well-designed tasks. By having opportunities to discuss deficits in ill-designed tasks and to modify the ill-designed tasks into well-designed realistic tasks, they might develop knowledge of tasks that can be transferred into their teaching in various situations.

Preservice Elementary Teachers' Understandings of Greatest Common Factor Versus Least Common Multiple

Kristin Noblet
East Stroudsburg University

Little is known about preservice elementary teachers' understandings of greatest common factor (GCF) or how they relate to their understandings of least common multiple (LCM). As part of a larger case study in which an emergent perspective (Cobb & Yackel, 1996) was used to investigate preservice elementary teachers' understandings of topics in number theory, task-based interviews elicited participants' conceptions about modeling GCF and LCM using manipulatives, pictures, and story problems and the procedures for finding GCF and LCM using prime factorizations. Additional classroom data served to support findings. Participants held stronger understandings of modeling LCM than they did with modeling GCF. In contrast, participants' understandings of the procedure for finding GCF were far more robust than their understandings of how to find LCM.

Key Words: Number Theory, Preservice Elementary Teachers, Task-Based Interviews

Number theory content is integrated throughout elementary and middle school mathematics education in the United States, ranging from learning about evens and odds in early elementary school to greatest common factor (GCF), and least common multiple (LCM) in 6^{th} grade (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010). However, research suggests that preservice elementary teachers may not have the understanding of number theory (e.g., Zazkis & Liljedahl, 2004) necessary to increase U.S. elementary and middle school student achievement, which is currently unsatisfactory (U.S. Department of Education, 2015). Zazkis and colleagues contributed the bulk of what is known about (Canadian) preservice elementary teachers' understandings of topics in number theory, such as even and odd numbers (Zazkis, 1998), multiplicative structure (Zazkis & Campbell, 1996), and prime numbers (Zazkis & Liljedahl, 2004). Many of Zazkis et al.'s participants exhibited procedural understandings of the content and difficulty working flexibly with various number concepts. For instance, Zazkis (1998) found that participants struggled to associate "evenness" with "divisibility by two" and the presence of a two in the prime factorization.

Brown, Thomas, and Tolias (2002) investigated preservice teachers' conceptions of LCM. They found that their participants used one or more of three approaches for finding the LCM of two numbers. Two of these approaches required a great deal of brute force. The third and most efficient approach made use of the prime factorization of the two numbers, identifying the highest power of each prime factor. Of the participants that attempted to use the prime factorization method, not all were successful. Successful participants did not adequately explain why this method works, with the exception of one student. For students to possess a conceptual understanding of LCM, the researchers suggested that they first need a flexible understanding of prime factorization and how it relates to factors, multiples, and divisibility. Brown, Thomas, and Tolias also suggested that students require a connected understanding of LCM across representations, including prime factorizations and story problems.

Greatest common factor and least common multiple are interrelated concepts, but little is known about preservice elementary teachers' understandings of GCF or how they relate to their understandings of LCM. This paper aims to illuminate this relationship using data from a qualitative case study that investigated the nature of preservice elementary teachers' understandings of topics in number theory. An emergent perspective (Cobb & Yackel, 1996) was used to analyze and interpret multiple forms of data, including classroom observational notes, student coursework, and responses from two sets of one-on-one task-based interviews.

Methods

The emergent perspective (Cobb & Yackel, 1996) served as the lens for collecting and analyzing data. Through their empirical investigations, Cobb and Yackel identified certain aspects of classroom microculture and their corresponding psychological constructs that all contribute to the construction of student understanding at the classroom level. The researchers did not mean for "the classroom level" to be a physical location; instead it refers to the types of activity in which students are engaged. Cobb and Yackel claimed that researchers can use this framework to explain the social influences on the individual's developmental understanding. The psychological perspective was the primary lens used in this study, because the bulk of the data represent individual conceptions. On the other hand, via the social lens, classroom norms, expectations, and experiences that framed participants' perspectives on mathematics teaching and learning were explored and used to inform individual conceptions.

This interpretive case study (Merriam, 1998) centered on preservice elementary teachers who were seeking a mathematics concentration and enrolled in a number theory course at a large doctoral-granting university in the western United States. This served as a bounded unit (Merriam, 1998). By seeking a mathematics concentration, participants could be certified to teach mathematics through 8^{th} grade. All participants were Caucasian and female, typical of the elementary education major. While data for this study came from multiple sources, one-on-one task-based interviews with six participants (Brit, Cara, Eden, Gwen, Isla, and Lucy) served as the focus of the data analysis. Open thematic and constant-comparative coding (Corbin & Strauss, 2008) were used as part of the coding process. Member and peer checking as well as data triangulation were used to ensure trustworthiness.

Results

The first three sections that follow outline specific tasks used to elicit participants' understandings of GCF and LCM, and they synthesize participants' responses. The fourth and final section informs participants' individual conceptions by describing the coursework experiences that may have influenced their responses.

Modeling Greatest Common Factor

During the one-on-one task-based interviews, the interviewer asked participants to create a GCF story problem that would require someone to compute the GCF of 28 and 32. All participants (with the exception of Eden) eventually attempted to create a GCF story problem. Aside from Brit, who began her response by attempting to create a GCF story problem, participants engaged in different activities to help them respond to this task. Eden and Isla verbally recalled the basic definition of GCF; others began by using numerical methods to find the GCF of 28 and 32. The interviewer prompted participants to model the GCF using pictures or manipulatives if they did already use these models to create a story problem.

Participants modeled GCF using two distinct types of representations, similar to the two types of meanings or models of division. Ball (1990) referred to these as the *measurement model* and the *partitive model* of division. However, participants were familiar with the phrasing used in Beckmann (2008) from previous courses, the "How many groups?" model and the "How many in each group?" model. Beckmann's language was adapted to account for the complexity of GCF structure. With "How many subgroups?" representations of the GCF, the groups of *A* and *B* objects are broken up into the same number of subgroups, and this number is maximized. In other words, to find the GCF of *A* and *B*, we find the largest number of subgroups that both *A* and *B* objects can be broken into. With "How many in each subgroup?" representations of the GCF, the groups of *A* and *B* objects are each broken into subgroups with an equal number of objects in each, and this number is maximized. In other words, to find the GCF of *A* and *B*, we find the largest number of objects in each subgroup of both *A* and *B*. Implicit in this language is that all of the objects are equally distributed amongst the subgroups without remainders.

Cara and Lucy modeled or described how to model the GCF to assist them in creating story problems. They both drew from the "How many subgroups?" representation of the GCF. After finding the GCF of 28 and 32, Cara described how to break up 28 and 32 objects to show the GCF is four.

Cara: So you would end up with four groups of a certain number in it. So for 28, you would have four groups of seven, and with 32 you would have four groups of eight. So the number in your groups would be different, but the amount of groups is the same, showing that that represents the [greatest] common divisor.

Here, Cara first found the GCF numerically and used that number to model the GCF, rather than using the model to *find* the GCF. Cara went on to create a "How many in each subgroup?" representation of the GCF, and she used it to assist in creating a second story problem. Cara compared her model using this representation to the one she described using the "How many subgroups?" meaning of GCF, again emphasizing how one of the factors of 28 and 32 was immaterial. Cara was the only participant to demonstrate flexibility with these meanings of GCF.

Cara: So if we wanted, we could do it the opposite way. Where the groups are even, or the amount in the groups are even, but then the amount of groups might not be even in this case. So you would put 4 in each group.

Gwen also used a "How many in each subgroup?" representation of the GCF to assist in creating a story problem. Brit and Isla attempted to create "How many in each subgroup?" story problems first, rather than start with a visual model. However, Isla felt her story problem needed further explanation, and she explained using a visual model.

In her attempts to model GCF, Eden demonstrated a conflated understanding of the two meanings of GCF. She wanted both the number of subgroups and the number of objects in each subgroup to be maximized and equal. She was the only participant to not produce a valid visual model of GCF. However, not all participants demonstrated a strong understanding of how to model GCF visually; only a few participants successfully explained how to use manipulatives or pictures to *find* the GCF of two numbers. Instead, participants appeared more comfortable calculating the GCF using numerical means and using it to model breaking up the two quantities.

In contrast to their relative success in modeling GCF using manipulatives and pictures, none of the participants created a valid GCF story problem. As the only participant to unsuccessfully model GCF visually, Eden did not attempt a story problem. The other participants' story problems had a variety of flaws. Cara and Gwen did not include a statement that required the reader to maximize the quantity in question, essentially asking for a common factor rather than the *greatest* common factor. Gwen, Isla, and Lucy did not successfully contextualize the GCF structure in their story problems; instead, they referred to "objects" and "things." Many of the participants also struggled to pose an appropriate question. For instance, Isla's question did not specify that each group of "things" needed to be subdivided equally.

Isla: You had 28 things and your friend had 32 things. How could you each group your things where you have the same number in your largest group, but you couldn't have remainders left over?

Brit's scenario was the most successful, but the wording of her story problem was not concise or clear; it required reorganization and clarification.

Brit: OK, so if I have 28 dinosaur stickers and 32 flower stickers and I want to group the dinosaur stickers and the flower stickers together… and I want to give them to individual students. So I want to know what is the greatest… how many, how many dinosaur stickers and flower stickers am I going to need in each group? I want to use all of them in an equal amount of groups. So I want to know how many stickers are going to be in each group.

Modeling Least Common Multiple

The interviewer also asked participants to create LCM story problems that would require someone to compute the LCM of six and eight. Unless participants also modeled LCM using manipulatives or pictures, the interviewer later prompted them to do so. Every participant successfully modeled LCM visually, using pictures, manipulatives, or both. And all six participants explained how to use their visual models to find the LCM of two numbers.

Participants were less successful at creating LCM story problems. The most common struggle with modeling LCM story problems was that most participants posed a question asking for *any* common multiple, rather than the *least* common multiple. However, participants were overall more successful in modeling LCM story problems than GCF story problems. Two participants began with visual models or the meaning of multiplication before suggesting an LCM story problem. For example, Brit started by modeling the LCM of six and eight using Cuisenaire rods. She determined that the dark green rod was six units long and the brown rod was eight units long. Then she created one-color trains using the rods. Brit presented her solution in terms of what she would have students do, even though the question was not phrased in that context.

Brit: What I would have kids do… is line up the blocks until they match, which turns out to be three brown ones and four green ones. Then they would do three times eight is 24 and six times eight is 24, would be the least common multiple.

Brit explained that it was a "really good way to visually see it… All you have to do is line up the blocks in a row and connect it back to the math." Brit used this representation to help her organize her story problem. While initially wordy, Brit produced a relatively successful LCM story problem.

Brit: So I have a nice society where my only money is \$6 coins and \$8 coins… I only have those two amounts. So I want to know what amount I can make using the \$6 coins, just the \$6 coins, can make the same amount as just the \$8 coins. And I want the least, because I don't want to carry around that many coins in my pocket at the same time. So I want the least amount that I can make with \$6 coins that is the same as what I can make with \$8 coins.

In contrast to Brit, Cara reminded herself that the LCM of six and eight was 24, which is four times six and three times eight, or four groups of six and three groups of eight, in order to create her story problem.

Cara: So if you have six chocolate chips in this cookie, how many cookies with eight chocolate chips would you need to have the same amount of chocolate chips… er, how many cookies of six do you need, or six chocolate chips, and how many cookies of eight to equal the same amount of chocolate chips?

Like Brit, Cara chose an appropriate context, and interpreting the problem in terms of the meaning of multiplication (i.e., $a \times b$ means a groups of b objects) appeared to help with her development of the problem. However, her question concerning the number of cookies was not asking for the LCM of six and eight. Rather, it asked the reader to find factors by which we would need to multiply six and eight in order to obtain a common multiple. Cara also did not qualify this multiple. She simply stated that the total number of chocolate chips needs to be the same, not necessarily the *least* number of chocolate chips.

Eden started the interview task by generating a story problem. "The microwave timer will go off every six minutes and the oven timer will go off every eight minutes. When will both timers go off at the same time?" While this was an appropriate context, it is necessary to have a statement comparing the two timelines; it is unclear when the microwave and the oven timers last went off at the same time. Additionally, Eden did not specify that we want the *next* time the two timers will go off, which would imply the *least* common multiple rather than any multiple. Isla and Lucy also posed story problems using the context of time, and they ran into similar issues with phrasing. Gwen generated a new type of story problem. She referred to a single quantity and described how to arrange the quantity into even groups of six and also rearrange it into even groups of eight. In other words, this quantity is both divisible by six and divisible by eight.

Using Prime Factorizations

The interviewer posed a series of tasks involving prime factorizations to each participant, including one modeled after a task from Zazkis and Campbell's (1996) study concerning preservice elementary teachers' understandings of multiplicative structure. Given the prime factorization of a number, $M = 3^3 \times 5^2 \times 7$, participants discussed whether M is divisible by two, seven, nine, 11, 14, 15, 26, and 63. Participants in this study accomplished this with ease, which differed from Zazkis and Campbell's participants, many of whom struggled. As a follow-up question, participants were presented with a second prime factorization, $N = 2 \times 3^2 \times 5^3 \times 13$, and asked to find the GCF and the LCM of M and N. All participants determined the GCF with ease and successfully reasoned through how to find the GCF (identify the common prime factors and the largest prime powers that they have in common, and multiply). Because participants gave well-reasoned accounts for why the procedure for finding the GCF using prime factorizations works, their explanations were coded as demonstrating conceptual reasoning.

Participants were less successful in identifying and reasoning about the LCM of M and N. Eden and Gwen immediately and accurately found the LCM of M and N, which was $2 \times 3^3 \times 5^3 \times 7 \times 13$. Eden was not sure why the procedure for finding the LCM works; "that's just what we do." Gwen recognized, however, that the LCM must have all of the prime factors of M and N in order for the LCM to be divisible by M and N. Gwen did not discuss the powers in the factorization.

Brit and Cara initially found incorrect values of the LCM, but could not reconcile their answers with what they knew to be true about the LCM. This led them to rethink how they found their LCMs and eventually find the correct value. Brit initially thought the LCM to be $2 \times 3 \times 5 \times 7 \times 13$, because it is "what's left over" once you divide *M* and *N* each by their GCF and multiply. However, Brit was convinced that the product of *M* and *N* was equal to the product of their LCM and GCF (a fact participants explored in their number theory class), which was not true for her LCM. "In this case, [*N*], [the LCM] has to include at least two 3s, at least three 5s, and a 13. And for here, [*M*], it includes the three 3s, at least two 5s, and a 7." This observation helped Brit find the correct LCM, but she was not confident in her answer. It was not until she multiplied *M* and *N*, then divided by the GCF, and found the same value for the LCM that she trusted her answer. Cara initially could not decide whether the LCM was $2 \times 7 \times 13$ or $2 \times 3 \times 5 \times 7 \times 13$. She eventually decided on the latter, reasoning that all of *M* and *N*'s prime factors need to be represented in the LCM of *M* and *N*. When she tried to explain her reasoning further, Cara brought up the example of 6 and 8, which caused a conflict because the product of their prime factors, 2×3, was not equal to their LCM, 24. By figuring out how to use the prime factorization of 6 and 8 to find their LCM, Cara was able to correctly find the LCM of *M* and *N*.

Neither Isla nor Lucy were successful in finding the correct LCM of *M* and *N*. Isla insisted that the LCM was $2 \times 3^2 \times 5^2 \times 7 \times 13$, because it accounts for all of the prime factors of *M* and *N*, and it takes the smallest of the exponents. Isla could not explain why that made sense. Lucy acknowledged that you multiply *M* by something to get the LCM of *M* and *N*, and you also multiply *N* by something to get the same number. When prompted to explain what that meant for the prime factorizations, she suggested that we take the prime factors that *M* and *N* have in common and multiply them, which would give her 15. This seemed completely unrelated to the valid conception she had only moments before. When Lucy was reminded of what she had said about having to multiply *M* by something, she immediately realized that 15 could not possibly be the LCM, but she could not think of a way to find it. In short, four participants eventually arrive at the correct LCM for *M* and *N*, but only Brit demonstrated a relatively complete understanding of why the procedure for finding LCM works.

Course Experiences

Observational notes and participant coursework revealed that participants had a number of experiences in their number theory course that may have contributed to their responses to the interview tasks. Data revealed that participants did not have an opportunity to create, or even answer, GCF story problems in their number theory class. They were, however, given the opportunity to briefly explore visual and story problem representations involving LCM. Participants were asked to create and analyze an LCM problem for elementary or middle school students to solve as part of a homework assignment. Some participants designed tasks that required students to use Cuisenaire rods to find the LCM of two numbers (a procedure introduced in their number theory course) while others wrote story problems involving LCM in other ways. Later in the course, participants also solved and created story problems related to the Chinese Remainder Theorem. Gwen's LCM story problem was phrased similarly to the Chinese Remainder Theorem problems that participants worked with in class.

Participants worked with prime factorizations quite a bit in their number theory class, and they consistently demonstrated a great deal of success with them. They found prime factorizations on homework assignments and tests in order to determine the GCF and the LCM of two numbers. The reasoning behind these procedures was discussed at length in class.

Participants also had to use the properties of exponents to fully factorize numbers such as $a = 10^8 \times 30^5$. Implicit in all of participants' work with prime factorizations was the idea that numbers are divisible by their prime factors and by the products formed by subsets their prime factors.

Discussion

Given the interrelated nature of GCF and LCM, one might expect preservice teachers' understandings of these topics to be similarly robust or weak, depending on the individual. However, data suggest this is not the case. Participants demonstrated significantly less difficulty when modeling LCM visually and with story problems than they did when modeling GCF. The opposite appeared to be true when participants attempted to find the LCM and the GCF of two numbers procedurally using prime factorizations. All six participants used and explained the GCF procedure with ease. Only two participants immediately and accurately found the LCM, but the other four participants had failed attempts at finding the LCM, with two eventually succeeding. Only one participant successfully explained the reasoning behind the procedure.

As Brown, Thomas, and Tolias (2002) suggested, a flexible understanding of prime factorization is necessary for a robust understanding of LCM. However, as the data in this report suggest, it is not sufficient. The reasoning that participants used for determining the GCF of two numbers given two prime factorizations was similar to the reasoning that they used to determine the divisibility of *M*, however. This may suggest why participants demonstrated a stronger understanding of GCF with prime factorizations than they did of LCM. Additionally, from a set theory perspective, the GCF of two numbers is obtained by finding the intersection of their sets of prime factors, whereas the LCM of two numbers is obtained by finding the union of their sets of prime factors. Finding the union of two sets is a more complex process than finding the intersection of two sets. Also, allowing for some duplicate prime factors but not others, especially in the case of finding the LCM of two numbers, further complicates the procedure. This could explain participants' struggle with the procedure for finding LCM.

In contrast, it is curious that participants demonstrated significantly more success when modeling the LCM of two numbers visually and with story problems than finding the LCM using prime factorizations. It is also interesting that the opposite was true of GCF. It is possible that participants' number theory course experiences enabled them to be more successful in modeling the LCM than modeling the GCF of two numbers, because they had done so in class and on assignments. However, participants also found the LCM and the GCF of two numbers using prime factorizations in class multiple times. And course experience did not necessarily lead to success in finding the LCM. The reasoning behind these procedures was also discussed in class, and participants only consistently recalled the reasoning for the procedure for finding the GCF.

It is important that preservice elementary teachers have robust understandings of the concepts that they could one day teach (e.g., Conference Board of Mathematical Sciences, 2012). Further investigation is warranted to determine the necessary interventions to ensure these future teachers have a flexible understanding of GCF and LCM, and their relationship. However, the additional success that participants demonstrated modeling LCM, as opposed to modeling GCF, does suggest that number theory courses designed for preservice elementary and middle school teachers provide more opportunities for students to model GCF using manipulatives, pictures, and story problems.

Examining Lecturer's Questioning in Advanced Proof-Oriented Mathematics Classes

Dimitrios Papadopoulos	Tim Fukawa-Connelly	Keith Weber
Drexel University	Temple University	Rutgers University

There has been a substantial increase in mathematics education research in how proof-oriented university mathematics courses are traditionally taught. In this paper, we focus on the questions that lecturers pose to students. Specifically, we audio-recorded 11 proof-oriented mathematics lecturers and analyzed all of the questions they asked their students. We categorized each of the 1,031 questions according to a coding system we describe as well as identified wait time and subsequent speaker. We describe trends across all 11 lecturers, highlighting the limited opportunities students had to engage in important mathematical practices, and identify variances between how different lecturers used questions. We present qualitative data highlighting common and uncommon questioning techniques and conclude with a discussion of our results.

Key words: Questioning, Proof-oriented mathematics courses, mathematical responsibility

In recent years, there has been a substantial increase in mathematics education research in how proof-oriented university mathematics courses are traditionally taught (e.g., Fukawa-Connelly, 2012; Fukawa-Connelly & Newton, 2014; Lew et al., 2016; Mills, 2014; Pinto, 2013; Weber, 2004; Weinberg et al., 2016). Our work differs from the cited literature in two ways. First, previous research in this area has tended to focus on the information that mathematics professors convey to their students and how they choose to convey this information. In the current study, we focus on the questions that lecturers pose to their students. Second, previous investigations into mathematicians' pedagogy of advanced mathematics are largely comprised of case studies that describe a single mathematicians' pedagogy. In the current study, we examine the pedagogical practices of 11 mathematicians, from which we can analyze consistencies and differences across our sample. The goal of this paper is to make three points: (1) Although teacher questioning was common in our sample of lecturers, students' opportunities to participate in lectures were usually limited. (2) There was substantial variation in the types of questioning that mathematics lecturers used, which suggests that lecturing in advanced mathematics is not a uniform pedagogical practice. (3) Although it was not common in our data set, some lecturers used questioning to engage students in important mathematical practices.

Literature Review

Teacher questioning can serve many purposes. Teachers can use questions to elicit student thinking (e.g., Martino & Maher, 1999), set the stage for future investigation (e.g., Boaler & Brodie, 2004), generate discussion (e.g., Stein & Smith, 2011), focus students' attention (e.g., Lew et al., 2016), and promote mathematical discourse in general (e.g., White, 2016). We focus on one specific role -- inviting student participation (e.g., Martino & Maher, 1999; Mesa, 2010).

According to White (2016), mathematics education researchers examining questioning have aimed to characterize teacher questioning in three different ways: First, some researchers have investigated patterns of teacher questioning. A notable example of this type of research is

Wood's (1998) funneling and focusing patterns of questioning. Second, other researchers focused on the cognitive level of questions that were asked, such as how teachers' questions relate to Bloom's taxonomy (e.g., Emerson, 2011). In the third category of research, "question types have generally been provided in broad categories to elicit students' thoughts and participation" (White, 2016, p. 20). The current paper fits into this third category of research; we categorize teacher questions by what types of mathematical products they are designed to elicit.

From our perspective, one way that we can characterize the extent that instruction is student-centered is by identifying the extent to which the teacher and the student are responsible for generating the mathematical content in the course. Rasmussen and Marrongelle (2006) claim that one end of this continuum would be "pure discovery," in which students are responsible for generating all of the mathematical ideas. The other end of this continuum is "pure telling"—a lecture with no teacher-student interactions. A weakness of a classroom based on "pure telling" is that the instructor is responsible for supplying nearly all of the mathematics in the classroom, including how concepts are defined and represented, the procedures that are used, and whether a solution is correct or not. Consequently, students are denied the opportunity to engage in important mathematical practices such as defining, conjecturing, and representing (Weber et al., 2010). However, few lectures in advanced mathematics consist of "pure telling." Professors usually make *some* attempt to elicit ideas from students, and the most common means to do so is via teacher questioning. The goal of this paper is to understand what types of mathematics are solicited in the questions that professors ask and the extent to which students are given genuine opportunities to participate in the advanced mathematics lectures that they attend.

Methods

We first describe our participants, including how we recruited participants and the content of their courses. We then describe data collection methods. We conclude by describing how we coded the lessons.

Participants. We recruited participants by sending e-mails to every lecturer at three institutions teaching a proof-oriented course in advanced mathematics. We asked if we could observe, take notes on, and audio record one of their lectures. Lecturers were not told the purpose of the study. Eleven lecturers agreed with at least three instructors from each institution. The course content included Number Theory, Real Analysis, Linear Algebra, Abstract Algebra, Geometry, and Differential Geometry.

Data collection. For each lecturer, a member of the research team attended a class in which an exam was not given. The researcher audio-recorded the lecture while transcribing everything that the lecturer wrote on the blackboard into the researcher's notes using a LiveScribe pen (i.e., a pen that one can use to simultaneously audio record and take notes so that the timing of the notes is coordinated with the audio-recording).

Coding the lectures. Each lecture was transcribed. Then a member of the project team flagged every instance in which a lecturer asked a question or provided an invitation for students to participate. We first categorized the content of each question as either mathematical (What is a ring?) or non-mathematical (e.g., Do you have any questions about the syllabus? Do you know when your exam is?). Questions that were non-mathematical were excluded from subsequent analysis. In what follows, we discuss how we coded the remaining 1,031 questions. For each question, we listened to the audio-recording and recorded the number of seconds that passed before the lecturer or a student spoke. We also noted who spoke next, the lecturer or a student.

In the next phase of analysis, we sought to categorize questions by the types of mathematics elicited from the students. We formed categories of teacher questioning using a semi-open coding scheme, drawing on grounded theory in the style of Strauss and Corbin (1998). Our initial coding scheme was adapted from the framework that Fukawa-Connelly (2012) developed to account for lecturers modeling of mathematical behavior in advanced mathematics (which was informed specifically by the work of Selden and Selden (2009) and Alcock (2010)). The categories included the selection of proof frameworks (Selden & Selden, 2009), choosing a next step in an argument, justifying or warranting a step in a proof (e.g., Weber & Alcock, 2005), and exemplifying a concept or step in a proof (Alcock, 2010). However, not surprisingly, these initial categories did not capture many of the questions that we encountered. In many cases, these questions were easily captured by existing categories described in the literature, including checks for understanding (Mills, 2013), verbal tics (e.g., adding "right?" at the end of sentences) (Mesa, 2010), and eliciting facts (Viirman, 2015). When these occurred, we expanded our list of categories to include these categories. Some questions did not fit into our initial categories or the categories from the extant literature. When this occurred, we created new categories and descriptions to account for these questions.

With the final coding scheme, each lecture was assigned to one of the original four coders for final coding of the questions. The codes, descriptions of the codes, and examples of each code, are provided in the results section. Subsequently, a second coder re-coded a randomly chosen 20-minute segment of each 80-minute lecture (approximately 25% of the duration of the lecture), or 258 questions. The coders agreed on 236 of the codes (91.47% agreement, Cohen's Kappa = .90), representing a very high level of agreement.

Results

We first present our final codes, descriptions, and examples of each code. We then present data highlighting how these question types were used across the lectures and how there was variation in individual lecturers use of questions. We then present qualitative data highlighting how we coded the lectures and notable questioning techniques we observed.

Coding and Categories. Table 1 details the final coding scheme agreed upon by the team.

Table 1
Descriptions, and example questions by code.

Code	Description	Example Question(s) (Source)
Check for Understanding (C)	Questions or invitations that ask if students are okay, understand, or are with the lecturer.	"Alright, any questions about this calculation?" (L4)
Tic (T)	Statements formulated as a question that are habitual and frequently repeated throughout a lecture.	"No matter where I am on the cylinder I am going to fall on one of the [student: circles] circles and one of the lines, yeah?" (L11)
Fact, Computation, or Recall (F)	Questions or invitations that ask for specific pieces of information (e.g. definitions, computations, theorems, etc.).	"So what is *f* plus *g*?" (L5) "[…] what was the identity element in Z_n?" (L9)
Big Idea (B)	Questions or invitations that address broad concepts that are explored throughout or across lectures.	"[…] in fact, the question was […] how can we characterize what's coming here?" (L9)
Next Step (NS)	Questions or invitations that ask students to recommend a course of action that would continue the logical progression of a proof or example.	"(Student name)? What can we do with this information?" (L2) "Therefore, now what?" (L7)

Proof Framework (PF)	Questions or invitations that address higher level logical structures of a proof.	"What would I need to prove in order to make this relevant to the Euler Phi function?" (L6)
Warrant (W)	Questions or invitations that ask for a justification for a statement or claim.	"How do I know that (Student name)?" (L2)
Evaluate a Claim (E)	Questions or invitations that provide a truth-value for a statement.	"Does *x* minus two divide this function?" (L5)
Addressing a Convention or Notation (CV)	Questions or invitations that address a convention or notation	"How do you write the identity in cycle notation?" (L5)
Clarifying Student Responses (CS)	Questions or invitations that seek clarification of students' ideas or restate what students say	"You're asking […] once it stabilizes from one step to the next is it stable all the way?" (L4)
Other (O)	Questions or invitations that do not fit into the other categories	"Are ideals that contain 1 very interesting?" (L2)

Examining findings across all lectures. We coded 1031 questions providing an average of 93.7 questions per lecture. Collectively, Table 2 highlights the limited opportunities lecturers provided their students to engage in important mathematical practices. For example, lecturers most often provide students with opportunities to address factual questions (F, 26.4 per lecture) followed by next step questions (NS, 10.5 per lecture). Excluding checks for understanding and tics, lecturers asked all other question types an average of 22.6 times per lecture.

Because we do not consider Checks for Understanding or Tics to be genuine invitations, we omit these categories from further analysis. Without these two question categories there are a total of 654 questions or 59.5 questions per lecture. Table 2 also provides the number of questions per lecture within each wait time category by question type. This data highlights the limited time students had to hear, consider, and respond to a lecturer's question. For instance, students had less than 3 seconds to respond on over 80% of questions. Only 4.5 questions per lecture had a wait time of more than five seconds. Although in many cases a student responded to questions in less than 3 seconds, we note that less than 3 seconds is likely not enough time for all students to hear, consider, and respond to a question.

Table 2
Total number of questions (N) and wait time (0 s. - >5 s.) per lecture by Question Type.

Question Type	N	0 s.	1-2 s.	3-5 s.	>5 s.
Check for Understanding	10.5	--	--	--	--
Tic	23.8	--	--	--	--
Fact, Computation, or Recall	26.4	13.1	6.8	4.0	2.5
Big Idea	1.4	1.1	0.1	0.2	0.0
Next Step	10.5	4.8	3.8	1.4	0.5
Proof Framework	2.8	1.5	0.9	0.3	0.2
Warrant	5.6	2.8	1.7	0.5	0.6
Evaluate a Claim	3.1	2.0	0.6	0.4	0.1
Addressing a Convention or Notation	2.5	1.2	0.9	0.3	0.1
Clarifying Student Responses	3.2	2.6	0.5	0.0	0.1
Other	4.0	2.1	1.3	0.3	0.4
Total	93.8	31.2	16.6	7.4	4.5

Students responded to an average of 24.1 questions per lecture. Further, whereas Table 2 highlights that lecturers infrequently gave students opportunities to participate in important mathematical practices (e.g., providing a warrant), Table 3 shows that, when given the opportunity, students addressed most question types with about the same relative frequency. Hence, students were willing to engage in important mathematical practices during a lecture but were not given significant opportunities to do so.

We defined a question as a *genuine invitation to participate* if the question was not a Check for Understanding or Tic and either a student responded or the lecturer provided more than five seconds of wait time. On average there were 26.6 genuine invitations to participate per lecture. Of the questions that meet the genuine invitation criteria, factual questions and next step questions accounted for 16.3 questions per lecture. In contrast, there were relatively few genuine invitations to provide warrants (2.7 questions per lecture), give insight into a proof's framework (1.5 questions per lecture), or evaluate a claim (1.1 questions per lecture).

Table 3

Number of questions (N), student responses (S), teacher responses (T), and genuine invitations (GI) per lecture (and as a percent) by Question Type.

Question Type	N	S	(%)	T	(%)	GI
Fact, Computation, or Recall	26.4	10.5	(39.7)	15.9	(60.3)	12.0
Big Idea	1.4	0.00	(0.0)	1.4	(100.0)	0.0
Next Step	10.5	4.1	(38.8)	6.5	(61.2)	4.3
Proof Framework	2.8	1.4	(48.4)	1.5	(51.6)	1.5
Warrant	5.6	2.5	(43.5)	3.2	(56.5)	2.7
Evaluate a Claim	3.1	1.0	(32.4)	2.1	(67.6)	1.1
Addressing a Convention or Notation	2.5	1.0	(40.7)	1.5	(59.3)	1.0
Clarifying Student Responses	3.2	2.5	(77.1)	0.7	(22.9)	2.5
Other	4.0	1.3	(31.8)	2.7	(68.2)	1.5
Total	59.5	24.3	(40.5)	35.5	(59.5)	26.6

Identifying differences across lecturers. Although lecturers generally limited students' opportunities to engage in mathematical practices, there was variance in regards to how lecturers used questions. As a way to compare this variance, consider Table 4. We note that 25 of the 31 proof framework questions and 78 of the 117 next step questions came from two lecturers, L2 and L8, and that a majority of the lecturers provided students with little (3 or less questions) to no opportunities to engage in the practice of writing proofs. We also note the wide variance in the number of genuine invitations per lecture, from as few as 0 (L2) to as many as 66 (L8).

Table 4

Number of instances of each Question Type and Genuine Invitations (GI) by Lecturer

Lecturer	C	T	F	B	NS	PF	W	E	CV	CS	O	GI
L1	4	1	12	3	4	2	4	4	11	1	4	10
L2	1	28	21	1	23	12	10	1	1	3	12	54
L3	12	6	29	0	8	0	12	2	1	11	1	29
L4	7	0	41	0	8	0	1	1	3	1	1	43

L11	5	25	8	0	4	0	0	4	0	0	1	7

Examples of lecturers' questioning. In this section, we provide qualitative data for two purposes: (1) to highlight how we coded questions within a lecture and (2) exhibit examples of common and uncommon questioning techniques we observed. For each question, we provide the question code and wait time using the convention [Code; WT (Wait Time): Number of seconds]. We annotated the transcripts for readability without changing the overall flow of the interaction.

A common questioning phenomenon we observed involved a lecturer posing a question to students without providing a genuine invitation to participate. In these cases, we often observed that lecturers responded to the question on their own, asked a follow-up question, or moved on without addressing the question. As an example of this, we present an excerpt from L8 discussing that any ring element is in the ideal *I* when the element 1 is in the ideal.

[1] L8: All right, here's a first question, okay, if *R* is a ring with 1, say *R* is commutative with 1 and *I*, an ideal in *R*. Okay? [T; WT: 1]. Is 0 in the ideal? [NS; WT: 1]. Yeah, how do I know that [S1]? [W; WT: 0].
[2] S1: The zero set is an ideal.
[3] L8: Yeah, but how do I know it has to be in there to begin with? [W; WT:0]. The zero set is an ideal, zero absorbs things. In particular, an ideal is what? [F; WT: 1].
[4] S2: A subring.
[5] L8: A subring. It has to have zero, right? [T; WT: 0]. *I* has zero. Does 1 have to be in *I*? [F; WT: 2]. Not necessarily. What if 1 is in *I*? [F; WT: 5]. What can you say? [NS; WT: 1]. Well 1 is what? [F; WT: 0]. The multiplicative identity, so what does that mean [S3]? [F; WT: 1].
[6] S3: That *I* is a ring with identity?
[7] L8: Yeah, but what does it mean for 1 to be the identity? [F; WT: 0]. What's the property of the multiplicative identity? [F; WT: 1].
[8] S3: An element times that [the multiplicative identity] is itself.
[9] L8: An element times that is itself. So *r* times 1 is? [F; WT: 2]
[10] S3: *r*.
[11] L8: *r*, okay? [T; WT: 0] But if 1 is in *I*, where is *r* times 1? [F; WT: 1].
[12] S3: In *I* as well in *R*.
[13] L8: Yeah. So what can I say about *I*? [NS; WT: 1]. It's all of *R*. Do you guys see that? [C; WT: 0]. If 1 is in *I*, then *I* is actually equal to *R*.

L8 posed several questions in this excerpt that she then answered herself ([1], [3], [5], [13]) or followed with another question ([1], [5], [7], [11]). In each of these cases, L8 provided little or no wait time. Of the 18 questions present in the excerpt, only 6 questions were genuine invitations to participate. Additionally, this excerpt exemplifies the high number of factual questions lecturers ask; nine of the eighteen questions in this excerpt were coded as factual.

Although generally lecturers did not provide students with significant opportunities to participate, this was not true across all lecturers. For example, L2, a real analysis instructor, provided students many genuine opportunities to participate by calling on students in a particular sequence, without the students necessarily volunteering to answer questions. The following excerpt shows the lecturer using his questioning technique to engage students in a proof of the fact that multiplying a converging series by a constant generates a series that also converges.

[1] L2: [S1 name], you want to start, how do you prove this one [*writing "Proof of 1" on the board]*? [PF, WT: 1]
[2] S1: Start with what you know.
[3] L2: Always a good strategy. What do you know? [PF; WT: 1].
[4] S1: We know that uh, a_n converges to A.
[5] L2: [*Writes "Given that* $\{S_N\}$ *converges to A, where* $S_N = a_1 + \ldots + a_N$"] Okay, [S2 name]. That's what we know. [NS, WT: 1].
[6] S2: Uhh, cS_n equals the [inaudible].
[7] L2: [*L2 indicates there are too many "S" letters on the board and decides to change his notation from* S_N *to* T_N *and writes "Need to show that* $\{T_N\}$ *converges to cA, where* $T_N = (ca_1) + \ldots + (ca_N)$"] Okay, so. Write what you know. Write what you're going to show. Now [S3 name], I guess you're next. So this is what you know, this is what you're trying to show. What would you do next? [NS, WT: 1].
[8] S3: I'd grab a c from each of the terms.
[9] L2: [*Writes* "$T_N = cS_N$"] Like that? [CS, WT: 0].
[10] S3: Yeah.
[11] L2: So what is true then? [NS, WT: 1].
[12] S3: It converges.

Overall, we noted that L2's technique of sequentially calling on students provided students with many genuine invitations to participate (54 across the lecture). Whereas on average there were only 2.82 proof framework questions per lecture, L2 asked two such questions ([1], [3]) in this interaction alone. L2 also used a clarifying question [9] to verify that he accurately represented what the student intended to convey in his board work.

Discussion

In this study, we examined the questioning techniques of 11 lecturers in advanced mathematics courses at three institutions. Recall that we defined a *genuine invitation to participate* as questions that were not Tics or Checks for Understanding that either a student answered or the lecturer allowed greater than five seconds of wait time. This data highlights that generally invitations for students to participate in advanced mathematics classes are limited. Further, on average, the vast majority of invitations for students to participate require students to cite facts, perform computations, recall previously covered material, or provide the next step in proof or example. Lecturers infrequently used questions to prompt students to consider or discuss a proof's framework or provide warrants.

Although we draw some generalizations by looking across all lectures, we also highlight that there is variance in how individual lecturers use questions. This variance can be seen both with respect to the use of certain question types and to the number of genuine invitations lecturers provided. Hence, we must be careful when making generalizations about lecturers questioning activities as our data suggests that lecturing in advanced mathematics is not a uniform pedagogical practice.

We also note that in some instances, lecturers used questioning to engage students in important mathematical activities. As presented, L2 was unique in calling on students in some order to answer questions, which resulted in providing students many genuine invitations to participate. Such novel questioning techniques that elicited genuine invitations to participate also highlight the variance in lecturer questioning in advanced mathematics.

Transitioning to Proof with Worked Examples

Dimitrios Papadopoulos
Drexel University

In this study, I explored the use of a worked-examples-based proof-writing framework as a pedagogical tool to improve undergraduate students' ability to construct proofs. Over the course of three months, I ran a series of three workshops with five undergraduate students who had no prior experience with formal mathematical proof. In each workshop, participants worked through worksheets containing completed worked examples of mathematical proofs, followed by partially completed worked examples of proofs (to be completed by the participants), and, lastly, exercises. I collected and coded participants' written work and reflections and explored changes in student proof-writing across workshop sessions. In this paper, I describe themes across student work and provide qualitative data supporting the benefits of incorporating the use of such a worked-examples-based proof-writing framework when introducing students to mathematical proof.

Key words: proof, worked examples, proof-writing framework

This study is motivated by the ongoing difficulties that students have in learning mathematical proof. As Moore (1994) points out, the transition from computational/procedural courses, such as calculus and differential equations, to proof-based courses is particularly difficult for undergraduate students. These difficulties are myriad and complex, and based on the experiences of both students and faculty, the traditional lecture-based classroom falls short of helping students overcome these difficulties. Fortunately, there is a growing body of knowledge on alternative methods of instruction such as guided reinvention, flipped classrooms, and worked examples. The purpose of this study is to explore the use of a worked-examples-based proof-writing framework as a pedagogical tool, implemented in a series of introductory workshops on mathematical proof-writing, to improve students' ability to construct proofs.

Literature Review

The instructional practice at the center of this research is that of *worked examples*. In mathematics education, the word "example" has several interpretations. The word example can refer to a particular instance of a concept (e.g. 7 is an example of a prime number). Alternatively, the word example can refer to the demonstration of technique as the written solution to a particular problem/exercise, a worked-out example – or simply *worked example*; worked examples are typical of undergraduate mathematics textbooks (Weber, Porter, & Housman, 2008). Lithner (2003) found that in procedure-oriented courses students "almost always" make use of worked examples in completing their homework and that this approach was used by students of varying mathematical ability. Other recent studies suggest that undergraduate students in proof-based courses might use worked examples to inform their construction of proofs (Weber, 2004). While Lithner (2003) expressed concern that the use of worked examples leads to students completing homework assignments without developing conceptual understanding, cognitive psychologists have emphasized the merits of having students use worked examples in problem solving (e.g., Zhu & Simon, 1987; Atkinson, Derry, Rankl, & Worthman, 2000).

As pedagogy, the *worked examples* model has, in recent years, received considerable attention from researchers and educators, especially in mathematics, physics, and computer science. While the defining features of the *worked examples* pedagogical model are subject to debate, the common thread is the goal of providing the novice (student) with an expert's problem solving framework, which is to be emulated in the interest of gaining conceptual understanding (Atkinson, Derry, Renkl, & Wortham, 2000). Three factors moderate the effectiveness of teaching by worked examples (Atkinson et al., 2000):

- Intra-example features – e.g. use of multiple modalities, clarity of substructure goals, completeness/incompleteness
- Inter-example features – e.g. example's proximity to matched problems, multiple examples per problem type
- Students' individual differences in processing examples – e.g. social incentives, self-explanation

In this study, I made use of findings in the *worked examples* literature to develop a proof-writing framework as well as a methodology for using that framework in a series of introductory workshops on mathematical proof-writing. In doing so, I took into consideration the inter- and intra-example features of successful *worked-examples-based* pedagogical models to create worksheets that deconstructed the proof-writing process according to that framework. This framework - that is, the specific way in which proof-writing is broken down into a series of subgoals - will be referred to as a *worked-examples-based proof-writing framework*.

Methods

Participants. The participants for this study were five second-year undergraduate students majoring in engineering, all with the very similar mathematical backgrounds. All of them had completed the first-year calculus sequence and were enrolled in an ordinary differential equations course at the time of the workshops. None of these students reported having any experience with mathematical proof, beyond high school geometry.

Materials. The theorems and exercises used in the workshops were drawn from introductory texts on mathematical proof-writing to reflect the material one would typically encounter in a transition to proofs course. For each session, worksheets were prepared which contained introductory information, such as definitions and descriptions of proofs types, fully worked-out examples, partially worked-out examples, and exercises.

Structure of Worked Examples. The structure of the worked examples was intended to decrease the cognitive load of the proof-writing process by encouraging students to deal with the various aspects of proof, as defined by Selden and Selden (2009), separately. These aspects of proof form the "conceptually meaningful chunks" or subgoals of the worked examples. The structure outline is as follows:

1. Proof construction
    a. Breakdown of problem/theorem statement into hypothesis and conclusion
    b. Brainstorming
        i. Identifying relevant and related definitions, axioms, and theorems
        ii. Identifying the end goal by considering the next-to-last step of the proof
    c. Translating the problem/theorem statement into hypothesis and conclusion into appropriate mathematical terminology and notation
    d. Application of definitions, axioms, and theorems to hypothesis

   e. Experimentation (attempts to connect definitions, axioms, and theorems logically or algebraically)
2. Formal proof write-up/presentation
3. Reflection (Only for Sessions 2 & 3)

As Catrambone (1994, 1996) argues, explicitly labeling subgoals improves the effectiveness of the worked examples. Furthermore, the subgoals of part (1) – the proof construction - are expected to elicit directed self-explanation from students. Part (1) of the worked examples corresponds primarily to *Hierarchical Structure, Construction Path*, and the *Problem-Centered* part of the proof, while part (2) – the formal write-up of the proof - corresponds primarily to the *Formal-Rhetorical* and *Proof Framework* parts of the proof.

Hierarchical Structure refers to "knowing what the proof has to accomplish and coordinating any sub-proofs or constructions" (Fukawa-Connelly, 2012, p. 328). By rewriting the problem/theorem statement in if-then form (assuming the original statement has not been presented in this way), the worked example identifies what the proof has to accomplish (conclusion) and the conditions under which this must be accomplished (hypothesis). For example, in Worked Example 1, the statement "Prove that the sum of two odd integers is even" is rewritten as "*If* two integers are odd, *then* their sum is even."

The brainstorming part of the worked examples addressed the *Hierarchical Structure* and the *Problem-Centered* part of the proof. Here, the goal of the proof is further clarified, key ideas are determined, and "the 'right' resources" are brought to mind. In Worked Example 1, the definitions of an odd integer and an even integer are called upon. The next-to-last step (x + y = 2N) is also written, further clarifying the goal of the proof.

In translating the proof statement into appropriate mathematical notation and terminology, the worked example introduces the *Formal-Rhetorical* part of the proof. This requires "primarily *behavioral knowledge* to complete" (Fukawa-Connelly, 2012). In worked example 1, the statement "*If* two integers are odd, *then* their sum is even" is rewritten as

$$If\ x, y\ \in \mathbb{Z}, then\ x + y\ is\ even.$$

The Application of definitions, axioms, and theorems to the hypothesis addresses the *Hierarchical Structure* and *Formal-Rhetorical* parts by "coordinating any sub-proofs or constructions" and "coordinating aspects of the proof"(Fukawa-Connelly, 2005).

The experiment phase of the worked example addresses the *Construction Path* and *Problem-Centered* parts of the proof. Here, a viable construction path is sought by exploring logical and algebraic connections between all aforementioned definitions, axioms, and theorems. During the presentation of this portion of the worked examples, I encouraged students to practice self-explanation.

Finally, having established a viable construction path, the formal write-up/presentation of the proof is focused on *Formal-Rhetorical, Construction Path,* and *Proof Framework* parts of the proof.

Data Collection & Analysis. In an interpretive qualitative study such as this, data is typically collected through interviews, observations, and document analysis (Merriam, 2002). In place of conducting individual interviews with participants, in Sessions 2 and 3 students were prompted to write written reflections for each problem. I coded their work and reflections for emergent themes, first on a granular level, then grouping those codes according to the five aspects of proof. Data collection methods are summarized in the following table:

Data Collection Method	Description
Written Reflections	For the Partial Examples in Sessions 2 & 3 students were asked to provide written responses to the following questions: 1. Why did you choose to prove this statement via direct proof/contraposition/contradiction? 2. What parallels can you draw between this proof and the examples above? 3. Which parts of our proof framework were most useful in working on this proof? 4. If you were unable to complete this proof, what gave you difficulty?
Observations	Each seminar session was audio recorded. Students were observed as they worked during each seminar.
Document Analysis	All student written work and reflections were collected and scanned at the end of each session.

Results

There were several notable themes in the ways in which students' proof writing changed over the course of the three workshop sessions. The most notable changes took place during the first session. Student work varied significantly on the Pretest, but, with only a small number of exceptions, no valid formal mathematical proofs were submitted by any of the students.

However, following the introduction of the work examples, all of the students were able to write at least one complete and valid proof on the Session 1 worksheet, with most doing so for more than one example/exercise. In the following table we see that the number of correct and mostly correct proofs increased significantly between the Pretest (PT) and Session 1, and that the number of incorrect proofs remained relatively low over the next two sessions. Here, "Mostly Correct" refers to proofs with minor errors or omissions, such as leaving variables undeclared and minor algebraic or arithmetic errors. Furthermore, while most of the proofs submitted on the Pretest were empirical or colloquial in nature, all of the proofs (or proof attempts) submitted after the introduction of the worked examples were deductive.

Session	Correct	Mostly Correct	Incorrect	Incomplete	Empirical or Colloquial	Deductive Proof	Out of
PT	1	1	20	2	17	7	24
1	9	9	4	3	0	25	25
2	5	9	2	2	0	18	18
3	6	6	7	0	0	19	19

Below are Rasa's and Paul's solutions for the same exercises on the Pretest and the Session 1 worksheet. The task in this case was to prove that for integers $a,b,$ and $c,$ if $a|b$ and $b|c$, then $a|(b+c)$.

	Pretest	Session 1
Rasa	If b is divisible by a and c is divisible by a, then b+c is divisible by a, because it is the same as adding the sum of the two separate fractions, since when adding two fractions with the same denominator, the numerators are added and the denominator stays the same.	If $a \mid b$ and $a \mid c$, then $a \mid (b+c)$ Let $b = m \cdot a$ and $c = n \cdot a$ $b+c = (a \cdot m) + (a \cdot n)$ $b+c = a(m+n)$ Let $N = m+n$ By definition since $b+c = aN$, then a is a multiple of b+c
Paul	$bn = a$ $cn = a$ n is any integer $b+c = a$ $bn_1 = cn_2 = (b+c)n_3$ $b = c = b+c$ $\frac{b}{n_2 n_3} = \frac{c}{n_1 n_3} = \frac{b+c}{n_1 n_2}$ n is a different integer for a, b, and b+c due to its difference in values for when a is an integer and the values $a \mid x$ where x is different for any value a is given	Let $a, b, c \in \mathbb{Z}$ an integer Then $\exists\, n, m \in \mathbb{Z}$ such that $an = b$ & $am = c$, $an + am = b+c$ • $a(n+m) = b+c$ where $n+m$ is P $aP = b+c$ Let $P \in \mathbb{Z}$ an integer such that $P = b+a$ $\therefore a \mid b+c$

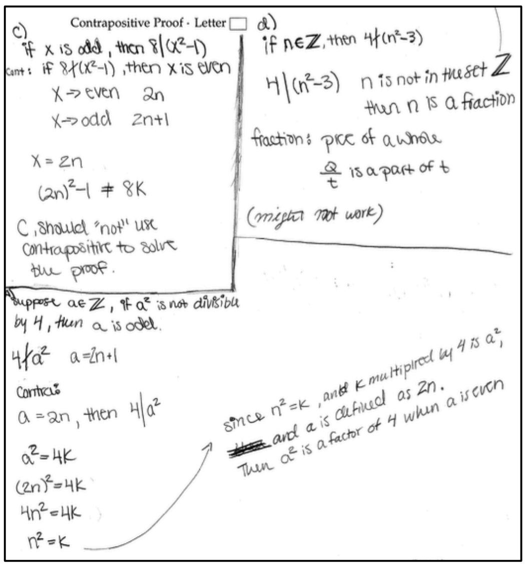
Rasa's proof on the pretest was primarily colloquial in nature, but her proof on the Session 1 packet was almost entirely correct, with the exception of undeclared variables, *m* and *n*. Modeling the formal write-ups in the worked examples, her proof followed mathematical convections such as use of notation, separating and labeling algebraic work, and writing in complete sentences. Paul, who attempted to operationalize the definition of divides on the Pretest, also wrote a correct proof on the Session 1 worksheet. Like Rasa, he wrote in complete sentences, indented his algebraic work, and clearly stated his conclusion.

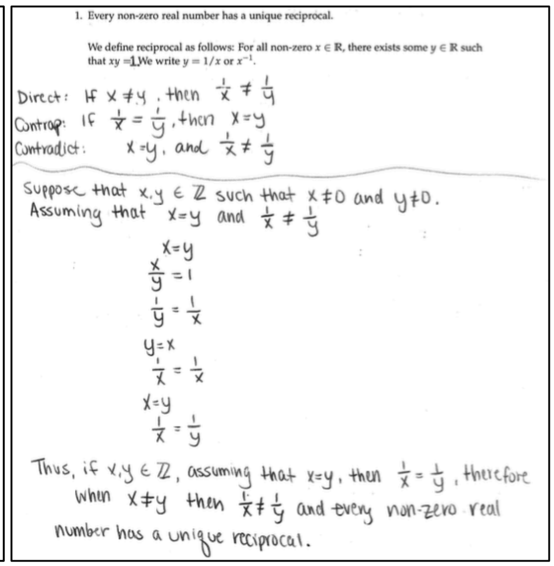
In addition to correctness, on a more granular level, the formal-rhetorical features of students' proofs continued to evolve over the course of the three sessions. In particular, all of the students included conventional notation and language, and declared all primary and secondary variables in the partial examples in Session 1. Here, primary variables refer to those which are used to represent quantities referenced in the hypothesis/assumptions of a given statement to be proven, and secondary variables refer to those used to operationalize a definition. In most cases students became less consistent with declaring secondary variables in the later sessions. The following table compares the total number of variables declared by all students in each session with the minimum number of variables required to construct correct proofs on those exercises. To establish these minima, I wrote out proofs for each example and exercise and had several mathematicians look over that work to determine if I had used the minimum number of variables possible to construct valid proof.

Example/Exercise	Primary Variables Total / Minimum	Secondary Variables Total / Minimum
Pretest Summary	27 / 40 = 67.5%	10 / 45 = 22.2%
Session 1 Summary	33 / 37 = 89.2%	33 / 45 = 73.3%
Session 2 Summary	17 / 20 = 85.0%	22 / 38 = 57.9%
Session 3 Summary	32 / 38 = 84.2%	25 / 48 = 52.1%

On average, students made and maintained significant progress after the Pretest in declaring primary variables, from 67.5% declared on the Pretest to 89.2% on the Session 1 worksheet and then maintaining roughly 85% for the last two sessions. However, in declaring secondary variables, there was a significant increase from the Pretest to Session 1, but then a decline in the final two sessions.

Finally, by Session 3, most students had begun to demonstrate a strategic approach to proof-writing, engaging in brainstorming and experimenting prior to attempting to write formal proofs. Consider, for example, Heather's work in Session 2 (left) and Rasa's work from Session 3 (right):





While Heather was unable to write an entirely correct proof for any of the exercises in this session, she did experiment with several statements to determine which might be most easily solved as either direct proof or proof by the contrapositive. In doing so, she started each proof and made notes regarding what "might work" and whether to use contraposition or not. For 6a, she did in fact write a mostly correct proof, although once again, variables were not properly declared. Rasa began her work on Exercise 1 in Session 3 by rewriting the given claim according to the three proof methods covered in these workshops, prior to selecting proof-by-contradiction and attempting to construct a proof. The work of both students here indicates planning as a separate activity from the formal writing-up of a proof.

In their written reflections, students most frequently identified brainstorming and experimenting as being the most valuable features of the worked-examples-based proof-writing framework. The following examples highlight some of their reasons for saying so:

Student	**Response**
Nadia	Definitely brainstorming is very important to understand what we are trying to proof but experimenting was important to fully understand the process.
Heather	There is NO way to know if the statements work w/ out experimentation.
Rasa	Experimenting and thinking which process would work best beforehand helped the most.

Paul	Experimenting and brainstorming are the easiest, without a plan to do the proof you cannot experiment to find answers and do trial and error methods.

Overall, these responses suggest that students found these steps useful because they allowed them to make sense of what the proof required prior to attempting a formal write-up.

Discussion

Most undergraduate mathematics students in the United States typically encounter formal mathematical proof-writing for the first time in a transition (or introduction) to proofs course. Such courses tend to following computation-centered courses, such as the typical freshman level calculus courses, and typically span only one semester. Because formal mathematical proof plays such a central role in advanced mathematics courses, it is important that we take full advantage of these transition courses to equip students with tools and experiences that will allow them to succeed in later proof-based courses. In this study, I aimed to explore the ways in which a worked-examples-based proof-writing framework could support students during this transitionary period.

This study was conducted independently of any transition to proofs course in order to focus on the ways in which this worked-examples-based proof-writing framework would affect novice students' proof-writing. However, the implications of this study for instruction lie primarily in the potential use of this type of framework as a tool to supplement instruction in an introductory course to proof. Worked examples are by their nature supplementary and of primary value to the novice.

Lithner (2003, 2004) expressed concern that in relying too heavily on worked examples to solve problems, students sacrifice opportunities to build on their conceptual knowledge and problem-solving strategies. For this reason, this study treats worked examples as a means to "provide an expert's problem-solving model for the learner to study and emulate" (Atkinson et al., 2000, pp. 181-182) and as a means to prompt guided exploration. As has been found in much of the worked examples literature, without examples to study, students may develop, and over time reinforce, novice strategies that ignore deeper structures in problem-solving activities (Weber et al., 2008).

The keys findings of this study suggest that a worked-examples based framework can both help novice students develop some of the basic proficiencies necessary for constructing and formally writing up mathematical proofs, and over time, facilitate productive habits, such as brainstorming and experimenting prior to attempting a proof write-up. These basic proficiencies include declaring variables, operationalizing definitions, using conventional mathematical language and notation, and structuring proofs in an organized, readable way. By encouraging brainstorming and experimenting, using this framework may help students develop some of the strategic knowledge required for mathematical proof-writing.

Regarding implementation, more research (see future research recommendations below) may be required to determine how one might best incorporate this framework into a standard transition to proofs course. However, given that the students who participated in this study received little instruction, and instead learned to construct proofs primarily by modeling worked examples, it may be that worksheets such as those used in this study could be used as supplementary materials in an introductory course on proof. Of course, they could be tailored to suit the specific content of the course and the needs of the instructor and students. The advantage to this type of purely supplemental use of the proof-writing framework is that little or no change is required of the instructor in terms of preparation or preferred teaching style.

Approaches to the Derivative in Korean and the U.S. Calculus Classrooms

Jungeun Park
University of Delaware

This study explored how one Korean and one U.S. calculus class defined the word "derivative" as a point-specific object through the limit process on the difference quotient, and as a function on its domain. The analysis using Commognitive approach showed that both class used similar visual mediators for the limit process/object, but addressed different components of the definitions; Discussion of the derivative as a function before it was defined were frequently found in the U.S. class but rarely found in the Korean class; Words for the derivative at a point, and words for the derivative as a function explicitly differed in the Korean class compared to the U.S. class; and the derivative was first defined as a function through correspondence between x-value and the derivative value in Korean class, but through expansion of x values from a number to variable and corresponding changes in the U.S. class.

Keywords: commognition, calculus, derivative, language, teaching.

Introduction

Calculus is considered as a first college level mathematics course that students encounter in the United States (U.S.). However, they often learn Calculus in high school as a form of Advanced Placement (AP) or a regular course. Similarly, in South Korea, most high school students who are on the college track learn basic calculus concepts because they are included in the national curriculum. This study looks at calculus lessons about the derivative from South Korea and the U.S. to explore how language specific terms for "the derivative at a point," and "the derivative of a function" are discussed in their lessons. In contrast to the English terms, both of which include "derivative," the corresponding terms in Korean, "Mi-bun-Gye-Sum" (translated to "differential coefficient") and "Do-ham-su" (translated to "leading function"), do not include a common term. Specifically, this study addresses the following research question:

> How is the derivative realized as an object at a point and an object on an interval in one high school class in South Korea, and one AP calculus class in the United States?

This study adopted Sfard's (2008) commognitive approach as an analytical tool. The purpose for the analysis was not to compare the way the derivative is taught in two countries, but to apply the same analytical lens in mathematical discourse involving two languages, focusing on how the two terms were addressed as a number or a function in each language.

Theoretical Background

Various studies considered languages as a factor for students' mathematical thinking. Some studies explored the relationship between specific language features and students' performance in mathematics in Chinese (e.g., Wang & Lin, 2005), Korean (e.g., Kim, Ferrini-Mundy, & Sfard, 2012), and Irish (e.g., Ni Riordain, 2013). Others considered cultural differences including languages in teaching and learning such as indigenous non-native English speaking students' learning, whose teachers were native English speakers (e.g., Favilli, Maffei, & Peroni, 2013; Russell & Chernoff, 2013); they revealed that the language difference was a main factor of teachers' decision on the content and the level of difficulty for the class, and teachers' knowledge about their students' native language was a key component of the teacher's knowledge for teaching mathematics. The current study also explores teaching mathematics in different languages, but also takes other means of communication into consideration such as use of visuals while exploring discussions of "derivative" in Korean and English by adopting the *commognitive* approach (Sfard, 2008) as a discourse analysis framework. It combines cognition and communication, and explains mathematical thinking through one's discourse through the four characteristics: *word use*, *visual mediators*, *routines*, and *endorsed narratives* (Table 1).

Table 1.

Features of Mathematical Discourse in Commognitive Approach

Feature	Descriptions	Further Descriptions
Word use	Use of words signifying mathematical objects	Different speakers can use a word differently. It is an "all-important matter" because "it is responsible to a great extent for how the user sees the world" (Sfard, 2008, p. x).
Visual Mediators	Non-verbal means of communication	Because ways people attend to visuals depend on contexts, mediators need to be viewed as part of the thinking process, not auxiliary means of pre-existing thought.
Routines	Well-defined repetitive patterns	Patterns can be found in speakers' use of words and visuals, or in the process of creating and endorsing narratives.
Endorsed Narratives	Utterances that speakers endorse as true	Students' endorsed narratives are often different from what the professional mathematics community endorses as true (e.g., "Multiplication makes bigger" changes to "Multiplication can make smaller.").

Note. Adopted from Park (2015, p. 234)

The first two characteristics are also considered as realizations. Sfard (2008) defined realizations of a signifier (either a word or visual mediator) as perceptually tangible entities that share Endorsed narratives, and mathematical object as a collection of these realizations. For example, a word "function" can be realized with a word, "mapping" or "relation," graph, equation, or gesture for a curve or straight line. With these four discursive characteristics, the development of various mathematical objects has been examined (e.g., Kim et al., 2012; Sfard, 2008). The current study addresses the development of "the derivative" through its realizations – words and visual mediators – in discourse from a Korean and an American calculus class.

The derivative, which is commonly mediated with symbols, is realized as a number (e.g., $f'(a)=\lim_{h\to 0}\frac{f(a+h)-f(a)}{h}$) and as a function (e.g., $f'(x)=\lim_{h\to 0}\frac{f(x+h)-f(x)}{h}$). The realization of "the derivative" includes several process and object transitions. First, for "the derivative at a point," the difference quotient (DQ) is considered as an initial object, and then the process of the limit over smaller and smaller intervals is applied, and then the final object from this process is be the derivative at a point. The limit process is often mediated with graphs of multiple secant lines; symbols for the limit; words such as "as *h* approaches 0, the DQ approaches..."; numbers for DQ. Through this process, the "derivative" is objectified as a number. Then, for "the derivative function," the derivative at a point is considered as an initial object, and the derivative process of finding the derivative at every point is applied. This process can be mediated with several tangent lines; several dots on an x-y plane; symbols including different letters (e.g., *x*); multiple numbers for the derivative. The derivative of a function would be objectified from this process.

Method

The purpose of this study is to explore mathematical discourse about the derivative from one Korean and one American calculus classroom. To this end, lessons for the derivative were videotaped 7 times for the U.S. classroom and 10 times for the Korean classroom when the teachers started the derivative unit. The video camera was located in the back of the classroom to minimize the interruption, and field notes were taken. The two instructors also participated in a 30-minute interview about what they believe as important to teach in their class. The interviews were also videotaped and used as a complementary data for the classroom data.

Participants

One Korean high school teacher, Mrs. Kim, and one U.S. AP calculus teacher, Mr. William (pseudonyms) (Table 2) were recruited via email sent to the group of teachers recommended by mathematics education professors at the researcher's institution.

Table 2.

Teachers' backgrounds and classes

	Mrs. Kim	Mr. William
First language	Korean	English
Degrees	BS in Mathematics	BS and MS in Mathematics
Teaching experience	13 years	10 years
Calculus teaching	3 times	7 times
Number of Classes/week	Three 50-minute classes	Five 90 minute classes
Teaching method	Blackboard and chalk	SmartBoard, interactive graphs
Number of Students	34	32

Coding Scheme

Videos from each class were transcribed, and then the excerpts including realizations of the derivative were selected. Excerpts for "the derivative at a point" were coded as a) *Initial Object: Location* where the initial object was defined; b) *Initial Object* where the limit process was applied; c) *Limit Process:Location* where the limit process was applied; d) *Limit process:Change* in the object; e) *Limit object* from the limit process, and f) *Limit Object*:*Location*: where the limit object was defined. Table 2 shows an example for such realizations. The first column shows codes for the limit process/object. The first row shows Mrs Kim's words or visual mediators.

Table 3.

Words and visual mediators in episode about limit process/object

Codes	Mrs. Kim's Words	Graph [Fig. 2]
Initial Object	ARC [is] the slope of the line	Top secant line
Initial Object: location	Passing through two points apart.	(a, f(a)), (b, f(b))
Limit Process: location	How do we move the points? Closer, closer…	$\rightarrow a$
Limit Process: Change	What happens to the slope? It's getting smaller and smaller (drawing three secant lines and arrows)	Three secant lines, arrow
Limit Object	We see the slope, the differential coefficient, and the instantaneous rate of change.	Tangent line
Final Object: location	At one point	A point *a*

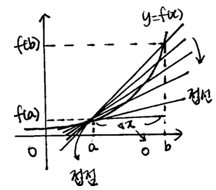

Figure 1. Realization of the differential coefficient with graphs

The excerpts about the derivative as a function were coded as a) *Limit Object*: the initial object where the derivative process was applied (e.g., the derivative at a point $x=a$); b) *Derivative Process-location: x* on the derivative process (e.g., as *a* vary); c) *Derivative Process-change*: change in the object (e.g., multiple numbers); d) *Final object*: the final object from the derivative process (e.g., graph or equation). The derivative process was categorized by five types: (a) *Expansion,* when excerpts expands from a number to a universal value on the location (e.g., "a certain point" to "any points") and/or the change (e.g., multiple tangent lines); (b) *Correspondence*, when excerpts map *x* values to the derivative function; (c) *Variation*, when excerpts include description of how the derivative varies on an interval (e.g., increasing); (d) *Universality*, when excerpts include explicit realization of the derivative defined at every point where the original function is differentiable; and (e) *Specification*, when excerpts include a transition from the derivative of a function to the derivative at a point (e.g., substitution).

Results

The results present realizations of "differential coefficient" and "leading function" in Mrs. Kim's class, and "the derivative at a point" and "the derivative of a function" in Mr. William's class. Only one of the visualizations for these cases was presented here due to the limited space.

Limit Process and Object in Mrs. Kim's Class

Among 44 episodes in Mrs. Kim's lessons about the differential coefficient, 25 of them included the limit process. The realizations for the limit process included words with symbols (11 of 25), symbols (7), words with graphs (5), and words (2) (Figure 2). These realizations highlighted the limited visual mediation of the limit process, but consistent use of words for the initial and final objects. First, most episodes only included the realization of the locations of the limit process with dynamic words or points on the curve without the change for the limit process. The change was addressed only once with graphs of secant lines. Second, uses of different visual mediators for the limit process were not consistent; two points on the curve were used for the location of the limit process, which was not consistent with the two *x* values in the symbol ($\lim_{x\to a}$). Third, in most cases involving symbols, both the location and change of the limit process were implicit; in the episodes about evaluating "differential coefficient" using the definition (e.g., Let $f(x+y)=f(x)+f(y)+3xy$, $f'(0)=3$. Find $f'(-4)$.), she transitioned from the difference quotient to the differential coefficient only with symbols ($\lim_{x\to a}$) without other explicit mediation of the limit process. It should be also noted that, Mrs. Kim consistently used the term "the differential coefficient" for the derivative as a point-specific object throughout the derivative lessons including the ones about the derivative process (e.g., the slope of a linear function, and the slope at any point on a graph). In most episodes, words mediating the initial and final objects were consistent (e.g., "slope" for both, or "average rate of change" and "the rate of change"). The term "differential coefficient" was defined synonymously with the terms for the final object.

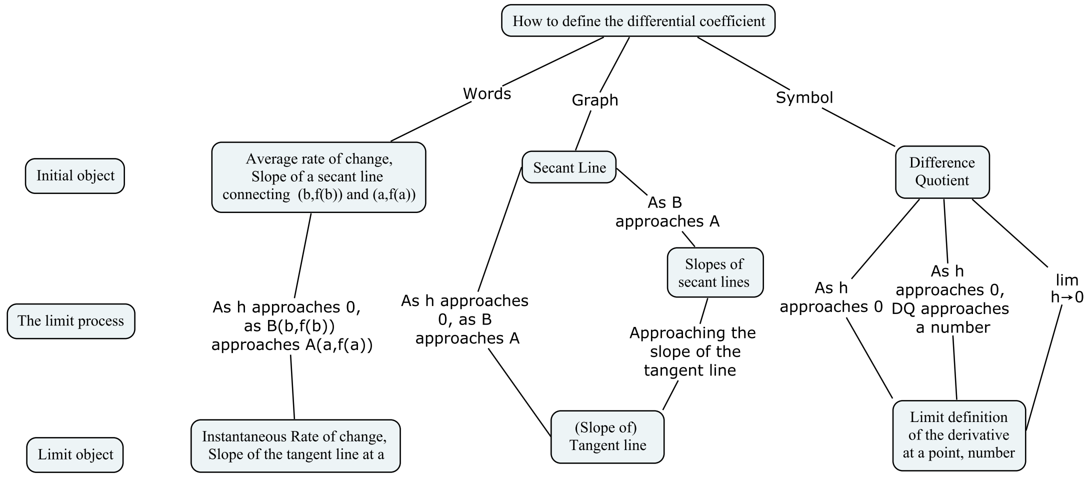

Figure 2. Realization tree for limit process/object in Mrs. Kim's class

Derivative Process and Object in Mrs. Kim's Classroom

Among 20 episodes about the leading function in Mrs. Kim's lesson, 17 addressed the derivative process, consisting of correspondence and expansion (6), computation (6), specification (4), and universality (1). Realizations of "the leading function" highlighted the limited use of visual mediators for the derivative process, and explicit word use of "differential coefficient" for the initial object, and "leading function" for the final object. First, the transition from the differential coefficient to the leading function was explained with symbols and words for the derivative process as correspondence; a diagram mapping a specific *x* value to "the differential coefficient," which was first realized as a "function" and then "the leading function." The two terms, "the differential coefficient" and "the leading function" were not directly related until "the differential coefficient " was computed as a value of "the leading function" with symbols (i.e., specification). "The differential coefficient" and "the leading function" were realized as the "same," only through symbols. Graphs were not used in any types of derivative process. Mrs. Kim mainly computed the leading function mainly following the limit process/object without mentioning any types of the derivative process. Her word use separating "the leading function" and "the differential coefficient" was also found. For example, she first described "the differential coefficient" of a linear function as "same" "always," and then used "the leading function" for the constant function. Also, she used "the leading function" for the equation, and "the differential coefficient" for its value at a point.

Limit Process and Object in Mr. William's class

Among 17 episodes in Mr. William's lessons about the derivative at a point, 11 of them included the limit process. The limit process was mediated with words (3), graphs, gestures and words (3), and symbols and words (5). Different components of the limit process/object was included in the discussion when the different types of realizations were used. First, when words and graphs were used, realizations included both the location and change for the limit process. However, when the symbols were used, the realization mainly included the location for the limit process besides one case where the words for the computation process mediated both the location (e.g., "substitute,") and the change (e.g., "zero over zero"). Second, the ways the limit process was discussed also differed across different mediators. The location for the limit process was mediated with words, gestures, and dynamic graphs for the values on the *x*-axis (e.g., " two *x* values," horizontal hand gestures, and "h" with numbers approaching 0), which corresponded to the limit notation in symbols (e.g., $\lim_{x \to a}$). However, on the stationary graph, his gestures for the location were mediating two points on the curve, not on the x-axis. Third, mismatches among realizations with different visual mediators were observed. Specifically, his gesture mediating the location for the limit process on a graph was not consistent with what is drawn on the graph. Also, the letter for a moving point included in a dynamical graph (e.g., (x+h) approaching x) differed from the letter included in symbols (e.g., x approaching a) that the graph mediated. Regarding word use, words for the initial object, the process for the limit process, and the final object were consistent in most cases (e.g., ARC and IRC; the slope for both the initial and final objects). However, there were several cases, the word "slope" was inconsistently used to mediate only either the initial object, the process for the limit process, or the final object. In some cases, secant lines and tangent lines mediated the limit process/object without word "slope."

Derivative Process and Object in Mr. William's Classroom

Among 16 episodes about the leading function in Mr. William's lesson, 15 addressed the derivative process, consisting of correspondence and expansion (1), variation (2), correspondence (2), universality (3), computation (4), and specification (3). He mainly used gestures and graphs to transition from the derivative as a value to a function. First, the location for the derivative process was mediated with his gesture of drawing and moving a tick mark on the board horizontally, and the change was mediated with multiple tangent lines. Second, the differentiability and velocity were addressed as specification after those words were realized as a function with graphs. "Differentiability" was addressed as a specification of the derivative at "every point" on its graph, and "velocity" at a point was realized as a specification of the velocity over time (e.g., gestures for the tangent lines on a curve, and then a hitting gesture for one point on the board). Similarly, the word "derivative" was used as a function after the graph of the derivative was drawn, and compared to the use of the same word "derivative" as a number, but the graphs for the "derivative" as a number (e.g., a tangent line, a point on the derivative graph) were not directly compared to the graphs of the derivative function. Regarding word use, transitions from the realization of the derivative as a point-specific object to a function were mainly made with the word "slope." The word "derivative" was not explicitly used in the derivative process. Although Mr. William specified two uses of "derivative" as a number and as a function several times while comparing the limit and derivative objects, he did not used the word in the derivative process through which he objectified the "derivative" as a function.

Discussion and Conclusion

The analysis of realizations of "derivative," in one Korean and one American calculus class led to 4 observations regarding word use and visual mediation. First, similar visual mediators were used in the realization of the limit process/object in both classes, but different components were included in the realizations in each class. While using words and graphs for the limit process, Mrs. Kim mainly mediated the location for the limit process, but Mr. William always mediated both location and change. Mrs. Kim's use for words and visuals for the initial object, limit process, and final object were consistent (e.g., "slope," "rate of change"), but Mr. William's words and visuals often varied (e.g., "the slope of a secant line" for the process and symbols for the final object without "slope"). They used the terms ("the derivative at a point" and "the differential coefficient") only for the final object mediated with symbols. Second, the realizations of the derivative as a function before it was defined were frequently found in Mr. William's class but rarely found in Mrs. Kim's class. Mr. William used "velocity" "acceleration" and "force," with the phrase "always changing," but Mrs. Kim never used "the leading function" before it was defined, or the synonyms for the "derivative" (slope, rate of change) as a function. Similarly, the word "differentiability" was realized as existence of "differential coefficient" at a point in Mrs. Kim's class, but was realized as a specific case of "the derivative function," in Mr. William's class. Similarly, the notation $f'(a)$ was used both classes, but only Mr. William used the word "any" for *a* before the derivative of a function was defined. Third, the words realizing the derivative at a point and the words realizing the derivative as a function explicitly differed in each class. The words differentiating the derivative as a point-specific object from the derivative as a function were nouns in Mrs. Kim's class. She explicitly used "the differential coefficient" for the derivative as a number, and "the leading function" for the derivative as a function, especially when discussing the relation between these two terms. In contrast, words realizing the derivative as a number or a function were often attached phrases to the "derivative," adjectives or adverbs, in Mr. William's class (e.g., "slope every point along *x,*" for the derivative function and "individual slope" for the derivative at a point). Fourth, the types of the derivative process through which the derivative was first defined as a function was different in each class: the *correspondence* between *x* values and the differential coefficients in Mrs. Kim's class, and the *expansion* of the derivative at multiple points in Mr. William's class. In Mrs. Kim's class, there was no direct transition from the term "the differential coefficient," to "the leading function." Instead, the word "function" was used between the terms "the differential coefficient," and "the leading function." In Mr. William's class, the main visual mediator for the expansion was graphs and the word "slope" throughout the initial object, derivative process, and the final object.

Although the differences in realizations between the two classes listed above seem related to their different use of words, the analysis does not imply such differences are caused by the two different words for the derivative as a point-specific object and the derivative as a function in Korean and English. However, the realization of the derivative as a function or the transition from the derivative at a point to the derivative function seems related to the key words mediating those objects. Considering the initial motivation of this study, the differences in language related terms, this study shows that Mr. William's use of words were more consistent while realizing the relation between the derivative at a point and the derivative of a function (e.g., use of "slope," or "velocity" throughout the initial object, derivative process, and the final object), than Mrs. Kim's. With the consistent use of words and corresponding visual mediators, the nouns realizing the derivative at a point and the derivative of a function were used in a more coherent way (e.g., one tangent line, multiple gestures for several tangent line, and then the graph of the derivative) in Mr. William's class. Their uses of words and visuals were also different when they transitioned from the derivative at a point to the derivative of a function, and when other related terms were realized (e.g., "differentiability" in each class), when and how the terms synonymous to "the derivative" was visually mediated (e.g., "rate of change" was realized as a function first, and then realized at a point in the flea example). Mr. William's consistent use of same words and visuals mediating both the derivative at a point and the derivative function, and Mrs. Kim's separate use of words for "the differential coefficient," and "the leading function" may not have been affected only by the different terminology. However, the differences in realizations of the derivative at a point and the derivative of a function seem consistent with the use of the word "derivative" for both objects in English, and use of two different terms, which does not show the relation between the two objects, in Korean.

Learning to Notice and Use Student Thinking in Undergraduate Mathematics Courses

Anna E. Pascoe
Michigan Technological University

Shari L. Stockero
Michigan Technological University

This study evaluated the outcomes of an intervention focused on developing mathematics graduate teaching assistants' (GTAs') skills of noticing and effectively responding to instances of student mathematical thinking that have significant potential to further students' learning. Four GTAs participated in a semester-long intervention that included individual analysis and group discussion of video of undergraduate mathematics lessons. The MOST Analytic Framework (Stockero, Peterson, Leatham, & Van Zoest, 2014) was introduced to aid in these activities. The GTAs also completed a pre- and post-interview to document their real time noticing and an assessment of common content knowledge. Results indicate that the intervention was successful in improving the GTAs' noticing skills in a variety of ways and in their ability to propose student-centered responses.

Key words: Graduate Teaching Assistant Training, Teacher Noticing

Research has shown that student-centered instruction leads to more effective learning for people of all ages (National Research Council, 2005). Higher education has been slow or unsuccessful in implementing student-centered instruction (Barr & Tagg, 1995; Felder & Brent, 1996), however, with transmissive instruction (i.e., lecturing) still prominent (Ramsden, 2003; Svinicki & McKeachie, 2014). Challenges for adopting student-centered instruction include student resistance, instructor comfort level, and the time needed to see results (Felder & Brent, 1996; Seymour, 2002). Some researchers suggest promoting changes in higher education teaching methods through GTA training (e.g., Cano, Jones & Chism, 1991). Since effectiveness of GTAs typically affects undergraduate students in their early years of study, GTA training is also important in student retention (Cano et al., 1991; Speer, Gutmann, & Murphy, 2005). With a workforce shortage in science, technology, engineering, and mathematics (STEM) fields (President's Council of Advisors on Science and Technology, 2012), student retention is crucial in university STEM departments (Seymour & Hewitt, 1997; Suchman, 2014).

At the K-12 level, a teacher's ability to notice aspects of instruction as it unfolds has been recognized as important in the implementation of student-centered instruction. Many studies have found that professional noticing of [students'] mathematical thinking—defined to include attending to, interpreting, and deciding how to respond to students' strategies and understanding (Jacobs, Lamb, & Philipp, 2010)—can be learned and improved through teacher education (e.g., Jacobs et al., 2010; McDuffie et al., 2014; Sherin & van Es, 2009; Stockero, Rupnow, & Pascoe, 2015). Although teacher noticing interventions are not widely practiced in higher education, the gains made with K-12 mathematics teachers suggest that similar results may be possible.

Also foundational to effective mathematics teaching are the six domains of mathematical knowledge for teaching proposed by Ball, Thames, and Phelps (2008). Critical to this study is common content knowledge (CCK), the mathematical understanding and proficiency used in diverse contexts not exclusive to teaching. Without CCK, a teacher could not adequately guide students in building such knowledge. In addition, mathematics teachers would not likely be able to determine which instances of students' mathematical thinking are important to notice without a strong command of CCK. Because both noticing skills and CCK are important for effective mathematics teaching, it would be of interest to investigate if and how these factors are related.

This work examines the outcomes of a GTA training intervention focused on analyzing undergraduate mathematics lesson videos with a teacher noticing framework as a means to support GTAs' use of student thinking more effectively, and thus the enactment of student-centered instruction in their classrooms. Of particular interest is measuring the effectiveness of the intervention in improving GTAs' noticing of mathematically significant pedagogical opportunities to build on student thinking (MOSTs) (Leatham, Peterson, Stockero, & Van Zoest, 2015) and in supporting their ability to propose student-centered responses to such instances. This work seeks to answer the following research questions: (a) How effective is the intervention in improving GTAs' noticing of MOSTs?; (b) How effective is the intervention in supporting the GTAs' ability to propose in-the-moment student-centered responses to instances they identified in video?; and (c) What is the relationship between the GTAs' CCK and their noticing skills?

Theoretical Framework

With the goal of improving GTAs' use of student mathematical thinking in undergraduate mathematics classrooms, this study used the MOST Analytic Framework (Leatham et al., 2015) to characterize instances of student mathematical thinking that are not only important to notice, but also the most fruitful to discuss in a lesson to support students' mathematical learning. MOSTs—**M**athematically Significant Pedagogical **O**pportunities to Build on **S**tudent **T**hinking—are defined as "instances of student thinking that have considerable potential at a given moment to become the object of rich discussion about important mathematical ideas" (p. 90). To be a MOST, a moment must satisfy three characteristics: student mathematical thinking, mathematically significant, and pedagogical opportunity. To satisfy these characteristics, the student mathematics must be inferable and related to a mathematical point, the mathematical point must be appropriate to the learning level of the students and a central goal for student learning, the student mathematics must create an intellectual need for students to understand the mathematical point, and it must be the right time to address the intellectual need at that moment.

Methodology

Participants and Intervention

The participants were four mathematics GTAs from a Midwestern U.S. university. They had completed one to two years of graduate study and taught for one to six semesters. They had all completed training required by the mathematics department: one week of GTA orientation prior to their first semester of study, a course entitled Teaching College Mathematics, and a six-week seminar during their first semester of teaching. Participation in the study was voluntary.

The GTAs engaged in a ten-week intervention facilitated by the first author in fall 2015. The goal was to improve the GTAs' skills in attending to, interpreting, and responding to MOSTs in a student-centered manner. The intervention design was adapted from Stockero and colleagues' work with prospective secondary mathematics teachers (Stockero, 2014; Stockero et al., 2015). Pre- and post-intervention, each GTA completed a one-on-one, video-recorded interview in which they watched an undergraduate mathematics lesson video clip, stopped the video if they thought a *mathematically important moment that the instructor should notice (MIM)* occurred, and then described why they selected the moment and what they might do if it had happened in their own classroom. A *MIM* definition was not given to the GTAs to establish baseline data.

In each week of the intervention, the GTAs used video analysis software to individually analyze an undergraduate mathematics lesson video in preparation for a weekly group meeting. In the first three weeks, the GTAs tagged *MIMs* and described in text what they noticed and why they chose each instance. After three weeks, the GTAs read a paper that defined the MOST Analytic Framework (Stockero, Peterson, Leatham, & Van Zoest, 2014). In that week, they reexamined two videos they had already analyzed and chose instances that they believed were MOSTs. In the remaining six weeks of the intervention, the GTAs were prompted to tag and describe MOSTs in new classroom videos. They were provided a text prompt to specifically address each MOST criterion in their written responses in the last five weeks of the intervention.

The researcher analyzed the same videos as the GTAs for MOSTs—the types of instances that were the goal for noticing. The researcher examined the GTAs' video timelines, compared their instances and the researcher-identified MOSTs, and selected instances to discuss at the group meeting. A variety of instances were selected, including those marked by multiple GTAs—both MOSTs and non-MOSTs—as well as MOSTs that were not noticed by the GTAs.

In the group meetings, the researcher pushed the GTAs to articulate what an instructor would have to notice in each moment and why it was mathematically important. The GTAs first worked toward building a definition of *MIMs* in group discussion. Later, discussion focused on whether instances fit the MOST criteria. In the last three weeks, the GTAs proposed *building* moves in response to the MOSTs discussed—a teacher move that engages students in collaboratively discussing the significant student mathematical thinking that is present in the instance (Stockero et al., 2014). These moves would use student mathematical thinking to further the learning of all students, which aligns with effective student-centered mathematical instruction (NCTM, 2014). The GTAs then proposed building moves in their subsequent video analyses.

At the conclusion of the intervention the GTAs completed the Calculus Concept Inventory (CCI) (Epstein, 2013) to understand whether there was a relationship between GTA performance on the CCI (a measure of their mathematical CCK) and their noticing of MOSTs.

Data Collection and Analysis

The data for this study included the CCI results and the video timelines produced by the GTAs, both during the intervention and the interviews. The CCI results were scored for correctness. The score of each GTA was then compared to the rest of the group to see if there were any obvious differences in scores that could account for differences in noticing skills.

Each instance identified by a GTA was coded to examine changes in the GTAs' noticing. First, like in the work of Stockero and colleagues (2015), each was coded according to *agent* (who or what was noticed) and *mathematical specificity* (the way in which the mathematics was discussed). Instances that had a student agent were also coded for *focus* (what about the student(s) was noticed). See Figure 1 for descriptions of coding categories and codes. Second, like Stockero, Rupnow, and Pascoe (under review), each instance was coded according to whether it was a MOST and whether the reasoning provided by the GTA was consistent with the MOST criteria. A GTA instance was coded as a MOST if it occurred at the same time in a video as a MOST identified by the researcher. In a consistent MOST, the GTA also identified the characteristics of the instance that qualified the instance as a MOST according to the framework.

Because a goal of this intervention was that the GTAs propose more student-centered responses, the pre- and post-interview instances were also coded according to whether the GTA-proposed response to each instance was student- or teacher-centered. A student-centered response is one in which the teacher would involve one or more students in responding to the instance, whereas a teacher-centered response would only involve the teacher.

Coding Categories and Descriptions	Codes	
Agent: Who or what was noticed	Teacher Teacher/ Student Student/ Teacher	Student Group Student Individual Math
Mathematical Specificity: Whether and how the mathematics was discussed	Non-Math General Math Specific Math	
Focus: For instances with a student agent, what about the student(s) was attended to	Affective Interaction General Understanding Mathematical Interaction	Noting Student Mathematics Analyzing Student Mathematics

Figure 1. Noticing coding scheme. Adapted from Stockero et al. (2015; under review).

After the coding was complete, the data were summarized to look for changes in GTAs' noticing and responding throughout the intervention, focusing on the components of noticing (agent, mathematical specificity, and focus), MOSTs, and how the GTAs might respond to the moments they selected. To provide a common unit of measure, percentages were calculated for each code out of each GTA's and the group's total number of instances in each video. The data was then split into three stages—early, middle and late in the intervention—and summarized accordingly. In this analysis, *baseline* refers to the first three videos of the intervention before the introduction of the MOST framework. *Middle* stands for the three videos immediately following the introduction of the MOST framework, and *final* refers to the last three videos of the intervention. Data from the interviews were analyzed separately due to the difference in the nature of the interviews, in which the GTAs engaged in in-the-moment video analysis where repeated viewings and lengthy deliberation about instances were not possible.

Results

Components of Noticing

Agent. Because the goals of the intervention placed an emphasis on students and their mathematical thinking, changes were examined in the GTAs' noticing of instances in which students were the primary agent (i.e., Student/Teacher, Student Individual, and Student Group agents). Table 1 provides the percentages of such instances in each stage of the intervention and the pre- and post-interviews. It can be seen that both individually and as a group the general trend was an increase in the GTAs' noticing that had a primary student agent from stage to stage. Impressively, the majority of GTAs averaged 100% and the group averaged 94% of primary student noticing in the final data. The table also shows improvement in the GTAs' noticing of instances with a primary student agent from pre- to post-interview, with GTAs 1 and 2 showing the most growth in this type of noticing. Most notably, 100% of the GTAs' noticing in the post data was primarily on students, indicating that they developed the ability to focus their noticing on students over the teacher or the mathematics itself in their in-the-moment analysis of video.

Mathematical Specificity. With mathematical significance and student mathematical thinking being two of the characteristics of a MOST, a possible indicator of improvement in noticing of MOSTs is the ability to speak about the mathematics of an instance in a detailed manner, aligning with the Specific Math code. Table 2 shows that baseline data percentages for

Table 1
Noticing of Primary Student Agent by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	41%	100%	100%	29%	100%
GTA 2	50%	89%	100%	41%	100%
GTA 3	63%	100%	100%	75%	100%
GTA 4	28%	67%	75%	80%	100%
Group	46%	89%	94%	56%	100%

Specific Math were rather high for all GTAs with the exception of GTA 4. The middle data showed an increase in mathematical specificity for all GTAs, with the most considerable increase of 77% being that of GTA 4. Perhaps most important is that all of the GTAs exhibited 100% Specific Math noticing in the final data. Table 2 also indicates improvement in Specific Math noticing from pre- to post-interview. GTA 1's Specific Math noticing was maximized and maintained from pre- to post-interview. GTA 4 showed the most improvement from 40% in the pre-interview to 100% in the post-interview data. Like the final data, the post-interview data demonstrated 100% Specific Math for all participants. Thus the GTAs not only discussed the mathematics with a high level of detail when they had time to reflect and write about each instance, but also in a real time video-based interview setting.

Table 2
Specific Math Noticing by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	97%	100%	100%	100%	100%
GTA 2	85%	100%	100%	59%	100%
GTA 3	81%	100%	100%	75%	100%
GTA 4	6%	83%	100%	40%	100%
Group	67%	96%	100%	69%	100%

Focus. The focus code most aligned with the goals of the intervention was Analyzing Student Mathematics, since the MOST Analytic Framework requires that an inference be made about what the student is saying mathematically. While the focus code only applied to instances with a student agent, the reported percentages are out of all instances identified by the GTAs to reflect an overall sense of their noticing. Table 3 indicates that Analyzing Student Mathematics was absent or low in the baseline data, both individually and as a group. By the middle data, substantial increases were made by all GTAs, with GTAs 1, 2, and 3 improving by 72% to 84%. GTA 3 reached 100% in the final data. The pre- and post-interview data exhibited remarkable growth for in-the-moment noticing with this focus. GTA 4 demonstrated the largest growth at 100% from pre to post, while increases for the other GTAs ranged between 75% to 87%. Interestingly, GTA 4 exhibited Analyzing Student Mathematics much more in the post-interview, an in-the-moment context, than in the final data. It is possible that GTA 4 more completely communicated what they noticed with spoken word in the interview than in written word in the text that accompanied their video timelines. In general, these results suggest that the intervention was successful in developing the GTAs' ability to focus on and interpret student mathematical thinking both when analyzing video individually and in an in-the-moment context.

Table 3
Analyzing Student Mathematics by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	16%	100%	94%	14%	100%
GTA 2	0%	72%	67%	0%	75%
GTA 3	24%	96%	100%	13%	100%
GTA 4	0%	33%	47%	0%	100%
Group	10%	75%	77%	7%	94%

MOST Analysis

Changes were examined in the GTAs' noticing of consistent MOSTs, the main goal of the intervention. Like the other analyses, the percentages presented were calculated out of the total set of instances marked by the GTAs. Table 4 shows that all GTAs improved in their noticing of consistent MOSTs in each stage of the intervention, with the group's average percentages increasing from a baseline of 19%, to 73% in the final data. The pre- and post-interview data showed considerable increases in the GTAs' in-the-moment noticing of consistent MOSTs, with increases ranging from 26% to 80%. However, the raw percentages in the post-interview data are not overwhelmingly high. It is worth recalling that the prompt for both the pre- and post-interview was to identify *MIMs*, which may explain why there was not a higher percentage of MOSTs identified in the post-interview. An idea underlying the intervention was that the MOST Analytic Framework would provide a way to characterize mathematically important moments that the instructor should notice, but perhaps the connection between *MIMs* and MOSTs was not seen by the GTAs. Still, the data suggests that the intervention was successful in improving the GTAs' ability to notice MOSTs and reason about them in accordance with the MOST Analytic Framework, both when analyzing video individually and in an in-the-moment context.

Table 4
Noticing of Consistent MOSTs by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	24%	61%	87%	14%	40%
GTA 2	19%	36%	76%	11%	50%
GTA 3	25%	57%	78%	13%	67%
GTA 4	8%	33%	53%	20%	100%
Group	19%	47%	73%	14%	64%

Responses

Another goal of the intervention was to increase the amount of student-centered responses that were proposed to instances identified in video. Table 5 indicates the percentage of instances in which the GTAs proposed a student-centered response. Substantial increases in the percentage of such responses were made from pre- to post-intervention for all GTAs. In fact, with the exception of GTA 4, 100% of the responses provided by the GTAs were student-centered in the post data. These results suggest that the intervention was successful in improving the GTAs' skills in proposing student-centered responses in an in-the-moment context.

CCI Scores

The GTAs' performances on the CCI assessment, both as a raw score and as a percentage, were quite similar to one another. Raw scores ranged from 17-19 out of 22 possible points, with an average of 18; percentages ranged from 77-86%, with an average of 82%. Because all of the GTAs had about the same aptitude for calculus concepts, there was no evidence that differences in mathematical content knowledge accounted for differences observed in their noticing.

Table 5
Student-centered Responses by Interview

Participant	Pre	Post
GTA 1	0%	100%
GTA 2	57%	100%
GTA 3	83%	100%
GTA 4	33%	50%
Group	43%	88%

Discussion

Results showed that the intervention was successful in improving the GTAs' noticing in a number of ways and in two different video analysis contexts. The GTAs greatly increased in their noticing of instances primarily focused on students, the percentage of instances in which they discussed the mathematics of an instance in a specific manner, their focus on analyzing the student mathematics of an instance, and their noticing of consistent MOSTs. These results add support to the successes of interventions in K-12 mathematics education that use video and a defined framework to improve the noticing skills of mathematics teachers (e.g., McDuffie et al., 2014; Schack et al., 2013; Stockero et al., 2015, under review) and suggest that such interventions can be successful at the undergraduate level as well.

The intervention was also successful in improving the GTAs' skills in proposing student-centered responses. This finding builds upon those of existing studies (Jacobs, Lamb, Philipp, & Schappelle, 2011; Jacobs et al., 2010; Schack et al., 2013) that suggest that professional development structured around noticing students' mathematical thinking in video and classroom artifacts can develop teachers' abilities in not only *attending to and interpreting [students'] strategies and understandings*, but also the skill of *deciding how to respond* (Jacobs et al., 2010).

While the results of this study suggest that similar interventions could be successful in training GTAs in noticing student mathematical thinking, the small number of participants is a limitation. Future work could involve replicating this study with more GTAs, at other universities, or with another set of videos. Limitations aside, the findings suggest that the intervention was a step in the right direction for advancing student-centered instruction in undergraduate mathematics courses. The development of noticing skills, while achieved in a professional development setting, has the potential to improve classroom instruction and thus the retention of first- and second-year undergraduate students (Cano et al., 1991; Speer et al., 2005).

Attention to Detail: Norms for Proof Evaluation in a Summer Mathematics Program

Cody L. Patterson
The University of Texas at San Antonio

Xiaowen Cui
Texas State University

In this study, we explore the norms by which students and undergraduate mentors in a summer mathematics program evaluate proofs of theorems in number theory. By utilizing cognitive interviews during which students and mentors evaluate number theory proofs written by a hypothetical student, we find that for students as well as mentors, "rigor" is a dimension of mathematical acceptability of proofs distinct from, though related to, proof validity. Additionally, we find that both students and mentors frequently adhere to strict unwritten norms that govern how they believe proofs should be constructed and presented, and that these norms may be more rigid than the intended proof-writing norms of the mathematicians who teach in the summer program. This study suggests some potential challenges associated with the growing practice of asking undergraduate student graders to evaluate proofs written by students in introduction-to-proof courses.

Key words: Proofs, Proof Validation, Cognitive Research, Informal Mathematics Education

One of the goals of a typical undergraduate program in mathematics is to instill in students an understanding of mathematical proof: the purposes for which mathematicians use proof, the process by which mathematicians prove results, and the ways in which we decide whether an argument is valid and should be accepted by the mathematical community. However, students learn about disciplinary norms governing proofs in varied and sometimes idiosyncratic ways. An instructor in an undergraduate mathematics course may rule a proof produced by a student acceptable or unacceptable according to rules that have not been made fully explicit for students. For example, an instructor in an introduction-to-proofs course may suggest that a proof of the formula for the sum $[1 + 2 + 3 + \ldots + n]$ using induction is more "rigorous" than the classic reordering argument that pairs this with the sum $[n + (n – 1) + (n – 2) + \ldots + 1]$. An instructor who says this may intend to signal to students that in formal mathematics, we are reluctant to accept reasoning that is hidden "behind" the ellipses in these expressions without careful investigation; however, students may infer from the instructor's choice that in formal mathematics, rigid proof schemata such as induction are more "rigorous" than arguments that use flexible reasoning. As a result of exchanges such as these, students may develop the belief that the acceptability of a proof is determined more by the manner in which an argument is written rather than by the logical coherence of the argument itself. In this study, we investigate ideas about "rigor" and proof acceptability co-constructed by faculty, mentors, and students in a summer mathematics program, and document some cases in which students demonstrate norms for proof evaluation that may be inconsistent with those that the faculty who teach in the program intend to convey.

Background

There is a growing body of literature on *proof validation*, the process of deciding whether a proof is valid, as performed by mathematics students and instructors. Validation of proofs is an intellectually complex process requiring many different types of reasoning, including the construction of formal and informal deductive arguments and example-based reasoning (Weber, 2008). Harel and Sowder (1998) suggest that many students, by the time they begin learning about formal mathematical proofs in college, have developed *external conviction proof schemes* in which validity derives from the "ritual of the argument presentation"; that is, degree to which a proof structurally resembles a formal argument scheme. Additionally, many students have *empirical proof schemes* and may be convinced of the validity of a conjecture by testing specific cases. These non-analytical proof schemes may interfere with students' ability to assess the validity of nonstandard arguments. Selden and Selden (2003) suggest that exclusive attention to surface features of a proof, or failure to attend to the global logical structure of a proof, may cause students to make incorrect judgments about the proof's validity.

Mathematicians use a variety of socially-determined criteria when evaluating a proof, such as whether they understand the concepts embedded in the proof, whether the argument is convincing, and whether the theorem being proven is consistent with the existing body of accepted mathematical results (Hanna, 1983). Courses that introduce students to proof-writing in mathematics often have the dual aims of helping students develop the ability to identify and produce valid arguments, and enculturating students into practices and disciplinary norms regarding the writing and evaluation of proofs that are typical among professional mathematicians. While several studies have addressed the mental processes involved in distinguishing valid proofs from invalid ones, relatively few have studied how students' judgments of proof validity interact with their (possibly separate) assessments of whether a proof is acceptably presented. While mathematicians do not share a single common standard for evaluating the validity and presentation of proofs (Inglis *et al.*, 2013), we view the instructor of a proof-writing course as an exemplar of a particular set of norms and practices that the course is intended to transmit, in part or in full, to its students, and are interested in the various pedagogical forces that influence how students assimilate these norms themselves.

In this study, we aim to address the following research questions:

1. What criteria, other than proof validity, do students who are learning to read and write formal mathematics use to judge proofs?
2. To what degree are novice proof writers able to distinguish flaws that make a proof less readable or less complete from those that render a proof invalid?
3. To what degree do novice students' and their mentors' norms for evaluating proofs conform to those of the community of professional mathematicians, as embodied by the instructors teaching their courses?

Setting of Study

Our study took place at a summer mathematics program for talented high school students in the United States. Students in the program are recruited from all geographic regions of the United States; while most enter the program with no prior formal experience in undergraduate mathematics, a few have learned to write proofs by participating in high school mathematics competitions.

During the program, students learn how to write mathematical proofs while taking a course in number theory; some students return to the program in subsequent summers and take other courses in undergraduate mathematics. Students are assigned to study groups, with each group supervised by a mentor who has attended the program for several years. Most mentors are undergraduate STEM majors at leading research universities, though some mentors are senior high school students.

Students in the program attend classes each morning and afternoon; during the evenings, they participate in extended study sessions with their groupmates, supervised by their mentors. They write proofs of theorems in number theory and submit these proofs for "grading" by their mentors. Although these proofs do not receive numerical grades, mentors provide feedback on the proofs' correctness and style, and sometimes recommend that students revise work that is incorrect or incomplete.

Method

We conducted a survey of the first-year students in the program, their mentors, and the mathematician faculty member who teaches the number theory course to determine whether participants in the program were familiar with the use of the word "rigor" as a criterion used to evaluate proofs, and to what extent participants view "rigor" as distinct from proof validity. When asked to agree or disagree with the statement, "When we talk about proofs, the word 'rigorous' has the same meaning as the word 'valid,'" 6 respondents strongly disagreed, 13 moderately disagreed, 13 moderately agreed, and 4 strongly agreed. The instructor of the number theory course was among those who strongly agreed. When asked to explain the distinction between validity and rigor, if they believed such a distinction exists, many respondents suggested that validity points to whether a proof is correct, while rigor deals with the level of detail in a proof and the extent to which the argument explicitly states and justifies each step.

Based on the survey results, we selected two study groups in the summer program for follow-up interviews. We invited students and mentors from these two study groups, along with the mathematician who taught the number theory course, to participate in cognitive interviews in which they evaluated several proofs written by a hypothetical student. Because we selected interview subjects from study groups in which multiple students shared the view that a proof is rigorous if and only if it is detailed, we make no claim that the interview results are representative of the proof-evaluation norms of the entire student body of the summer program. However, we conjecture based on the results of the preliminary survey that the views of rigor and proof validity demonstrated by the students and mentors we interviewed were shared by many other students and mentors in the program.

In the interviews, we asked six students, their two mentors, and the mathematician instructor to review the first theorem shown in Table 1 on the next page, either produce a proof of the theorem or write some notes on the main ideas of the proof, and then evaluate three hypothetical student proofs of the theorem on three dimensions – validity, rigor, and understandability – each on a scale of 0 to 3. We then repeated this routine with the second theorem below. In asking interview subjects to rate these proofs, we hoped to gain additional insight about whether students and mentors made distinctions between validity and rigor in their evaluations of specific arguments, and about whether students' and mentors' overall evaluations of proof quality were consistent with the norms the instructor intended to set.

Results

Students' and mentors' responses to the proofs given in the interview, and in particular their assessments of the rigor of these proofs, varied considerably. Table 2 on the next page shows the ratings the interview subjects gave the three proofs of Theorem 1 for Validity, Rigor, and Understandability, along with the proof each subject rated the best overall and the most rigorous.

Table 1: Descriptions of Hypothetical Student Proofs

Theorem	Proof	Description of Proof
If a, b, and n are integers such that a < b and n > 0, then an < bn.	1A	Detailed argument that omits essential step demonstrating that difference between *bn* and *an* is a natural number
	1B	Correct argument that omits names of algebraic properties that justify steps
	1C	Correct and detailed argument by induction on *n*
If a, b, q, and r are integers with b > 0 and a = bq + r, then GCD(a, b) = GCD(b, r).	2A	Correct argument carefully using definition of GCD
	2B	"The common divisors of *a* and *b* are the same as the common divisors of *b* and *r*" argument
	2C	Argument that makes incorrect inference

Table 2: Interview Subjects' Ratings of Proofs of Theorem 1

Subject	Proof 1A			Proof 1B			Proof 1C			Best	M Rig
	V	R	U	V	R	U	V	R	U		
Student X1	3	2	2	2	1	2	3	3	2	1A	1C
Student X2	3	2	2	2	1	1	3	2	2	1A	1A
Student X3	3	2	3	3	3	3	3	3	2	1B	1B
Student X4	3	3	2	2	1	2	2	2	3	1A	1A
Mentor X	2	3	1	2	1	2	2	1	2	1A	1A
Student Y1	3	3	3	3	1	2	3	2	3	1A	1A
Student Y2	3	3	2	3	2	2	3	3	2	1B	1C
Mentor Y	2	1	2	3	2	3	3	1	1	1B	1B
Instructor	2	2	3	3	3	3	3	3	3	1B	1B/1C

We asked each subject to explain his or her ratings after evaluating each proof. Several themes emerged during these explanations, suggesting discrepancies between proof-evaluation norms of students and those of their mentors, or discrepancies between norms of students and mentors and those of the mathematician teaching the number theory course.

Level of Detail Versus Essential Reasoning: The Case of Proofs 1A and 1B

We constructed Proofs 1A and 1B to differ in two essential ways. The first is that Proof 1A obfuscates its argument slightly by introducing a new variable t that is equivalent to n, while Proof 1B is more direct. The second is that while Proof 1A is more generous in including names of algebraic properties used in the argument, such as the substitution principle, Proof 1B is the only argument that uses the class's definition of "less than" (that $x < y$ if there exists a natural number k such that $x + k = y$) to establish that $an < bn$. (Proof 1A states that because $at + kt = bn$, we have $at < bn$, without stating or showing that kt is a natural number.) Thus while Proof 1A includes an overall greater level of detail, Proof 1B arguably gives more attention to the most crucial step of the argument.

While both mentors and the instructor noted the key omission in Proof 1A and rated the proof's validity accordingly, all six students rated the proof's validity a 3, and five of the six rated Proof 1A more rigorous than Proof 1B. Most of these five students stated that they rated

Proof 1A more rigorous because it more consistently stated reasons for the algebra steps in the proof and named the algebraic properties used. However, Student X3 mentioned specifically that while Proof 1B left out a greater number of details overall, Proof 1A left out reasoning that seemed more essential. This suggests that Student X3 had a way of thinking about proof quality that took into account the relative importance of various details.

Rigidity in Methods and Styles of Proof: The Case of Proof 1C

We constructed Proof 1C in order to see how interview subjects would respond to the hypothetical student's use of induction to prove a theorem that can be proven directly using the definition of "less than" and the distributive property. The ratings and interviews suggested that while some students found Proof 1C to be the most rigorous of the three (despite preferring one of the other proofs), others considered the proof less rigorous than others in part because of the specific induction language used in the argument. Student X4, who gave this proof a rating of 2 for rigor, said, "It's kind of like, why are you using induction for something that probably could save you some time?" She later clarified that the use of induction was not the reason for her rating, but rather that the author of the proof might have written a better argument had he or she chosen a different method. Mentor X also took issue with some of the language used in the induction proof; most of her concerns revolved around the fact that the argument, at various times, specified a value for n (*e.g.*, for the base case) and proceeded to make statements based on that assumption rather than writing these statements in conditional form. For example, the base case assumed that $n = 1$ and later said that $an < bn$; of this, Mentor X said, "That's not like… that's just not true… you would say, maybe, 'thus, when $n = 1$, $an < bn$,' right. That language sort of implies that they don't understand what a base case does, what the significance of a base case is." It seems that in this case, Mentor X read the claim that "$an < bn$" at the end of the base case as a general claim rather than as an instantiated claim about the case $n = 1$. These comments, along with her other markings on the proof, suggested that Mentor X had adopted a rigid way of reading induction arguments that had some difficulty accommodating differences in how students might represent the inductive logic of a proof.

In addition, Student X3 expressed concern that parts of Proof 1C had been written as indented chains of algebraic steps rather than in paragraph form. When pressed on this, subjects suggested that some mentors in the summer program encouraged students to write proofs in paragraph form, rather than block-indenting sequences of calculations. This is one of several stylistic choices about proof-writing that students in the program may infer to be norms of the mathematical community, but that in fact are artifacts of the program culture and of the way mentors grade proofs. We have collected scanned images of the graded proofs of students in the summer program and hope to perform a more in-depth investigation of the norms for mathematical writing that mentors in the program convey to students.

"Logic" Versus Chains of Axiomatic and Definitional Reasoning: The Case of Proof 2B

We constructed Proofs 2A and 2B to differ in only one significant way. While Proof 2A explicitly uses the formal definition of greatest common divisor given in class (that d is the GCD of a and b if d is a natural number; d divides both a and b; and if c divides both a and b, then c is less than or equal to d), Proof 2B proves Theorem 2 by showing that a and b have precisely the same common divisors as b and r, and thus concluding that these two pairs must have the same GCD. Under the surface lay a structural difference that, in our preliminary investigations, seemed to have some import for students and mentors in the program: while Proof 2A proceeds through a sequence of steps, most of which can be directly justified using axioms or definitions from the number theory course, Proof 2B ends with a verbal argument that appeals to the notion of GCD as the maximum of the set of common divisors of two integers, and attempts to persuade the reader that if two pairs of integers have the same set of common divisors, they must have the same GCD. The latter approach departs slightly from the norm of precise definitional reasoning to which students become accustomed early in the number theory course, though the number theory course itself includes a number of theorems (such as Fermat's Little Theorem) whose proofs contain steps that appeal to nonlinear, *ad hoc* reasoning rather than axioms.

Of the five students and one mentor who finished reviewing the proofs of Theorem 2, only two students rated Proof 2B as entirely valid. Two students rated the proof's validity a 2, and Student X4 and Mentor X rated the proof's validity a 1. Student X1 rated the proof a 3 for validity but only a 2 for rigor; when asked to explain his ratings, he said, "some of the steps aren't explained clearly, such as the end, where it says that… it's sort of just explaining logic instead of using any theorem or previous axiom." In the preliminary survey, two other respondents, including Student Y1, mentioned the use of "logic" as a possible source of disagreement among students and mentors over whether a proof is rigorous; one respondent stated that "sometimes our [mentors] tell us to use more algebra instead of just logic and assuming."

Student X3, whose interview responses suggested the least commitment to rigid, style-based norms for proof acceptability among those students interviewed, rated the proof a 3 for both validity and rigor, but rated it a 2 for understandability. She suggested that the author of the proof should have constructed the set of common divisors of a and b and the set of common divisors of b and r, and shown that these two sets are equal. Responses to Proof 2B suggest that the students interviewed were not entirely comfortable with arguments that depart from chains of reasoning based on axioms and previously proven theorems and that include steps for which the justification is fluid and unfamiliar.

Norms of a Professional Mathematician: The Case of the Course Instructor

After we completed interviews of students and mentors, we interviewed the instructor of the number theory course using the same protocol. Prior to rating any proofs, the instructor stated his position that "validity" and "rigor" are not separate constructs, and expressed concern that students might believe that rigor is a separate or stronger standard for proofs than validity. When rating each proof, he assigned the same rating for both validity and rigor.

The instructor initially rated each of the three proofs of Theorem 1 a 3 in all three categories; he changed his validity and rigor ratings for Proof 1A to 2 only after considering that the author of the proof made, in his view, two mistakes: failing to use the substitution principle correctly, and failing to observe that kt is a natural number. He expressed little hesitation in giving ratings of 3 for Proofs 1B and 1C, and showed little concern about the justification steps skipped in Proof 1B.

When the instructor was given the opportunity to review Theorem 2 prior to seeing the proofs, he noted that he is familiar with two different approaches; he then described the approaches used in Proofs 2A and 2B. When shown Proof 2B, he expressed amusement that he had foreshadowed the argument given, and rated the proof a 3 in all three categories, as he had with Proof 2A.

We can envision two different hypotheses to explain the fact that the instructor awarded higher ratings for most of the proofs in the interview than the students and mentors did. One possible explanation is that the instructor's extensive experience teaching number theory has familiarized him with the arguments provided and desensitized him to possible errors in logic that may reveal unclear thinking on the author's part. Another hypothesis is that the instructor, when rating a proof, was more interested in whether the author had a complete chain of reasoning linking the hypotheses to the desired conclusions than in issues of how the proof is written. At various points in the interview, the instructor pointed out instances of writing that he did not consider optimal, but openly dismissed these as inessential to the central issue of whether the proof under review was valid, in contrast with mentors and students who considered some of these issues (such as the explicit naming of axioms about the algebraic structure of **Z**) crucial in evaluating the validity and especially the rigor of proofs. This contrast suggests a disparity between the proof-evaluation norms of students and mentors in the summer program and those of professional mathematicians as embodied by the instructor of the course.

Discussion and Implications

The interview results suggest that some students in the summer mathematics program had criteria for "rigor" or completeness of proofs distinct from the criteria they used to evaluate the validity of proofs. In some responses to interview questions, students rated proofs as valid, but indicated that they believed that their mentors may not find these proofs entirely acceptable. In some cases, students indicated that they themselves did not consider certain proofs (such as Proofs 1A and 1B) totally acceptable despite finding them entirely valid.

We conjecture that in some introduction-to-proof courses, instructors pay explicit attention to issues of style and detail in proof-writing in the belief that strict attention to these issues supports the development of students' ability to read and write proofs. We make no claim that our study sheds light on the validity of this particular belief. However, we observe that in most of the interviews conducted in this study, subjects did not always make clear distinctions between flaws in a proof that render it more difficult to read or follow and flaws that render a proof invalid. Although the instructor of the number theory course gave little direct instruction on norms for writing and evaluating proofs in class, mentors provided regular feedback on students' proofs and, based on a preliminary analysis of their markings, sometimes advised students to rewrite proofs in ways that would have yielded at most negligible improvements in their readability. We hope to ascertain through follow-up interviews of the subjects of this study whether the mentors' feedback instilled in students norms for writing and reading proofs that are more rigid than those shared by most of the community of professional mathematicians. We also hope to conduct a more thorough analysis of the graded proofs we collected over the duration of the program to develop a more precise inventory of the norms that governed the mentors' evaluations of proofs.

We believe that our study has implications for the teaching of undergraduate mathematics in light of the growing practice of appointing relatively inexperienced students to grade papers in courses that involve proofs, borne of funding decreases that have forced mathematics departments to shift some of this intellectually challenging work from graduate teaching assistants to undergraduate graders. At minimum, we suspect that some undergraduate graders tasked with grading proofs may benefit from professional development that encourages flexibility in evaluating different approaches and styles of proof presentation. We acknowledge, however, that such professional development may not mitigate the intellectual demands associated with evaluating whether unfamiliar arguments are mathematically valid.

Student Mathematical Connections in an Introductory Linear Algebra Course

Spencer Payton
Washington State University

In an introductory linear algebra course, students are expected to learn a plethora of new concepts as well as how these concepts are connected to one another. Learning these connections can be quite challenging for students due to the vast number of connections and student inexperience with mathematical logic. The study reported here consisted of an investigation into how inquiry-oriented teaching methods could be employed in an attempt to create opportunities for students to develop mathematical connections in an introductory linear algebra course.

Key words: linear algebra, mathematical connections, inquiry-oriented teaching

Introductory linear algebra courses have traditionally been quite challenging for students. There are several reasons for this, including the fact that students are introduced to a plethora of brand new concepts and terminology. Further, many of these concepts are connected to one another in various ways, and students are expected to learn these connections as well. While many researchers and teachers would agree that students should be able to make mathematical connections, the phrase "mathematical connection" is often loosely defined. This study considers one particular type of mathematical connection in an introductory linear algebra course: *logical implication connections*. Relationships between various linear algebraic concepts are often summarized in theorems of logical equivalence such as the Invertible Matrix Theorem (IMT) (Lay, 2011). The statements in this theorem are all logically equivalent, meaning any statement in the theorem logically implies another (and vice versa). Thus, the logical implications present in the IMT could be described as logical implication connections.

While the IMT provides a convenient presentation of logical implications in introductory linear algebra, it is somewhat restrictive due to the fact that it only applies to square coefficient matrices (as only square matrices can be invertible). However, subsets of the logical implications inherent in the IMT could be applied to non-square matrices. The IMT could actually be divided into two "sub-theorems," which will hereby be known as the First and Second Theorems of Logical Equivalence; these theorems are presented in Figure 1.

Theorem 1: Let A be an $m \times n$ matrix. Then the following statements are logically equivalent.

a) The equation $A\mathbf{x} = \mathbf{b}$ has at least one solution for each $\mathbf{b}$ in $\mathbb{R}^m$.
b) A has m pivot positions; that is, A has a pivot position in every row.
c) Every vector $\mathbf{b}$ in $\mathbb{R}^m$ is a linear combination of the columns of A.
d) The columns of A span $\mathbb{R}^m$.
e) The linear transformation $T: \mathbb{R}^n \to \mathbb{R}^m$ defined by $T(\mathbf{x}) = A\mathbf{x}$ maps $\mathbb{R}^n$ onto $\mathbb{R}^m$.

Theorem 2: Let A be an $m \times n$ matrix. Then the following statements are logically equivalent.

a) The equation $A\mathbf{x} = \mathbf{b}$ has at most one solution for each $\mathbf{b}$ in $\mathbb{R}^m$.
b) For each $\mathbf{b}$ in $\mathbb{R}^m$, the linear system corresponding to $A\mathbf{x} = \mathbf{b}$ does not have a free variable; that is, the linear system only has basic variables.
c) A has n pivot positions; that is, A has a pivot position in every column.
d) The equation $A\mathbf{x} = \mathbf{0}$ has only the trivial solution.
e) The columns of A form a linearly independent set.
f) No column of A is a linear combination of the other columns.
g) The linear transformation $T: \mathbb{R}^n \to \mathbb{R}^m$ defined by $T(\mathbf{x}) = A\mathbf{x}$ is one-to-one.

Figure **1**: Unlike the Invertible Matrix Theorem, these theorems of logical equivalence are not restricted only to the case of square matrices.

As learning these mathematical connections can be challenging for students, it would be beneficial to improve the teaching of these connections. The study described in this report was part of a larger study that attempted to determine how inquiry-oriented teaching methods could be implemented in an introductory linear algebra course that, due to considerations such as large class size and limited amount of class time, would not lend itself to the traditional demands of inquiry-oriented teaching. Regarding the teaching of mathematical connections, one goal of this study was to answer the following research question: How do students take advantage of inquiry-oriented teaching to make connections in an introductory linear algebra class?

Literature Review

It is not uncommon for students to know that two linear algebraic concepts are connected but not understand *why* they are connected. This issue was well described by Harel:

> So if a student thinks of 'linear independence' to mean 'the echelon matrix which results from elimination has no rows of zeros,' without being able to mathematically justify this connection, then he or she does not understand the concept of linear independence. (Harel, 1997, p. 111)

This issue of the quality of student understanding has been previously discussed by Skemp (1987) in his description of instrumental and relational understanding. The understanding presented in Harel's example is *instrumental understanding*; that is, knowing what to do but not why. According to Skemp, true understanding of a concept involves *relational understanding*, which is "knowing both what to do and why" (Skemp, 1987, p. 153). This characterization of the quality of understanding could be applied to mathematical connections. Thus, a student has made an *instrumental connection* if the student has formed a connection but does not understand why that connection exists; similarly, a student has made a *relational connection* if the student has formed a connection and understands why that connection exists. For example, a student could present relational understanding of a logical implication connection if he or she can form a chain of logical implications beginning with one statement in a theorem of logical equivalence and ending with another. Unfortunately, students at this level often struggle with mathematical logic, and in particular, many students struggle to form these chains of reasoning (Dorier & Sierpinska, 2001).

Regarding inquiry-oriented teaching, there are several ways to define inquiry depending on the context or academic subject. Rasmussen and Kwon (2007) characterize student inquiry in a mathematics class through Richards' (1991) definition of mathematical inquiry, which is the mathematics of mathematically literate adults. Thus, mathematical inquiry involves participating in mathematical discussion, solving new problems, listening to mathematical arguments, and proposing conjectures. With this interpretation of mathematical inquiry, inquiry-oriented teaching involves creating opportunities for students to engage in mathematical inquiry.

Setting and Methods of Analysis

This study was conducted through an action research methodology that began with a pilot study in the summer of 2015 and continued into the fall of 2015 and spring of 2016. Each of these action research cycles consisted of research in an introductory linear algebra course that was taught by the researcher. While the results of the pilot study and fall 2015 research cycle informed the spring 2016 research cycle, this report will primarily focus on the spring 2016 cycle.

In the spring of 2016, the researcher taught an introductory linear algebra course at a large state university in the Pacific Northwest. The class consisted of sixty students; the majority of these students were engineering majors, while others were mainly math and computer science majors. The course was a two credit course, which placed considerable time constraints on the instructor. As a result of these constraints, inquiry-oriented teaching activities were largely reserved for concepts closely related to logical implication connections. In particular, students worked on several activities focusing on span and linear independence, as these concepts play parallel roles in the first two theorems of logical equivalence; two of these activities are presented in Figure 2.

Without solving a linear system or using any elementary row operations, determine whether the following sets of vectors span the given space. For each set of vectors, formulate a conjecture about span based on that set.	Without solving a linear system or using any elementary row operations, determine whether the following sets of vectors are linearly independent or dependent. For each set of vectors, formulate a conjecture about linear independence or dependence based on that set.
• Do the vectors $\begin{bmatrix}1\\-2\end{bmatrix}, \begin{bmatrix}-2\\4\end{bmatrix}$ span all of $\mathbb{R}^2$?	• $\left\{\begin{bmatrix}1\\-2\end{bmatrix}, \begin{bmatrix}-2\\4\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\2\end{bmatrix}, \begin{bmatrix}3\\4\end{bmatrix}, \begin{bmatrix}5\\6\end{bmatrix}$ span all of $\mathbb{R}^3$?	• $\left\{\begin{bmatrix}1\\3\\-5\end{bmatrix}, \begin{bmatrix}3\\9\\-10\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\2\\3\end{bmatrix}, \begin{bmatrix}4\\5\\6\end{bmatrix}$ span all of $\mathbb{R}^3$?	• $\left\{\begin{bmatrix}1\\2\end{bmatrix}, \begin{bmatrix}-3\\-4\end{bmatrix}, \begin{bmatrix}-2\\4\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\7\\0\end{bmatrix}, \begin{bmatrix}3\\8\\0\end{bmatrix}, \begin{bmatrix}-2\\9\\0\end{bmatrix}$ span all of $\mathbb{R}^3$?	• $\left\{\begin{bmatrix}2\\3\\4\end{bmatrix}, \begin{bmatrix}0\\0\\0\end{bmatrix}, \begin{bmatrix}1\\1\\8\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\0\end{bmatrix}, \begin{bmatrix}0\\1\end{bmatrix}, \begin{bmatrix}2\\3\end{bmatrix}$ span all of $\mathbb{R}^2$?	

Figure **2**: Each of these activities were designed as opportunities for students for explore span and linear independence in ways that would allow them to develop logical implication connections involving span and linear independence.

Data on student mathematical connections was largely collected from interviews with nine students from the aforementioned class. These interviews were conducted shortly after the Invertible Matrix Theorem had been covered in class. Each interview was approximately an hour in length and consisted of students finding the solution set of a linear system, a vector equation, and a matrix equation. Each problem lent itself to a different theorem of logical equivalence. For example, the coefficient matrix corresponding to the linear system had a pivot position in every row, thus making every statement from Theorem 1 true for that coefficient matrix. Similarly, the vector equation lent itself to Theorem 2 and the matrix equation lent itself to the IMT. After an interviewee completed one of the problems, the interviewee was asked to describe his or her work. The researcher would then present the interviewee with a list of vocabulary terms that had been discussed in class. The interviewees were asked to discuss as many of the vocabulary terms as they could and how they relate to each problem. The interviewer would often ask for justification of particular claims that the interviewee had made and would sometimes directly ask the interviewee whether he or she could discuss a particular vocabulary term. This was all done in an attempt to determine what logical implication connections the interviewees could evoke that incorporated some of the familiar terms involved in the theorems of logical equivalence.

In analyzing the interviews, the researcher attempted to determine what mathematically correct logical implications corresponding to the three theorems of logical equivalence each interviewee evoked. Evidence of logical implication connections took several forms. Many logical implications involved words such as if, then, means, because, and so. For example, "The vectors, if a linear combination of those produce every single vector in that space, then they span that space" would be considered a logical implication connection. While many logical implications were evoked entirely by the interviewees, some logical implications were evoked as a result of an interviewee responding to a question asked by the interviewer. After determining what logical implications the interviewees evoked, the researcher then attempted to determine which of these connections were relational connections; this was largely accomplished by determining which logical implication connections a student was able to justify.

Results

In general, the interviewees tended to evoke more connections relevant to the second theorem of logical equivalence than they did the first. This is in itself not entirely surprising; the theorems presented in Figure 1 were the versions of the theorem discussed in class, and the second theorem contains more statements than the first. As the concept of invertibility and the IMT were still new to the interviewees, they tended to evoke relatively few connections exclusive to the IMT. Due to this, the results reported here will primarily focus on connections that are not exclusive to the IMT.

Logical Implication Connections Relevant to the First Theorem of Logical Equivalence

In evoking connections relevant to the first theorem of logical equivalence, the interviewees tended to reference span, pivot positions, and linear combinations. Interestingly, several interviewees presented interpretations of span that were likely consistent with the formal definition of span, but interviewees rarely explicitly referenced the formal definition. That is, several interviewees were able to provide geometric interpretations of span or were able to describe span via linear combinations without explicitly saying the phrase "linear combinations." For example, consider Will's explanation of why two particular vectors span $\mathbb{R}^2$:

Will: Because these two aren't scalars of each other, they're going in different directions. They each have their own x_1 and x_2 components. If they were the same, they'd just end up looking like that.

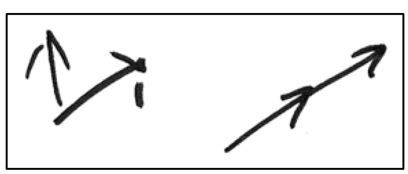

Figure **3**: Will provided a geometric description of what it means for two vectors to span $\mathbb{R}^2$. The illustration on the left represents an example Will provided of two vectors that span $\mathbb{R}^2$, while the illustration on the right represents an example Will provided of two vectors that do not span $\mathbb{R}^2$.

Seth provided an explanation that incorporated both matrix and geometric interpretations of span:

Seth: If you had a matrix, let's take this one [Seth draws the 2×2 identity matrix], then this one would span all of $\mathbb{R}^2$ because no matter how you rearrange this, you can create – uh, I'll expand it [Seth then changes his matrix to the 3×3 identity]. So uh, this one can create, because you can multiply this by infinitely many scalars outside for each row, you can create infinitely many planes, like, if you think about this geometrically, planes in any coordinate system.

Jimmy appeared to allude to linear combinations, but also referenced a geometric interpretation of span:

Jimmy: Well, for spanning, you want, uh. Every direction to be covered, every direction on the plane to be covered by some scale, er, some combination of those vectors, I think.

Jason explained that three particular vectors span $\mathbb{R}^3$ because "they go in different directions. They're not, uh, linear combinations of each other." While Jason referenced linear combinations, it was not in reference to the formal definition of span, but rather, as a description of what must be true of a set of vectors in order to span an entire space. Bill heavily alluded to linear combinations but did not explicitly reference linear combinations:

Bill: Span is having the ability to make any vector within a space. You can, like I said, manipulate any piece of the outcoming vector. You can change it by changing one of the more, one of the scalar multiples along there, not scalar multiple, scalar weights along the way you go. In this case we did at x_1, x_2, x_3. If you could change each of those to then manipulate one of the vectors in the overall value within the system, you could then change the outcome. That goes into the span. If you can do that then it does span $\mathbb{R}^3$, it does span $\mathbb{R}$ whatever. It has the ability to reach any vector, any point within that space.

Bill's description of scalar weights and manipulating vector may provide evidence that he is describing linear combinations, although he does not explicitly reference linear combinations. Thus, Bill's interpretation of span is likely consistent with the formal definition of span, even if he cannot provide the formal definition.

It should be noted that while several students provided geometric descriptions of span, geometric interpretations were not heavily emphasized in class. They were briefly referenced from time to time, but concepts were never defined from a geometric perspective. Further, prior to span being defined, the class had discussed the problem of determining whether any vector in an $\mathbb{R}^n$ space can be expressed as a linear combination of a particular set of vectors. However, when span was formally defined, it was defined more generally as the set of all linear combinations of a set of vectors. Despite this, several interviewees appeared capable of determining whether a particular set of vectors spans an $\mathbb{R}^n$ space by determining whether the vectors were linearly independent, linear combinations of each other, or go in different directions. Thus, it is likely that students developed these alternative, yet mathematically correct, interpretations of span as a result of the inquiry-oriented activity previously described.

Logical Implication Connections Relevant to the Second Theorem of Logical Equivalence

Many of the connections the interviewees evoked relevant to the second theorem of logical equivalence involved pivot positions, linear independence, and basic and free variables. The interviewees tended to refer to basic and free variables in their logical implications more than any other concept; this was particularly interesting, as the interviewees from the previous semester tended to refer to pivot positions more than any other concept. The interviewees also appeared to have serious misunderstandings of the homogeneous equation. For example, Fred appeared to believe that *any* homogeneous equation can only have the trivial solution:

Interviewer: If I had given you zeroes here instead of 3 and 2, would that still have a solution? That homogeneous linear system?

Fred: Yes, because homogeneous equation always have at least one solution, which is the trivial solution.

Interviewer: And what was the trivial solution again? Can you remind me one more time, what was that?

Fred: Trivial solution is $A\mathbf{x} = \mathbf{0}$, so zero is always the solution, for example $\begin{bmatrix} 0 \\ 0 \end{bmatrix}$

Jason appeared to hold a similar view:

Interviewer: Can you define homogeneous equation for me? What does that mean?

Jason: It means there's only one solution. I can't remember what it was.

Seth appeared to confound the trivial solution with the homogeneous equation:

Interviewer: Do you remember what the trivial solution is?

Seth: Uh, it's when $A\mathbf{x} = \mathbf{0}$.

Cecily, who was incredibly close to relational understanding of the connection between pivot positions and linear independence, made a similar mistake:

Interviewer: Why is it that not having a pivot position in every column tells you that these columns cannot be linearly independent?

Cecily: Because if there's not a pivot position in every column, then it can have infinitely many solutions. And for it to be linearly independent, it can only have the trivial solution.

Interviewer: Okay. So what can only have the trivial solution?

Cecily: The matrix, the linear system.

Interviewer: Okay. So what is the trivial solution?

Cecily: That's $A\mathbf{x} = \mathbf{0}$, right?

I reminded Cecily that she was describing the homogeneous equation before asking her what the trivial solution is; she claimed she did not know. As these interviewees had misconceptions about the homogeneous equation, it is likely that any connections evoked that involved the homogeneous equation could only be instrumental; further, it suggests that these several interviewees have misunderstandings of the formal definition of linear independence. Indeed, similar to span, some students provided geometric descriptions of linear independence; Bill, for example, claimed that a particular set of vectors was linearly independent "because they can all point in different directions." Others essentially appeared to instead interpret linear independence through basic and free variables instead of the homogeneous equation. For example, consider Seth's explanation of linear independence:

Interviewer: How, how come if it has no free variables, that means it's linearly independent?

Seth: Well if it has no free variable, that means that there was a pivot in every column, which would mean that it would have no free variables, because there wouldn't be, like, say a 2 out here. And, uh. This vector would always have a solution.

Seth's response was not unique. Several other interviewees tended to refer to basic and free variables often in their descriptions of linear independence, as did many students on one of the class exams.

It should be noted that when we discussed the homogeneous equation in class, we did not do this through an inquiry-oriented activity; I believed that the concept did not warrant such an activity, as students in the pilot study and fall semester appeared to understand the homogeneous equation fairly well through a mixture of lecture and whole class discussion. Looking back at the day that we discussed the homogeneous equation in the spring semester, I noticed that we concluded our initial coverage of the homogeneous equation with the following discussion of a homogeneous matrix equation that only had the trivial solution:

Instructor: So, could I have free variables?

Student: No.

Instructor: Kay. I can't have any free variables. Why not? Why can't I have free variables?

Student: You'd have infinitely many solutions.

As this was how we concluded our initial coverage of the homogeneous equation, it is possible that some students essentially replaced the concepts of trivial and nontrivial solutions with basic and free variables. That is, students made an instrumental connection between the homogeneous equation and basic and free variables, and as they did not quite understand what the homogeneous equation is and when it has nontrivial solutions, they instead considered when the homogeneous equation would have free variables. Then, when the formal definition of linear independence was provided in terms of the homogeneous equation, they tended to view linear independence in terms of basic and free variables instead of the homogeneous equation. Thus, many students in this semester relied on their instrumental connection between the homogeneous equation and free variables in order to compensate for their lack of understanding of the connection between the homogeneous equation and linear independence, thus interpreting linear independence largely through basic and free variables. This was likely exacerbated by the aforementioned linear independence activity, in which students could refer to the familiar concept of basic and free variables to determine whether the sets were linearly independent or not. Students who had not come to rely as heavily on free variables likely developed more geometric interpretations of linear independence as a result of the linear independence activity, as the sets in the activity were in $\mathbb{R}^2$ and $\mathbb{R}^3$, which can be easily visualized. Once these students had developed a more geometric interpretation of linear independence, they may have felt that the formal definition was no longer necessary for an understanding of linear independence.

Conclusions

In light of the results from the interviews, it appears as though the inquiry-oriented activities that focused on span and linear independence were successful in creating opportunities for students to develop their own interpretations of span and linear independence. The role of geometric descriptions in the class was limited, yet several students developed interpretations of span that appeared to be more geometric in nature; further, these interpretations often heavily alluded to linear combinations while not explicitly referencing linear combinations in an algebraic sense. Regarding linear independence, the activity allowed students to reinforce interpretations of linear independence that heavily relied on basic and free variables; it also allowed students to develop geometric interpretations of linear independence that relied on the notion that linearly independent vectors are not linear combinations of each other.

While the inquiry-oriented activities were successful in creating opportunities for students to form their own interpretations of span and linear independence and how they relate to other concepts, the implementation of these activities could be improved. Students appeared to replace their understanding of the formal definition of span and linear independence with the understanding they developed as a result of the activities. This may have limited the students' ability to form logical implication connections involving these concepts and their formal definition. In retrospect, the instructor should have devoted time to exploring how these student developments relate to the formal definitions of span and liner independence. Investigating how the inquiry-oriented activities could be improved in this regard remains an avenue for future research.

Mathematicians' Collaborative Silences

Matthew Petersen
Portland State University

In this paper I re-analyze the transcripts from Smith (2012) to investigate silence in mathematicians' collaborative work. I provide an existence proof that silence, at times, forms a significant aspect of mathematicians' embodied work. Based off a discussion of the nature of embodied interaction, the paper concludes that it is likely that silence forms a significant aspect of mathematicians' collaborative work, more generally, both in discovering new mathematics, and in ordering the mathematicians together toward the task of discovering new mathematics. Because this use of silence is different from that of everyday conversation, this raises important pedagogical questions regarding students' apprenticeship into the mathematics profession.

Key words: [Silence, Ethnography, Mathematical Practice, *Habitus*]

It may seem paradoxical to study the use of silence in mathematical activity—to study, as it were, the times when mathematicians are *not* doing something. However, as St. Ambrose notes, we are at least as likely to err due to inopportune speech as to silence—for instance, we all can remember blurting out a comment that derailed a productive and interesting conversation, when we should have listened carefully, and held our tongue. Indeed, we often "speak because [we] do not know how to be silent" and are "rarely silent, even when nothing is gained by speech." Therefore "it is more difficult to practice silence than speech," and "we ought to learn silence, so we can speak well" (*De Officiis*, I.5).

The appropriate uses for silence, like the appropriate uses for speech, however, are context specific. Not only must we learn how to be silent, we must learn how to be appropriately silent, in the various activities and interactions we undertake. For instance, in English, silence following an invitation can communicate a rejection of the invitation (Liddicoat, 2011); and this fact needs to be learned by second language learners. Or, both teachers and students learn to respond to the silence at the end of a designedly incomplete utterance (Koshik, 2002) which marks that a teacher's statement has been left incomplete and so transformed into a question. Or, to take an extreme example, in some Apache interactions, silence is the predominate form of communication, and speaking during the silence would be disruptive (Basso, 1970).

Mathematical collaboration, is, like all concerted activity, coordinated and accomplished through perceptible non-linguistic actions (e.g. eye-gaze, speech rhythm), including silences, through which people position themselves and their colleagues around the tasks they undertake, and direct themselves and their colleagues together toward achieving common goals (McDermott, Gospodinoff, & Aron, 1978; Liddicoat, 2011). Because actions have this social function the bodily actions mathematicians use in their collaboration, even when those actions do not signify mathematical realities, are important aspects of mathematical collaboration.

In learning to be a mathematician, then, it is important to learn not only the disciplinary norms regarding kinds of speech and reasoning, but to learn when speech would be *inopportune* and disruptive; and to learn to respond appropriately to a colleague's silence. One can investigate empirically whether mathematicians employ silence in their collaborative activity. Moreover, because silences longer than a second are unusual in everyday conversation, and communicate the need for someone to speak (Liddicoat, 2011), if silences are used more extensively than in everyday conversation, that fact is pedagogically important.

Theoretical Perspective

In an influential essay (1973 [1935]) Marcel Mauss, a leading French Anthropologist, developed the concept of technique or technology of the body. This concept continues to be employed in leading anthropological works (e.g. Asad, 2003; Mahmood, 2005; Strhan, 2015), literary theory (e.g. Allan, 2016, though he doesn't explicitly use the term; Saussy, 2016), and theories of embodiment (e.g. Saussy, 2016). Without an analysis of the techniques of the body, an anthropological investigation of technology is incomplete (Mauss, 2007).

Mauss defines a technique as "an action which is *effective* and *traditional*" (p. 75), that is, learned. A technique of the body, then, is an effective, learned action which employs the body as an instrument for achieving a goal. Because the French, like the English, terms that could be employed to describe a technique of the body do not quite convey the correct sense, Mauss used the Latin term *habitus* to refer to a technique of the body, a usage which has been carried over into the English writings that draw off his work.

Mauss used the concept of technology of the body to explore diverse activities like walking, swimming, sleep, sexual positions, child-birth, etc. and argued that in fact all our bodily techniques that, as adults, we employ in our day-to-day activities are technologies of the body; that is, in part psychological, in part physiological, and in part learned. For instance, the human body is well suited for walking, but the particular gait we employ is culturally specific, and so learned.

It is the learned aspect of *habitus* that makes his notion educationally relevant. In addition to learning to know particular ways of reasoning, and particular facts, there are particularities of *habitus* that we learn as we apprentice into various professions. Because mathematicians are, like all of us, embodied, the work of doing mathematics includes a particular *habitus* and in their course of studies, students are apprenticed into this *habitus*.

Though the concept is widely used and valid, one shortcoming of Mauss' description of techniques of the body is that he doesn't adequately attend to the spatial and interactional aspects of our *habitus* (Crossley, 1995). Techniques of the body not only achieve goals like walking across a room or proving a mathematical theorem, they accomplish what McDermott, et al. (1978) call positionings, the ongoing, in the moment, work of orienting a group of people together toward a common activity.

Two aspects of positionings are worth mentioning. First, the guestures involved in positionings are often not overt, macro gestures like "look over there", but the whole panoply of subtle cues like eye-gaze, body posture, and sort of speech (or lack of speech) particular members of a group use. Indeed, all the perceptible gestures potentially contribute to the positioning, and cannot be, over the long-term, opposed to the over-all configuration the group has taken up. The gestures are not contrary to the order because of the second aspect worth mentioning: When people depart from an order, the group may nevertheless maintain that order. They do so when the departure treated as a breach of the order, and the person who departed, directed (through overt or covert means) to return.

The perspective sketched here is similar to the one employed by Nemirovsky, Kelton and Rhodehamel (2013), which "propose[s] that mathematical knowing is constituted by—not dialectally related to—embodied tool use." However, it differs in two key ways. First, it recognizes that, as Muass states, our "first and most natural technical object, and at the same time technical means, is [the] body" (p. 75), so that the body *itself* is a tool. This addition facilitates an attention to the ways learned embodied actions constitute mathematical knowing, even in the absence of, or in abstraction from, other technologies. Second, my approach is more attentive to the ways we use our bodies not only as a tool for doing mathematics, but as a tool for positioning each other in a given mathematical task, and so using our bodies *in concert*. An emphasis on the *habitus* also has the potential to make an explicit link with examinations of the Politics of mathematics education and so and critically interact with Foucauldian, Bordieuan, and perhaps even Marxist examinations of mathematics education (Burkitt, 2002; Asad, 2003; Mahmood, 2005; Bang, 2014; for the Politics of mathematics education, see e.g. Pais & Valero, 2012; Kollosche, 2016).

Literature Review

There has been relatively little anthropological or sociological investigation of the materiality of doing mathematics, and the face-to-face communicational practices indigenous to the mathematics community. Indeed, sociological investigations of doing mathematics *at all* are rare (Greiffenhagen, 2006; Greiffenhagen & Sharrock, 2005).

Those studies that have investigated the doing of mathematics have tended to focus on the linguistic aspects of doing mathematics. For instance, Weber (2008) and Weber and Mejia-Ramos (2011) investigated the techniques mathematicians use to evaluate proofs. Their investigations, however, focused on the types of reasoning (e.g. formal or informal) and the goals of reading proofs; but not on the techniques of the body the mathematicians used to undertake those styles of reasoning and reading, and to achieve their goals.

On the other hand, sociological investigations of the embodied nature of abstract mathematical reasoning—that is, of mathematical *habitus*—though few in number, do establish that mathematics is not a purely mental phenomenon, but that the doing of mathematics employs various bodily and material techniques and technologies. For instance, Greiffenhagen (2006; 2014) demonstrates the importance of the blackboard, and its spatiality, in doing a mathematics proof, particularly through the facilitation of particular gestures which embody mathematical activity. For instance, when attempting to create "space" between two numbers in order to prove an inequality, a mathematician may orient him, or her, self to that metaphorical space by gesturing along the blank spaces created by blackboard inscriptions.

Smith (2012) also investigated the material practice of doing mathematics. He found that when mathematicians struggle with mathematics, their actions and perceptions make use of particular material and bodily aspects of their world. For instance, several mathematicians he studied exhibited what he called *proximal inhibition*, in which they are both drawn toward a physical representation of the mathematics, and yet, because of a lack of knowledge of *where* to approach the symbolized mathematics, are held back.

These three studies establish that mathematicians use various *habitus* in their doing mathematics—mathematics is not a purely mental operation, rather, like a harp player, or someone walking across the room, mathematicians employ their body as an instrument for accomplishing their work. However, the analysis of this *habitus* has never attended to silence.

Silence also tends to be a neglected, but important, aspect of communication (Saville-Troike, 1989, p. 148) and of *habitus* (Acheson, 2008). Furthermore, communities have specific communicational norms regarding the toleration of silence in interaction, the meaning of silences, and the function of silences in achieving various goals, and so an investigation of the functions and uses of silence in a particular community is pedagogically relevant: If silence

Table 1

	Episode name in Smith, (2012).	Total time (s)
Joseph & Bill	Tubes	70
	Chain Map	241
	Odd Scalars	158
	Indexical Map	120
	Finger Moves	140
Matt & Bart	Bart Pushed Back	67
	Inverted Pyramid	183
	Adjusting a Triangle	167
Fay & Martha	Graph Confining	158

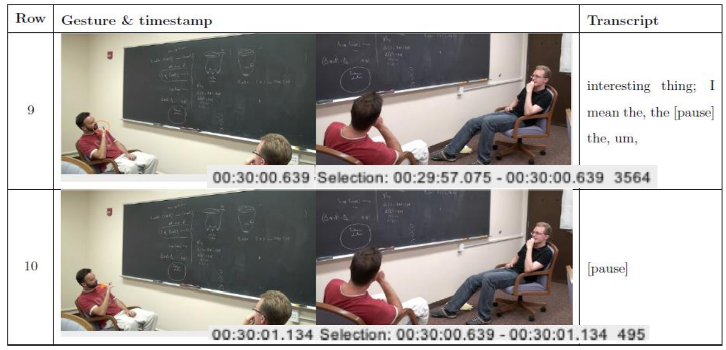

Figure 1: A page of Smith's (2012) transcript (p. 261), taken from episode 3 (Joseph & Bill). The top frame includes an unmeasurable silence, the bottom contains the first half second of a 5 second silence (at the beginning of the episode).

forms a part of the *habitus* mathematicians employ in their work, in positioning themselves and their colleagues around the (symbolized) mathematics, and so orienting themselves to the task at hand and achieving the goal of discovering new mathematics, that use of silence is learned.

This leads to the research question addressed in this paper: Is silence an aspect of the *habitus* cultivated by mathematicians, that is, an aspect of their body technique employed both in their collaborative work of doing mathematics, and in their positioning themselves and their colleagues in relation to their task of doing mathematics.

Methodology

For this study, I reanalyzed the transcripts included in Smith's doctoral dissertation (2012). Smith's research question was "What are some ways in which mathematicians structure their experiences of struggle while working in pairs in person on a current problem?" (p. 46) To answer this question, he recorded ten total hours of collaboration between practicing mathematicians (Matt & Bart), and between PhD students nearing their defense and their major professor (Joseph & Bill and Fay & Martha). (I use the pseudonyms Smith used.) He included the latter two pairs based on a judgment that their collaboration was sufficiently similar to the collaboration of mathematicians to answer his research question but also regular enough to schedule video-recording. After collecting the data, he narrowed his investigation to 9 episodes, between 1:09 and 4:01 long, 21:43 total, that were particularly salient for his research question. Joseph and Bill's activity was analyzed in 5 episodes, Matt and Bart's in 3, and Fay and Martha's in 1.

Smith (2012) includes a transcript of all the episodes in appendices. These are intended to allow the reader to verify the results of his in depth microethnography (Erickson, 1996). The transcript consists of 1,029 screen shots—0.79 frames per second—time stamps, arrows indicating motion, and transcriptions of speech (see Figure 1 for a sample). If the participants were silent for all or part of the time recorded in a screen-capture, the transcript says [pause]. 309 frames (30%) record pauses, though the length of many of these pauses is unmeasurable (I assume it is less than 1 s. for this analysis). The only text accompanying a number of frames, however, is [pause], and the length of these silences can be measured by recording the initial time-stamp of the frame the silence starts on, and the final time-stamp of the frame the silence ends on. When the length of a silence can be measured, I call it a measurable silence.

To determine how prevalent silence was in these mathematicians' cooperative work, I recorded the length of all the measurable silences by noting the initial and final time stamps for any pauses in their speech. In five frames there was only a very small amount of text (for instance, one letter), but the rest of the text was recorded as [pause]. I included these frames as parts of measurable silences, though I adjusted the total time of the slide slightly. For this analysis I did not attend to their gestures, but it is worth noting that any time was spent writing on or erasing the board in only three silences, all under five seconds.

Some very short pauses were measurable, and, because Smith was not attending to silences, we cannot conclude that pauses shorter than a particular time are measurable—Fay and Martha's session in particular includes a number of silences that would be unmeasurable in the transcripts of other groups' works. In order to have a relatively uniform grain-size, and because silences shorter than 1 second are common in American English (Liddicoat, 2011), only silences longer than one second are included in this analysis. Silences shorter than one second are assumed to be a part of the natural rhythms of speech, and not a separate phenomenon.

Because ten two second silences may be very different from one twenty second silence, to get more information about the length of the silences, I also collected data on silences longer than 5, and 10, seconds.

Table 1 lists the names Smith (2012) gave to the episodes he analyzed, and the total length of each episode. The episodes are ordered, first, based on participants, and then, within each category, on percentage of time spent in 1+ second pauses. Throughout this paper, episodes are listed in the same order as in Table 1. In Figure 4, where the episodes are arranged vertically, the same top-to-bottom order is preserved. In Figure 2 and 3, the episodes are arranged horizontally, and the top-to-bottom order is preserved left-to-right in those Figures.

Results

The results are summarized in Figures 2-4. Figure 2 presents the percentage of time in each episode spent in silences longer than one, five, and ten seconds, respectively. In five of the nine episodes, four of them involving Joseph & Bill, the mathematicians spent more than 20% of the episode silent; in two of the episodes, more than 50% was silence. In four of the nine episodes, more than 20% of the time was spent in 5+ second silences. In three of nine episodes, more than 15% of the time was spent in silences longer than ten seconds, and in a fourth, 13.4% of the time was spent in silences longer than 10 seconds. In two episodes, more than 35% of the time was spent in silences longer than 10 seconds.

Figures 3 and 4 help visualize that use of silence. Figure 3 displays all the silences longer than 1 second in each episode. Because the episodes are not all the same length, the total time of each episode is displayed as a secondary category. Figure 4 contains a timeline of each episode. Time in which both mathematicians were silent are symbolized with a line, time in which either spoke, or the silence was shorter than a second, are displayed by blank space. An inspection of Figure 4 suggests that the mathematicians' work may be divided into periods in which silence is common and periods in which silence is rare; however, there is not enough data here to address that conjecture.

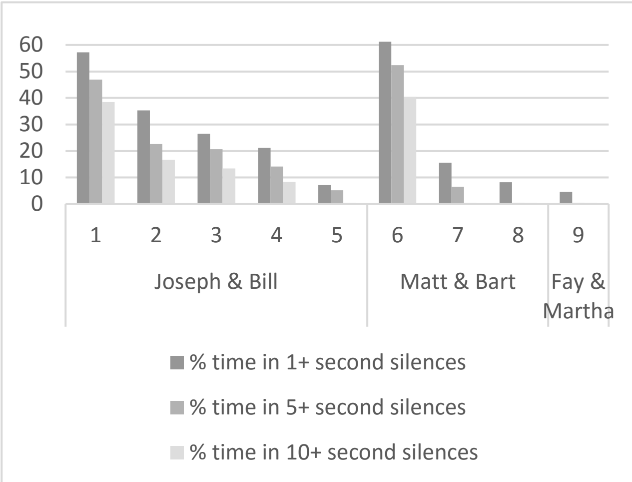

Figure 4: Percentage of time, per episode, in 1+, 5+, and 10+ second silences

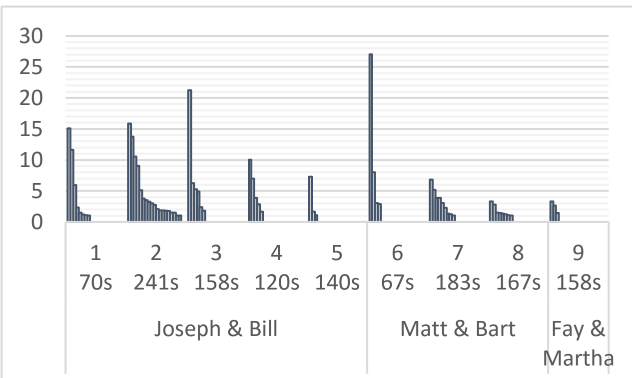

Figure 3: Length of each silence, in seconds, in each episode. The subcategories on the horizontal axis list the total time of each episode.

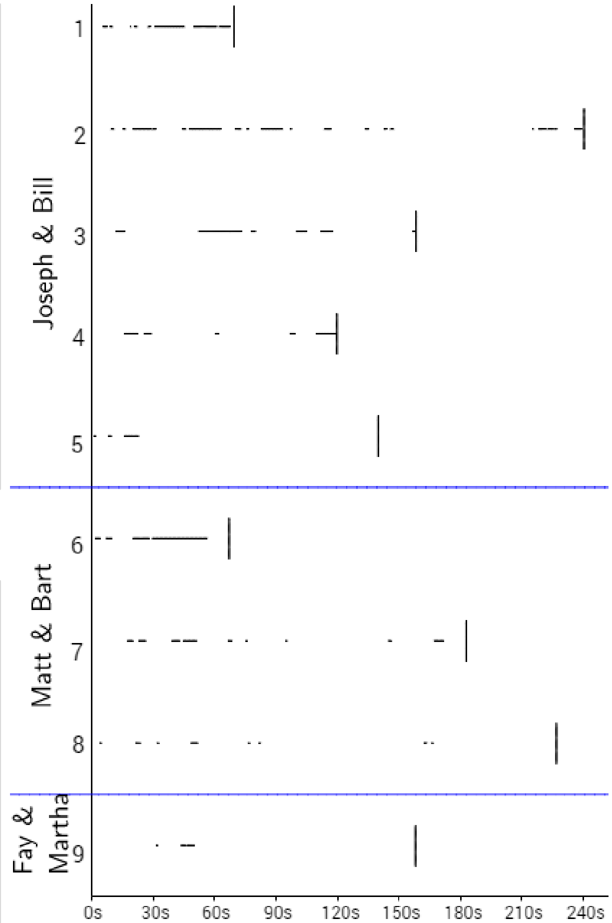

Figure 2: Timelines of the episodes analyzed in Smith (2012). Silences of over one second are represented with a line, times when the mathematicians were speaking are left blank.

Discussion

It would, obviously be invalid to try to generalize these findings statistically. The significance lies in the fact that, in episodes that a researcher selected as an interesting example struggle with mathematics, without any reference to silence, the researcher still selected episodes containing a very large amount of time in lengthy, mutual, silences. These are not times of inactivity, but of intense activity. Moreover, the fact that the mathematicians engaged in lengthy silences implies that these silences are a part of efficient, learned, bodily mathematics activity. That is, they form an aspect of the *habitus* of four of the mathematicians whose work was analyzed in Smith's dissertation. (Fay and Martha are not seen employing it much.)

Furthermore, in American English, silences of over a second are often treated as a lack of speech (Hepburn & Bolden, 2013), and people orient to the silences themselves. Contrary to the usual expectation, the mathematicians whose work is analyzed here are not only silent for long periods of time, they are silent *together*. That the silences are co-produced is important for two reasons.

First, this provides evidence for the generalizability of the episodes analyzed here. In not quickly breaking the silences, and attempting to redress the breach of the conversation, the mathematicians treated the lengthy silences as an *entirely normal* element of their work. That the silences are treated as normal indicates that while silence may not be a universal feature of the *habitus* of mathematicians, it is a relatively common aspect of the mathematical *habitus*.

Second, because in all our activities we are engaged in positionings of the people we are interacting with, and because silences are usually noticeable, it seems likely that silence was an element of their mutual positioning—that is, that the mathematicians oriented each other to the task at hand, in part, through their silence.

Conclusions

In these episodes, silence was an important aspect of the mathematical *habitus*, that is, both in its orientation to solving a mathematical conundrum, and critically, in positioning a peer toward the same goal. The mutual tolerance for silence is in contrast to findings regarding silence in student group-work. In student work, silence is sometimes an aspect of the effective embodied practices students employ to answer vexing mathematical problems; however, other students often read the silence as a problem, and attempt to rectify the problem by eliciting a response (Petersen, 2015; Petersen, under review).

It may, at first glance, be that mathematicians use silence more extensively in their attempts to resolve vexing questions than students do, or they may use it roughly the same amount. However, they have learned not to treat the silence as a breach of group work, and a lack of speech needing rectified, but to respond to it, at least sometimes, by silently engaging with the mathematics. This response to silence is pedagogically relevant, because it differs sharply from student responses, and from the use of silence in every-day conversation.

We can also, perhaps, conclude form this response that in fact, mathematicians incorporate silence into their work more extensively than students do—if they did not, they would treat the silences like students have tended to—though there may also have been specific gestures accompanying the silence that communicated the quality of the silence, and its use.

The difference between the mathematicians' use of silence and the students' use raises several questions for future research: Is there something specific to the practice of mathematics that mathematicians utilize silence in their work, and this use of silence needs to be learned as students are initiated into doing mathematics? Was there something specific about the gestures that accompanied the silence in these episodes that communicated that the silence was a potentially productive, active silence, not an awkward pause, or lapse in the work? How do various teaching styles help students to learn to use silence as mathematicians do, and how do they inhibit that learning? If these silences were accompanied by gestures that communicated the potential productivity of the silence, how are we teaching our students to subconsciously notice those gestures, and to be positioned toward engagement with the mathematics, or at least, to recognize that their peers are actively working, even if not speaking? And finally, are there technological aspects to these silences—do different external technologies provide affordances or hindrances to employing silence like these mathematicians did? Further fine-grained analyses of student and professional mathematical practices are needed to address these questions.

Graduate Student Instructors learning from peer observations

Daniel L. Reinholz
San Diego State University

Graduate Student Instructor (GSI) professional development addresses an urgent need to improve STEM retention. This paper focuses on a semester-long professional learning community in which six mathematics GSIs engaged in regular cycles of peer observation, feedback, and reflection. In contrast to most GSI development work, this approach emphasized that GSIs give, not just receive, peer feedback. Analyses of post-semester interviews indicated that all GSIs enhanced their noticing of students. Moreover, insight into peer feedback was developed along three dimensions: (1) the importance of being an objective observer, (2) the impact of working with equal-status peers, and (3) the value of critical feedback.

Keywords: Graduate Student Instructors (GSIs); Graduate Teaching Assistants (GTAs); Professional Development; Noticing; Reflection

Introduction

Introductory college calculus is a major barrier for students pursuing STEM careers (Bressoud, Carlson, Mesa, & Rasmussen, 2013); low student success rates in calculus contribute to a lack of persistence, which has become an issue of national concern in the US (PCAST, 2012). Fortunately, a growing body of evidence highlights the positive impact of student-centered teaching practices (Freeman et al., 2014), particularly in improving student persistence (Kogan & Laursen, 2014). Despite this evidence, college mathematics classrooms are still dominated by instructor-centered teaching (Lutzer, Rodi, Kirkman, & Maxwell, 2005). Thus, there is an urgent need to improve instruction in introductory undergraduate mathematics courses in the US.

Graduate Student Instructors (GSIs) play a crucial role in teaching these introductory mathematics courses. Yet, GSIs typically receive little professional development (Austin, 2002). To implement student-centered teaching practices, GSIs need to learn to attend to and respond to student thinking (Franke, Carpenter, Levi, & Fennema, 2001; Sherin, Jacobs, & Philipp, 2011). Accordingly, this paper explores how peer observations help GSIs enhance their noticing of student thinking. In contrast to observations by faculty or more experienced GSIs (Miller, Brickman, & Oliver, 2014), peer observation supports noticing through giving, not just receiving, feedback. It also helps alleviate the costs of scaling and sustaining traditional methods of observations, which may create an undue burden on faculty members and more experienced graduate students. In the present study, six mathematics GSIs met regularly in a professional learning community (PLC; Stoll, Bolam, McMahon, Wallace, & Thomas, 2006) and engaged in cycles of peer observation, feedback, and reflection through the PLC.

This paper addresses two research questions: (1) how was GSI noticing impacted by peer observation? and (2) which features of peer observation supported or inhibited noticing? Analyses of post-semester interviews indicated that all six GSIs felt more reflective about their teaching. Moreover, they described: the importance of being an objective observer, the impact of working with equal-status peers, and the challenges of providing critical feedback. Based on these results, this paper argues that peer observations provide a number of additional learning benefits that extend beyond traditional observations of GSIs.

Theoretical Framing

Enacting student-centered pedagogies requires GSIs to build on the resources that students bring to the classroom. To build on these resources, GSIs need to engage in three related processes: attending to, making sense of, and responding to student thinking (Jacobs, Lamb, & Philipp, 2010). The study of such decision making comprises the field of *teacher noticing* (Sherin et al., 2011). The goal of the present work was to help GSIs enhance their noticing of students, rather than focusing primarily on themselves.

PLCs can enhance noticing, as instructors reflect on their practice with peer support (van Es & Sherin, 2008). PLCs are *communities of continuous inquiry and improvement,* with five key features: (A) shared values and vision, (B) collective responsibility, (C) reflective professional inquiry, (D) collaboration, and (E) group, as well as individual, learning (Stoll et al., 2006). In this study, the PLC gave GSIs opportunities to provide feedback, not just receive it. Given the benefits of peer assessment (Reinholz, 2015c), it was hypothesized that this would enhance noticing more than simply receiving feedback from others. Recognizing that not all feedback is equal (Hattie & Timperley, 2007), GSIs were helped to provide critical, supportive feedback to their peers. When feedback focuses on *processes*, it is more likely to draw attention to student thinking, in contrast to feedback focused on *people*, which will draw attention to the GSIs themselves (Reinholz, 2015b). Person-focused feedback, such as praise, actually inhibits learning (Hattie & Timperley, 2007; Mueller & Dweck, 1998).

Providing feedback position GSIs as competent (Engle & Conant, 2002), and there is evidence that individuals may learn as much from providing feedback as receiving feedback (Reinholz, 2015c). Thus, conducting observations rather than just being observed provided GSIs with opportunities for enhanced noticing. In particular, it allowed GSIs to enter the classroom as a third party without the cognitive load of teaching. This paper adds to the study of noticing and GSI professional development by elaborating these opportunities for improved noticing.

Method

Participants

Six GSIs teaching either calculus 1 or 2 at a large research-intensive university participated in the study. The calculus classes were comprised of (each week): (a) three 50-minute lectures, (b) one 50-minute recitation, and (c) one optional 100-minute workgroup. The GSIs each taught a combination of 3-4 recitations or workgroups. The recitations consisted of GSIs: answering homework questions, completing examples, providing short worksheets, and administering quizzes. The workgroup sessions were collaborative problem solving sessions, modeled on the Emerging Scholars Program (ESP; Treisman, 1992). A key insight from the ESP was that providing students with additional challenge, rather than remediation, was a more effective way to support their success in calculus. The collaborative groupwork sessions were also designed to promote community and collaboration amongst the students.

GSIs received no incentives for participation in the PLC; all four calculus 2 workgroup instructors participated as a part of the department's efforts to improve instruction, and two calculus 1 instructors were chosen by the department to participate. There were four female and two male GSIs, five domestic GSIs and one international GSI, and the GSIs had a variety of teaching backgrounds; the four female GSIs were in their first year of teaching in the department, and the male GSIs had been teaching for a number of years.

Design

The GSIs in the study met as a PLC and conducted regular peer observations during a single semester. The PLC was facilitated by a mathematics educator, who shared videos, articles, and feedback on teaching with the GSIs. The facilitator also assigned short "homework assignments," which required GSIs to implement active learning strategies in their recitations or workgroups. The PLC typically met every other week, for a total of seven one-hour sessions.

To help GSIs develop a shared vision (PLC principle A), GSIs reflected on and discussed their prior experiences as learners during the first PLC meeting. To support collective responsibility (principle B), reflective professional inquiry (principle C), and collaboration (principle D), the facilitator refrained from providing "answers" to the GSIs, instead creating opportunities for collective reflection and discussions of teaching. To support individual and group learning, GSIs had one-on-one conversations with their peers after observation, and the observations were later discussed collectively in the PLC (principle E). To create a safe space for these public conversations, the facilitator promoted a culture of sharing: each meeting began with a debrief on GSI experiences during the past two weeks. Moreover, the PLC discussed norms of giving feedback and normalized struggle as a part of learning.

The GSIs each completed 5-6 peer observations total, with three of their peers (two observations per peer). These observations were based on Peer-Assisted Reflection (Reinholz, 2015a). Each observation involved: (1) the GSI setting goals for the observation, (2) a peer observing and video recording the session, (3) a debrief conversation between the two GSIs after they both observed each other, and (4) a whole-group debrief during the next meeting.

To support feedback and reflection, the GSIs each completed peer feedback forms. The observed GSI began by listing their goals for what they wanted a peer to pay attention to. Then the peer provided specific examples to answer three questions: (1) What opportunities did students have to talk about mathematics?; (2) What opportunities did students have to work with other students?; and (3) What else did you notice, both related to the instructor's goals and otherwise?

Data Sources and Analysis

Pre and post interviews were conducted with the GSIs. In addition, all group meetings were audio recorded, and peer observation forms were copied. The pre-interviews provided context and background on the GSIs; the post-interviews were used as the basis for the analyses that follow. The post-interviews focused on the following areas: teaching philosophy, Peer-Assisted Reflection, experiences exchanging feedback, and beliefs about feedback. The goal of the interviews was to holistically understand how the GSIs experienced exchanging peer feedback, including: how they felt, what they learned, and what challenges they encountered.

All interviews were transcribed and coded by the researcher. The goal of coding was to understand how GSI noticing was impacted by peer observation. Drawing from techniques in grounded theory (Glaser & Strauss, 1967), a first pass of coding was conducted to identify emergent themes. These themes were: (1) objective observers, (2) equal-status peers, and (3) critical friends. Once these themes were identified, the researcher completed a second pass of coding to look for the prevalence of themes across the six post-interviews. The presentation of results that follows is illustrative, intended to highlight important areas for future research. All names below are pseudonyms.

Results

Objective Observers

All six GSIs discussed how they became more reflective about their teaching and improved their noticing of student thinking as a result of observing their peers. For example, Leo contrasted his years of prior experience with his engagement in the PLC,

> I didn't really think that much about teaching. I would sort of hope my students did well on the tests and give me good [ratings], but thinking about the process is something that I've really gotten out of this, and to really try to empathize a little and put yourself in the students' shoes and ask what is this teacher doing, or what should this teacher be doing.

Leo describes that teaching was something he did for many years, but "didn't really think that much about." In contrast, the PLC provided Leo with time and space to reflect on his teaching, learning to put himself in "students' shoes." Leo described the importance of observations, which allowed him to be in a classroom unburdened with the responsibilities of teaching,

> Well when you're not constantly running around helping people with math, it's really easy to tell when groups have sort of lost focus. You also get a better feeling for, I think, the dynamic between people, seeing how certain groups view their teacher…

In other words, peer observations supported Leo to improve his noticing of students, because they provided him with an opportunity to focus *only* on students, rather than all of the other responsibilities associated with teaching. Similarly, Tina described enhanced noticing resulting from being an observer,

> I was able to pay more attention to students' interactions in other workgroups. I guess I learned something about how the students interacted...I feel like there were the different groups. There was the group that had a ringleader that would get everyone going and would lead everything, and then there were some groups that would just not be working, and then there were groups that would be working pretty well together.

Broadening from the specifics of student-student interactions, peer observations allowed the GSIs to compare the different types of classroom environments that their peers created. For instance, Celeste reported on insights developed by comparing three different peer classrooms,

> I knew that I have some problems with my recitations, I knew that I'm not as good as I should be. And observing Tina and Tara and Elayne I saw, OK, this one's not working so probably I should not do it, and this one is working.

Celeste describes noticing what was "working" and "not working" in her peers' classrooms, which informed what she herself would do as a teacher. In this way, being present in a variety of peer classrooms allowed Celeste to see various gradations in teaching practices, which is a key aspect of identifying a high-quality performance (Sadler, 1989).

The observations also provided GSIs with concrete instances of student-centered teaching. For example, Elayne emphasized the value of watching Edgar teach, who focused on "guiding students" rather than just "giving them the answer,"

> Well I learned a lot about just the whole guiding students to the answer instead of giving them the answer, just watching other people- like I keep bringing up Edgar, because I think he was one of my favorite people to observe because he would literally just ask questions the whole time and not give any answers.

Elayne further described how such observations changed her views on teaching,

> A big role that I found this semester was just learning to ask the right questions and having patience… if the student is able to get to the answer on their own instead of you just giving them the answer, it builds their confidence and they retain it longer. Even though it might take three times as long for the student to get there instead of you just showing it to them, in the end they're going to do better in the class and be able to learn the math better if you allow them to get to it eventually.

As the above interview excerpts highlight, observing their peers provided opportunities for the GSIs to notice new things in the classroom. Although changes in GSI teaching practices were not analyzed, prior research showed that working with GSIs in the same department in a similar setting resulted in measurable changes in practices (Reinholz et al., 2015).

Equal-Status Peers

An important feature of the PLC was that the GSIs observed peers of relatively equal status. This contrasts approaches that focus on "experts" (experienced GSIs or faculty members) observing or being observed by "novices" (new GSIs). This allowed the GSIs to form community with their peers. As Leo noted, the PLC helped him shift from competition to collaboration,

> It was kind of a nice supportive environment. I really liked our group meetings where we sort of realized we're all in the same fight. Sometimes there's a little bit of competition, at least in my mind, between [GSIs], because you really want to have good [student ratings] and that's sort of only measured relative to a baseline. So you're like I want to be the best, I want my students to love me the most. But really more interesting are these questions of how do we prepare our students, all of our students, the best, and how do we teach the best. It was good to have actual regular meetings with other teachers in a way that... I don't know. It was a good emphasis on pedagogy, reminding myself why I'm actually there. It's not to get high scores, it's to teach kids math.

The GSIs also discussed the culture of mathematics and the pressure to understand all of the mathematics that they were teaching at a deep level. When the GSIs observed their peers and realized that their peers also found aspects of the mathematics challenging, it was reassuring for them. Even Edgar, who was a relatively experienced GSI, noted that the peer observations helped him overcome aspects of his imposter syndrome,

> [T]hey're also not crazy experts with the material. In learning that I felt more comfortable…There were instances where I was like I know how sequences and series work, and then I'd try and teach somebody how sequences and series work and I'd be like ah, fair enough, I don't know how sequences and series work…just seeing that [other

> GSIs] were also struggling with that is reassuring, that I shouldn't feel the imposter syndrome or anything like that.

Edgar's comments speak to broader cultural issues around mathematics, in which mathematics is often equated with intelligence (Nasir & Shah, 2011) and there is great pressure for the GSIs to act as authorities in the discipline. In observing Tina, Edgar noticed that she would often look at the solutions to problems during in the middle of workgroup sessions, and he realized that it was all right for him to do the same thing,

> So I was like, OK. I've always kept the solutions in my back pocket, so then it feels weird to, like, here are the solutions right in front of the group. Leaving and saying work on this and then refreshing privately, so to speak, so you maintain the aura of knowledge.

Here Edgar describes a concrete strategy, leaving and looking at answers away from the group, that allowed him to maintain what he perceived as his necessary authority as an instructor, while "refreshing" his understanding of the mathematics.

The idea of an "aura of knowledge" speaks strongly to narratives tying mathematics and intelligence (Nasir & Shah, 2011) and the perception of authority that GSIs felt that they had to maintain. Related to these narratives, Tara expressed anxiety in being observed,

> I mean sometimes the students would ask really hard questions and I wasn't completely sure of the answer, so I was worried that I'd be judged for being stupid by the other [GSI] basically.

As Tara expressed, the GSIs felt pressure to be experts. Addressing this "anxiety" has potential to support GSIs through peer observation and in GSI development more generally.

Critical Friends

All six GSIs stated that they found critical feedback to be more helpful than praise. For instance, Celeste discussed how overly positive feedback did not support her learning,

> Tina and Tara…they were always happy with the things that I wanted them to look at and I don't think that's very accurate…I think they wanted to be encouraging, like keep doing that, it's good. But I kind of liked Elayne's [feedback] the best because she actually provided actual things that I have to improve.

Upon receiving this not-so-helpful feedback, Celeste recognized that when she provided the same types of feedback to her peers it must also not be so helpful for them. As such, she altered the feedback she provided to peers to be more critical,

> I know that at the beginning I was like everything's great, nice, you're doing good. So I did that, and I know I did it. I didn't know them or what they would think, how they would react, would they get angry, so I wanted to be positive. But after Elayne I understood that's not the point. I knew when we talked that that's not the point, but it's different when you actually experience it. After that I tried to be more critical.

Celeste describes the initial barrier to providing critical feedback; she did not want to hurt the feelings of her peers or be judged by them. Yet, as she received critical feedback from Elayne, she realized that this was an important part of supporting her peers to grow, and changed her feedback accordingly. Edgar similarly described critical feedback as supportive,

> It's kind of like if I have to write a cover letter for my next job application and I hand it to my good friend Joe, and Joe says this is awesome, well done, I think you're going to get the job, you're a cool person, I would hire you. I'm like thanks Joe, you're nice. And then I give it to my good friend Stephanie – and I don't have any friends named Joe or Stephanie, these are made up names – and she says well, you know, it's passable. I've seen cover letters like this, I've written cover letters like this. It's good, but you could do better. There's this and this. I write like this, so when I read your handwriting doesn't make any sense to me. Take it or leave it, because when people read my handwriting they say the same thing to me. Tonal choices. This whole paragraph, what does it mean? It doesn't mean anything, I didn't get anything from it. What were you saying with that paragraph? It's like thanks Stephanie, I feel like I'm going to get the job now because I'm going to get rid of that paragraph and write something useful.

Here Edgar contrasts being "nice" with being "supportive." Edgar describes two imaginary friends, Joe and Stephanie giving him feedback on a cover letter. Joe is *nice* because he provides encouragement, but Stephanie is *supportive* because she provides critical feedback that can be used as fodder for improvement. In this professional context, Edgar emphasizes that support is more useful than niceness, and will actually help him get a job.

Discussion

The present paper provides evidence that peer observation can enhance noticing. In particular, when GSIs are positioned as competent to provide meaningful feedback to their peers, they can learn through observing others and form meaningful community with equal status peers. As such, equal-status peer observation can improve GSI professional development. For instance, it offers a low-cost alternative to observations conducted by faculty or experienced peers, because the very process of observing GSIs becomes a learning experience for the observer rather than a "cost" for the observer in service of another GSI's learning. Moreover, it gives GSIs an opportunity to interact with students in a different capacity, increasing their understanding of their students. Despite the benefits, peer observations can be inhibited by the inter-personal challenges of GSIs criticizing other GSIs who they view as friends or colleagues. Addressing this issue requires building an environment that supports supportive, critical exchange.

This paper also suggests new directions for research in teacher noticing. While peer observation as a tool for noticing appears promising, further research is required. In particular, the mechanisms through which peer observation can support individual reflection need to be further elaborated. Moreover, further research is required to understand how this type of reflective community practice impacts the actual teaching of GSIs in the classroom. These are promising avenues to continue this work.

McNuggets, Bunnies, and Remainders, Oh My!

Nina C. Rocha & Jennifer R. Zakotnik-Gutierrez
University of Northern Colorado

Given its applications in computing, coding, and cryptography, the Chinese Remainder Theorem is a worthwhile, accessible, and unexplored area of number theory. The purpose of this qualitative case study was to investigate strategies and reasoning that students exhibited while solving problems chosen to elicit thinking in elementary number theory topics related to the Chinese Remainder Theorem. We interviewed pairs of students from three different courses in order to investigate the similarities and differences that may occur as a result of varying mathematical backgrounds and partner dynamics. We identified a range of strategies including manipulating final digits, listing multiples while accounting for remainders, and implementing divisibility rules. This paper presents a portion of our findings discussing strategies for two of our three cases on several tasks from our interviews.

Key words: Chinese Remainder Theorem, Frobenius Problem, Pre-Service Teachers

Objectives and Background

Although many mathematicians would agree that knowledge of elementary number theory helps students to build a firmer foundation upon which other mathematical knowledge is based, the area remains relatively unexplored in mathematics education research. For instance, several studies have revealed the difficulties that undergraduates have with divisibility, prime factorization and remainders (Campbell, 2002; Zazkis, 1998). However, authors have yet to investigate students' understanding of subjects including the Chinese Remainder Theorem and Frobenius Problem. We believe these areas deserve further study, given students may be able to develop an intuitive understanding of the Chinese Remainder Theorem by exploring concrete problems that elicit the concept of modular arithmetic.

The purpose of our research was to investigate the strategies and reasoning that students exhibit while solving problems chosen to elicit thinking in elementary number theory topics. We interviewed pairs of students from three different courses—Mathematics and Liberal Arts, Fundamental Mathematics II, and Calculus 1—in order to investigate the similarities and differences that may occur as a result of partner dynamics and varying mathematical backgrounds. More specifically, our aim was to investigate the following: What strategies do students in the different undergraduate mathematics courses use when attempting to solve the Frobenius problem and Chinese Remainder Theorem tasks? Additionally, we explored the extent to which partner dynamics influenced the strategies that were used.

Existing literature on elementary number theory has centered around students' understanding of divisibility, parity, and primality. We identified two areas within elementary number theory in which the research has shown students struggle: preference for procedural demonstration over conceptual demonstration of knowledge, and general difficulty with rational and whole number division and remainders (Brown, Thomas & Tolias, 2002; Campbell, 2002; Kaasila, Pehkonen, & Hellinen, 2010; Zazkis & Campbell, 1996). Students at all levels have demonstrated difficulty in these areas, and these findings had bearing on the strategies that our participants used.

A recurring issue from the literature revealed a preference for performing algorithms and processes over utilizing conceptual knowledge as a source of certainty with division. Zazkis and

Campbell (1996) found that rather than investigate the prime factorization of a number, preservice elementary teachers preferred to multiply all of its factors and then divide that result by the possible composite factor. The students lacked both understanding of prime factorization and the confidence that comes with a more conceptual understanding. Brown, Thomas and Tolias (2002) note that participants concentrated on "the role of division and a consistent tendency to choose to perform procedures rather than making inferences" (p. 51). For example, students referenced the specific action of dividing and "seeing if it would go evenly" to justify identifying the factors of a given integer (p.52). Participants in Campbell's (2002) study were determined to perform long division in order to verify the remainder of a prime decomposed number, instead of identifying the remainder in terms of the remaining factors.

Undergraduate mathematics majors showed similar difficulty in a number theory course, understanding the concept of congruence operationally rather than relationally (Smith, 2006). Specifically, they viewed a congruence statement in terms of a completed operation, instead of as a relationship between two equivalent quantities. Additionally, students would often solve linear congruences using complicated memorized procedures rather than the properties of the congruence relation. While our students did not work directly with congruence, we found that they encountered similar difficulties and very much relied on procedural manipulation over conceptual.

Students at all levels also demonstrate issues with whole number and rational division, specifically in that students attempt to apply ideas from whole number division to rational number division, and are thus unable to correctly identify remainders. Campbell's (2002) study exposed this issue by allowing participants the use of a calculator during tasks. Not a single participant was able to correctly identify the whole number remainder from the rational quotient displayed on a calculator, though many attempted a fractional approach. For example, students would calculate 68/3, which would display as 22.666..., and claim the remainder was 6. Given that whole number division provides an answer with two parts, the quotient and the remainder, participants experienced cognitive conflict with interpreting the responses from their calculators. These preservice teachers struggled to incorporate their intuitive knowledge of remainders with their decimal representation as part of a rational number.

In a wider-reaching study, Kaasila, Pehkonen, and Hellinen (2010) found that roughly 55% of preservice teachers and 63% of upper secondary students were unable to correctly represent the remainder of an abstract division problem. The subjects either recognized that the result of the division problem should not be an integer but could not determine the remainder, or completely ignored the remainder and responded with an integer answer.

The Chinese Remainder Theorem is built upon these aforementioned concepts of divisibility and remainders. Prior to our research, we anticipated that our participants would encounter difficulties similar to these discussed, but we were hopeful that they would be able to develop strategies to construct solutions to the problems. Our study yielded both of these results.

Theoretical Perspective

Merriam and Tisdell (2016) describe the goal of qualitative research as determining how people make sense of their lives and construct meaning. Thus, the role of the researcher is to both interpret and narrate these meanings and experiences. Given our stance that the individual learner is inseparable from "the realm of the social," this research is framed by the theory of social constructivism (Ernest, 2010, p. 43). A major tenet of social constructivism is the notion that "human beings are formed through their interactions with each other as well as by their individual processes" (Ernest, 2010, p. 43). With this perspective in mind, we sought to explore the strategies of our individual participants, as well as how the dynamic of working with a partner influenced or altered their approaches to our tasks. The structure of our project lent itself to collective problem-solving as well as solo work. However, the assumptions of social constructivism were still applicable in the instances of individual problem solving, as individual thought originates through internalized conversation. Implementing this framework allowed us to address the social influence that the presence of another participant had on the construction of knowledge.

Methods

As mentioned above, participants were undergraduate students recruited from three undergraduate mathematics courses: Mathematics and Liberal Arts, Fundamental Mathematics II, and Calculus I. We chose these three courses because we feel that each has a student population that differs from the others, which we thought might result in the use of different strategies and allow us to perform a comparative case study analysis of the data.

Three 60-minute video-recorded interviews were conducted, each with a pair of students from one of the target classes. The semi-structured clinical interviews began with general information regarding the students' majors, previous math classes, and mathematical experiences. The main focus of the interview was to have participants solve a set of problems that we chose in order to reveal cognitive resources for understanding elementary number theory concepts, including the Frobenius problem and the Chinese Remainder Theorem (see Findings for descriptions of tasks). Participants were encouraged to work together, discussing problem solutions and sharing their reasoning aloud, and follow up and clarifying questions were asked as needed. Each participant had access to a graphing calculator and was instructed to think aloud when performing different procedures or checking various solutions. Lastly, artifacts recording student work were collected at the end of the interviews. Students were not asked to delineate their strategy entirely on paper, though several participants opted to do so.

We chose to analyze the data as three cases: the three partner groups defined from the three different mathematics courses. Due to the nature of the experience that students in each of these courses have, we believe that the strategies that students used when attempting our tasks were somewhat dependent upon the mathematical backgrounds from which they came, including which mathematics course they were taking. In addition, each pair exhibited different partner dynamics which likely contributed to the choices of strategies used.

We used a grounded theory approach to analyze the data, including interview video transcripts, artifacts, and interview notes. The literature informed the open coding process that we used for the first pass individually (Miles & Huberman, 1994). We then used a constant-comparative method, individually and in collaboration with each other, to identify the strategies that participants used in solving the tasks (Strauss & Corbin, 1990). Following the individual passes through the transcripts, we met to address any differences in coded strategies until we reached a consensus. Two distinct themes were of interest from the video-recorded data: student strategies and partner dynamics. Our final list of codes included 9 distinct student strategies, as well as a code for identifying student issues with remainders. Field notes and transcripts were simultaneously coded and discussed for the distinct working relationships of the partners in each interview, including isolated individual work and pairs working in unison. Finally, we compared the student strategies across our three cases to identify similarities and differences discussed below.

Findings

The remainder of this paper will focus on two of the three cases from our study. Yolanda[1], a freshman theater and history major, and Rose, a freshman secondary history education major, were both enrolled in Mathematics and Liberal Arts, although they came from separate sections of the course. This appeared to affect the manner in which the two approached working together. Yolanda was typically the leader in her classroom group, taking charge and delegating work. Rose's classroom group, however, generally approached problems as a whole unit, talking through strategies and steps together. These differences caused some tension throughout the interview as the students negotiated the activity of working together. Their collaboration did increase as the interview progressed, with Yolanda assuming the role of the leader, but this was not without its faults. This was particularly evident during Task 3, when Rose mentioned that she did not want to solve the problem using guess and check, and Yolanda replied "Well, that's what we're doing. We don't know how to do your equations, we're gonna have to do something else." Rose shrugged and proceeded to follow Yolanda's lead.

Our second case was Marie and Fiona, who are both elementary education majors and enrolled in the same Fundamental Mathematics II course, the second in a three-course sequence of mathematics content for preservice education majors. All three of the courses in this sequence are student-centered courses with a heavy emphasis on collaboration and problem solving within small groups. This training was evident while the two were working on the interview tasks, as they consistently shared ideas and fed off of each other's results. The two took turns taking the lead on tasks. In addition, Marie and Fiona were the only group of the three to persevere and find a solution to Task 3, which may be the result of their prior experience in problem solving and group work.

We present our analysis of three of the five tasks, giving first an overview of the task and then the students' solution strategies.

Task 1: McNuggets (Contextual Frobenius Problem)

Task 1 required students to determine the number of boxes of size 6, 9, & 20 needed to buy 53 McNuggets. Rose and Yolanda began the task separately. Yolanda used an additive strategy that transitioned into a multiplicative strategy, starting by subtracting six from 53 twice to get 41. Then she subtracted nine, and noticed that the result, 32, was not divisible by 6, but that if she subtracted twenty, that result would be divisible by 6. Her strategy was based on guessing, and she started by subtracting six because it was listed first in the problem.

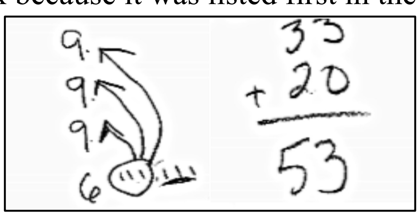

Figure 1: Rose's work showing the groups of 10s created from 9s and 6

Rose immediately decided to work with ensuring a 3 was in the ones place, because "getting to the 50, [she felt], would be easier after getting to the 3." She decided to work with the nines: "well, I was thinking, like, a 9, a 9, and a 9, 'cuz if you do a 6, then it breaks up into like 3 and

[1] All student names are pseudonyms.

those 3 go into those three 9's, and then you have 3 left over for the 53." By breaking a box of 6 into a 3 and three ones, Rose noted she was making the nines into groups of ten and getting the three leftover (See Figure 1). At this point, she knew she had thirty-three McNuggets and needed only to add a box of twenty to finish. We argue that Rose was more strategic in her process, and her use of the 'groups of nine' shows a progression toward a multiplicative strategy rather than an additive one.

Fiona and Marie began Task 1 by dividing 53 by each of the possible box sizes and determining if either that box size or a combination of that box and a single box of another size would work. They then used a strategic guess and check method, starting with the largest number: "subtracting 20. And then I got 33. Then I did 33 divided by 9 and got 3 even boxes of 9 and then you'd have 27, so then there was 6 left, 'cuz 33 minus 27 is 6." Their strategy had elements of both multiplicative reasoning ("33 divided by 9 and got 3 even boxes") and additive reasoning.

Tasks 3 and 5: Bunnies and Construction with Remainders (Chinese Remainder Theorem)

The Bunnies task proved to be the most challenging for all of the pairs. The intent of the problem was to introduce the concept of division with remainders through the context of grouping bunnies for various activities on a ranch that would allow students to construct a number satisfying specific constraints. Participants were asked to find a number of bunnies that satisfied divisibility by 5 with remainder 4, by 8 with remainder 6, and by 9 with remainder 8.

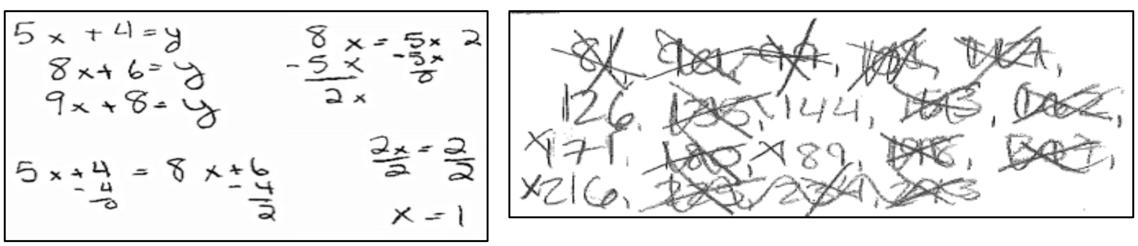

Figure 2: Rose's attempt at solving a system of equations (left) and Marie & Fiona's first attempt at multiples of 9 (right).

Yolanda and Rose utilized mainly guess and check. At first, Rose wrote a system of equations, but when the two were unable to solve the equations (Figure 2), Yolanda took the lead suggesting that they try 249, since it was "less than 250." The two then checked whether 249 yielded the correct remainders when divided by 5, 8, and 9. When 249 did not work, they examined 248 in the same manner. Here Yolanda recognized that in order for the number to have a remainder of 4 when divided by 5, it would have to end in a 4 or a 9, limiting the possible numbers that they would need to check. This was a good example of a guessing strategy that became more strategic and incorporated an understanding of divisibility rules. Unfortunately, the problem proved too challenging and the pair decided to move on.

Marie and Fiona were the only pair to persist to a solution for Task 3. They immediately recognized that the number cannot be evenly divisible by 5, 8, or 9, and they used divisibility rules to note that it would not end in 0 or 5. They started with 249, which helped them recognize that the number would "have to be 4 away from a multiple of 5." This particular understanding of the remainder proved problematic, because the students treated numbers that ended in a 1, which would be *four less than* a multiple of five, as a number that would satisfy the condition of having a remainder of 4 when divided by 5. Later, the students used a similar reasoning to justify the inclusion of numbers ending in 6 (again, four less than a multiple of 5). Their primary strategy on the task was to create a list of multiples of 9 and systematically check those multiples based on their rules for division by 5. They were left with a much smaller list on which to verify the remainder requirement when dividing by 8 (Figure 2).

It is interesting to note that both students were attentive to remainders when considering division by 5 and by 8, but neither recognized an initial mistake of *not attending to* remainders when divided by 9. Once they recognized this error, the students created a new list of the multiples of 9, adjusting for the remainder of 8. They then listed multiples of 8 adjusted for the remainder of 6, and multiples of 5 adjusted for the remainder of 4.

Task 5 was a decontextualized Chinese Remainder Theorem task similar to Task 3. All pairs identified the similarity of this task with “the bunny problem.” Pairs were asked to find a number that satisfied divisibility by 3 with remainder 2, by 4 with remainder 1, and by 5 with remainder 3. Marie and Fiona used the same strategy of listing multiples of the divisors and adding the remainder to each multiple in order to identify a number common to all three lists.

Similarly, Yolanda and Rose chose to explore the final digits of each of the divisors and adjusted the digits for the remainder each time. Yolanda first noted that the desired number could not end in a 0 or a 5 as that would make it divisible by 5. Rather, she claimed that the number should end in a 3 or an 8 by adding the remainder of 3 to each final digit. The pair listed the ones digits of multiples of 3 and then added 2 to each digit to account for the remainder (Figure 3).

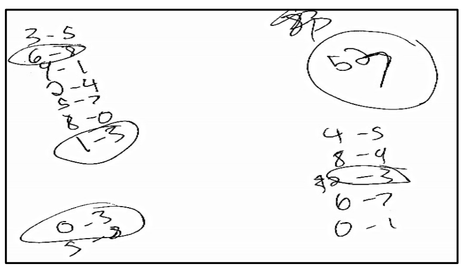

Figure 3: Yolanda and Rose’s solution for Task 5 identifying the ones digit.

They then repeated this process for the ones digit of multiples of 4 until they saw that 3 appeared in all three lists. Yolanda concluded that she and Rose only needed to check the “decades that end in 3” until they found a number that satisfied all of the requirements. Once again we found a preference from our participants to begin with the divisibility rule for 5 and build a strategy from this starting point, because this rule depends only on the ones digit.

Conclusion

We found nine different strategies, six which were exhibited by these two groups while they completed the number theory tasks: guess and check, divisibility rules, use of equations, consideration of final digit, additive reasoning, and multiplicative reasoning. We note that participants often incorporated multiple strategies on each problem, making it difficult to attach a single label to certain tasks or groups. For example, we saw that guess and check was often a starting point, but the strategy evolved into a more sophisticated use of additive or multiplicative reasoning.

We were also interested in comparing the strategies used across our cases in order to investigate the possible effects of participants’ background and partner dynamics on choice of strategy. While our data set is small, we did see some differences. Marie and Fiona were perhaps the most flexible in strategy use. When they ran into roadblocks, they pushed through the frustration and tried something new. They were unafraid to be incorrect, despite the fact that their teacher was in the room with them. We believe that this was largely due to the problem-solving mathematics environment that they were used to. They were accustomed to collaborating equally with others and encountering difficult problems.

Although Yolanda and Rose were somewhat accustomed to working in groups, we saw that they had different conceptions of what group work looks like, which caused difficulties for them. Working together did serve them well, however, as they were able to push each other past areas where they struggled on the tasks and they exhibited different strategies as a result. We believe that the evident success of working together on Task 5 would have likely led to success on Task 3 had the participants chosen to revisit it.

The results of this study gave us some insight into what cognitive resources students rely upon in order to understand the Chinese Remainder Theorem and Frobenius Problem, which can be applied to their understanding of modular arithmetic. This is important to those who teach number theory courses, as these basic strategies can provide a foundation upon which to build more formal topics. We also found that these topics are accessible to a number of different populations, independent of mathematical background. This provides an avenue through which to investigate preservice teachers' understanding of division and remainders in general, which can inform classroom instruction on divisibility.

Limitations and Areas for Future Consideration

We chose to present contextualized problems before decontextualized problems in order to provide students with problems that appeared more applicable to their own lives. However, we noticed that participants frequently fixated on minute details of the wording of the problems, making comments about animal hoarding and the absurdity of wanting to purchase exactly 53 McNuggets, derailing their solution process. It may have been beneficial to present decontextualized problems first for this reason.

We note that the students in both partner groups were enrolled in classes taught by the authors. In order to minimize reactivity, we structured the interviews so that students were not interviewed directly by their instructor, although she did remain present in the room and responsible for operating the video camera. In both interviews there were moments when the participants would look toward their instructor for a sign of approval or disapproval regarding their work on the tasks. Although each researcher attempted to remain expressionless and limit comments regarding clarification to any of the strategies, we recognize that this still likely had an impact on the participants' responses.

Furthermore, we acknowledge the choice in soliciting individual students rather than pairs. Marie and Fiona had been working together in their math class, but Yolanda and Rose were paired together from different classes. Having never collaborated before, the partnership was somewhat inauthentic as the two had different conceptions of what working together would look like. For future extensions, it would be worth attempting to solicit pairs of students that would sign up together rather than individual students.

We are disappointed that we did not have enough time to fully investigate the effect of classroom culture on our interviews, as was initially intended. We had also hoped to see some models of student strategies that resembled the Chinese Remainder Theorem in our interviews. Although this was not a result in this study, we believe that constructing a design experiment would be a worthwhile endeavor. One could also explore participants' previous mathematical knowledge and how they transfer these experiences into a number theory class, adopting actor-oriented transfer as a theoretical framework (Lobato, 2003).

Students' Conceptions of Mappings in Abstract Algebra

Rachel Rupnow
Virginia Tech

In an effort to understand ways students approach constructing homomorphisms and isomorphisms between groups, six undergraduate math and engineering students in a lecture-based introductory abstract algebra course were interviewed. These students experienced varied success in creating isomorphisms and homomorphisms, which allowed both successful techniques for map creation and stumbling blocks to map creation to emerge from the data. Some successful techniques for determining if groups were isomorphic included checking the orders of the groups, looking for invertible maps between groups, and determining the identity element and orders of elements of each group. Successful strategies for approaching the creation of homomorphisms included checking if the groups were isomorphic, seeing if a proposed map would preserve closure, and using strategic trial and error. Stumbling blocks included the inappropriate use of definitions, an inability to interpret definitions, and misunderstanding the distinction between the names and roles of elements in different groups.

Key words: Abstract Algebra, Homomorphism, Isomorphism, Qualitative

Purpose and Background

Experts have identified isomorphism and homomorphism as two of the most central topics to abstract algebra (Melhuish, 2015). Yet though some research has been done on how students approach isomorphism, including designing an inquiry-oriented curriculum that addresses isomorphism (Larsen, Johnson, & Bartlo, 2013), research explicitly on students' understanding of homomorphism has been scarce. Thus, the purpose of this study is to examine students' approaches to finding both isomorphisms and homomorphisms and what prevents students from finding appropriate mappings between groups.

A homomorphism between groups is defined as follows: "Let $(G,\star)$ and $(H,\boxdot)$ be groups. A map $\varphi\colon G \to H$ such that $\varphi\colon (x \star y) = \varphi(x) \boxdot \varphi(y)$ for all $x, y \in G$ is called a homomorphism" (Dummit & Foote, 2004). Thus a homomorphism is a map that preserves the structure of the original group in the second group. It does not require the groups to have the same cardinality; group G may be larger or smaller than group H. There is always at least one homomorphism between groups; namely, the trivial homomorphism, in which every element of G is mapped to the identity in H. Further, an isomorphism between groups is defined as follows: "The map $\varphi\colon G \to H$ is called an isomorphism and G and H are said to be isomorphic or of the same isomorphism type, written $G \cong H$, if φ is a homomorphism, and φ is a bijection" (Dummit & Foote, 2004). Thus isomorphisms are a specific type of homomorphism in which the cardinalities of both groups are the same. For example, V, the Klein four-group, is isomorphic to $\mathbb{Z}_2 \times \mathbb{Z}_2$. However, $\mathbb{Z}_2 \times \mathbb{Z}_2$ is not isomorphic to $\mathbb{Z}_4$ because the homomorphism property is not satisfied.

Previous studies have examined isomorphism in different ways. Early studies mostly provided students with two Cayley tables or stated two groups and asked if they were isomorphic or how they could tell they were isomorphic. The Dubinsky, Dautermann, Leron, and Zazkis (1994) study indicated that when students considered isomorphisms between groups, they considered the cardinality of each group, but not whether the homomorphism property was satisfied. Leron, Hazzan, and Zazkis (1995) also noted students' tendency to check the cardinality of a group, but their students continued to test multiple other properties by finding the identity element (in Cayley tables), the orders of individual elements (the smallest positive integer m such that a^m is the identity for each element a), the number of elements of given orders in each group, whether a group is generated by a single element, and if it is commutative. Despite the many factors to check, students would still struggle if more than one way to construct an isomorphism existed, demonstrating a "craving for canonical procedures" (p. 168).

Other studies have considered isomorphism in the context of proof. In related studies, Weber and Alcock (2004) and Weber (2002) asked undergraduate and doctoral students to prove a number of theorems related to isomorphism and to prove or disprove specific groups were isomorphic. While both doctoral and undergraduate students were able to prove the initial simple propositions, the doctoral students continued to be successful in proving the remaining five propositions, while collectively only two (of twenty) proofs of the remaining propositions given by undergraduates were successful. Much like in Dubinsky et al. (1994), these difficulties largely related to undergraduates' tendency to form arbitrary mappings once they had ascertained that a bijection between groups could be formed. They would not apply other properties of the groups when trying to find or disprove the existence of an isomorphism.

Recent studies on isomorphism have shifted the focus to how to develop local instructional theories that could be transformed into an inquiry-oriented curriculum that included topics such as isomorphism. In the process of examining how students used their existing ways of reasoning to engage with mathematically rich tasks, other student views of isomorphism have come to light. In 2009, Larsen recorded a teaching experiment in which participants were expected to generate a definition of isomorphism. In that study, participant Jessica noted that the definition of isomorphism should include bijection because "…it has to go both ways" (p. 133). Her statement brought to light another approach to isomorphism: invertible mapping. Later, Larsen et al. (2013) noted that the homomorphism property was more challenging for students to unpack than the bijection property. Additionally, Larsen (2013) noted, "students' use of the homomorphism property is usually largely or completely implicit" (p. 722). Thus a number of tasks in his curriculum engage students in forming an explicit homomorphism in order to help students formulate the definition of homomorphism and, later, isomorphism.

In these isomorphism studies, some research has been conducted on homomorphism in the process of researching isomorphism. However, a few studies have examined homomorphism more closely in the context of proof. Nardi (2000) noted students' struggles in proving the First Isomorphism Theorem for Groups stemmed from three major sources: an inability to recall definitions or a lack of understanding of definitions, poor conceptions of mapping (such as thinking a homomorphism was an element of a group), and not realizing specifically what each part of the proof was proving. Weber (2001) observed that despite undergraduates' ability to recall relevant theorems, they struggled to move past syntactic, "definition unpacking" techniques when trying to prove theorems related to isomorphism and homomorphism, such as proving a group was abelian given the map was a surjective (onto) homomorphism. He also noted doctoral students had a tendency to use conceptual knowledge to formulate proofs more strategically and experienced more success in proving.

Methods

The participants for this study were six sophomore or junior university students in a lecture-based introductory abstract algebra course. Four were mathematics majors and two were engineering majors considering double majoring in math or transferring into the math program. Students' college math backgrounds other than introductory calculus and a proof course varied but included courses in combinatorics, discrete math, vector geometry, linear algebra, multivariate calculus, differential equations, operational methods, and real analysis.

Students were recruited from two instructors' courses with one student coming from Instructor A's section (denoted participant A1) and five from Instructor B's section (denoted participants B1, B2, B3, B4, and B5). Instructor A had taught both group and ring homomorphisms earlier in the semester and his students, including A1, had been tested on that material. Instructor B had just begun teaching about homomorphisms and isomorphisms when his students were interviewed. Four of his students were interviewed after learning about isomorphisms but before learning about homomorphisms in class (B1-B4), and one student was interviewed after learning about both isomorphisms and homomorphisms (B5).

Participants were recruited in two ways. The author asked for an announcement to be sent to Instructor A's students with interested students sending the author a message. In Instructor B's section, the author visited the class and asked interested students to provide their email address in order to be contacted. Students were given their preference of $10 or an hour of tutoring to avoid biasing the sample towards strong or weak students.

Each participant engaged in a semi-structured interview (Fylan, 2005) lasting approximately one hour. The interview questions were drawn from those in Figure 1, but time and students' backgrounds prevented some students from seeing certain questions. However, all students answered questions 4, 10, 11, and 12. The interviews were all audio-recorded and five of the six were video-recorded. Participants' written work was also collected. To analyze the data, participants' interviews were transcribed and open coded for students' problem solving strategies regarding isomorphism and homomorphism. This coding generated themes, which were verified by utilizing multiple iterations of coding (Anfara, Brown, & Mangione, 2002).

Results

Participants' approaches to mappings fell into three major categories: successful methods of determining if a map was an isomorphism or if such a map could be generated between groups; successful methods of determining if a map was a homomorphism or if such a map could be generated between groups; and stumbling blocks to success.

Isomorphisms

Students exhibited a variety of successful strategies when trying to determine if two groups were isomorphic or if a given map could be an isomorphism. Because a one-to-one and onto mapping must exist for a bijection to exist, groups must have the same cardinality to be isomorphic. Thus, one strategy students used was to check if the groups were the same size. Four of the participants (A1, B2, B3, and B5) utilized this strategy at some point with three of them checking this characteristic first when faced with any of problems 11-17. For example, in response to the isomorphism part of question 11 ($\mathbb{Z}_5 \rightarrow 5\mathbb{Z}$), B2 answered, "I don't think, um, I can form isomorphism between them because, um, I don't think it is bijective, um, because I think this group [points to $5\mathbb{Z}$] is larger than this one [points to $\mathbb{Z}_5$]."

Another successful strategy was to look for an invertible map between given groups or to note that a previously stated map was invertible. A1, B1, and B2 all utilized this strategy, with B1 using this as her main approach. For example, consider the following exchange when asked the isomorphism part of question 16.

B1: I believe so. Like, to get from $\mathbb{Z}$ to $2\mathbb{Z}$, you just multiply by 2. To get from $2\mathbb{Z}$ to $\mathbb{Z}$, you just divide by 2.

I: You said $\mathbb{Z}$ to $2\mathbb{Z}$, multiply by 2. Is that an isomorphism? Homomorphism?

B1: Well that in itself is, that's only a one way mapping. Its inverse also exists so paired together, isomorphism, I'd say.

When pressed on details of the inverse map, namely explaining why it was acceptable even though division was not the operation defined for $\mathbb{Z}$ and $\frac{1}{2}$ was not an element of $\mathbb{Z}$, she said it did not matter because "1 isn't in $2\mathbb{Z}$. There is nothing that will get you to a non-integer. If it's written as 2 times something, dividing by 2 just gets rid of that." She realized that the maps she had defined were one-to-one and onto. In reference to the same problem, A1 noted $2\mathbb{Z}$ to $\mathbb{Z}$ was "the same one. Since they were isomorphic before, it works the other way." He realized that when an isomorphism exists, the mapping between the groups can be inverted so each group is the domain of an isomorphic mapping to the other.

1. What is a homomorphism?
2. How do you determine if [a map or whatever used above] is a homomorphism?
3. What is an example of a homomorphism?
4. What is an isomorphism?
5. How do you determine if [a map or whatever used above] is an isomorphism?
6. What is an example of an isomorphism?
7. Is the homomorphism example you gave also an isomorphism?
8. Is the isomorphism example you gave also a homomorphism?
9. Interpret the following definitions of homomorphism and isomorphism.
   Definition: Let $(G,\star)$ and $(H,\boxdot)$ be groups. A map $\varphi: G \to H$ such that $\varphi: (x \star y) = \varphi(x) \boxdot \varphi(y)$ for all $x, y \in G$ is called a homomorphism.
   Definition: The map $\varphi: G \to H$ is called an isomorphism and G and H are said to be isomorphic or of the same isomorphism type, written $G \cong H$, if
   φ is a homomorphism, and φ is a bijection.

For each of the following pairs of groups in 10-17, is it possible to form an isomorphism between them? Why or why not? Is it possible to form a homomorphism between them? Why or why not?

B2 and B4 considered another potential strategy for determining if groups were isomorphic: creating a Cayley table for each group. Additionally, B2 recognized this was only a feasible option for small groups. In question 5, when asked how to determine if a group was an isomorphism, he said he would like to make a Cayley table if possible, but if the group was too big, it would be challenging: "a Cayley table will be 16x16 and I cannot make it, but, you know, 4x4, that would be fine, so kind of [a] small example." In the reverse situation, when presented with the Cayley tables in question 10, A1 and B1 also compared the orders of elements or mapped the identities of each group to each other without being prompted to do so.

Homomorphisms

The most straightforward argument given for determining if a mapping was a homomorphism stemmed from determining it was an isomorphism. Because all isomorphisms are homomorphisms, if a student determined an isomorphism could be formed between groups, a homomorphism could automatically be formed too. A1, B1, and B5 clearly recognized this property, making statements similar to what A1 said: “It’s part of the definition to be isomorphic: you have to have homomorphism in there.” The other three participants may have also recognized this concept based on their explanations of the definitions of isomorphism and homomorphism, but they never directly used this concept to answer other questions.

Closure (associated with cardinality arguments) was a property students used to check if a map they proposed could be a homomorphism. This idea was especially used to rule out maps they had created in response to questions 11 and 13. Five of the students successfully used this strategy, with B4 making a typical response as shown in Figure 2. She used her work with Cayley tables that would not close (on the mid-right and bottom right of Figure 2) to conclude she could not map all of the elements in $\mathbb{Z}_5$ (pictured on the mid-left) to distinct elements in $5\mathbb{Z}$ and have a closed group result. From this, she concluded that she could not create a homomorphism or isomorphism. Note that although her conclusion that she could not form an isomorphism was valid, her conclusion that there was no possible homomorphism was flawed because the trivial homomorphism, $\theta\colon \mathbb{Z}_5 \to 5\mathbb{Z}$ such that $\theta(x) = 0 \;\forall\; x \in \mathbb{Z}_5$, would be possible. In fact, only A1 recognized the trivial homomorphism would be a homomorphism without being prompted to consider it. He and other participants who successfully generated homomorphisms appeared to notice patterns in the orders of the groups, which allowed maps to be generated quickly. For example, when looking for a map from $\mathbb{Z}_3$ to $\mathbb{Z}_6$, B1 noticed the 0’s should

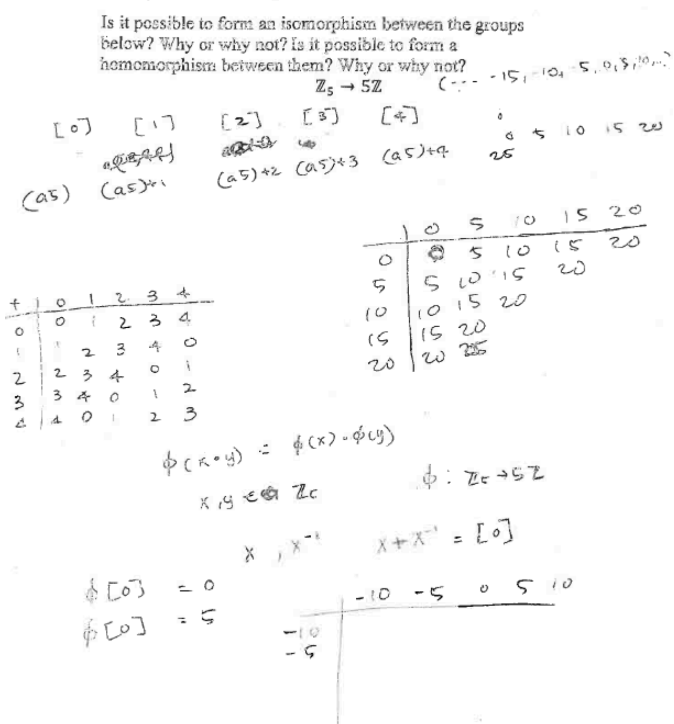

Figure 2. Work sample from B4 examining possible maps between $\mathbb{Z}_5$ and $5\mathbb{Z}$.

correspond and that $\{0,2,4\}$ acted just like $\mathbb{Z}_3$. Similarly, B2, who had successfully answered question 15 before being asked question 13, noted a non-trivial homomorphism could not be created between $\mathbb{Z}_5$ and $\mathbb{Z}_6$ because "3 divides 6 right? So, like, it should have something important about mapping…."

Although most students attempted to use one of the strategies above first, most students eventually resorted to trial and error to look for homomorphisms. Some students used pure trial and error techniques, such as B5, who attempted to map elements of $\mathbb{Z}_6$ to $\mathbb{Z}_3$ in seemingly random order and then check if the homomorphism definition was satisfied (i.e. mapping $\{0,3,4\} \to 0, \{1,2\} \to 1, \{5\} \to 2$). Both he and B3, who used this seemingly random approach, stated that they thought these problems were "trick questions" because there was no obvious technique to apply. Participants who had more success in finding suitable maps and in ruling out incorrect maps tended to use their knowledge of the orders of the groups to narrow possible choices for mappings, such as in B1's comparison of $\{0,2,4\}$ to $\mathbb{Z}_3$.

Stumbling Blocks

A number of participants struggled to recall and utilize definitions effectively. Although most students defined an isomorphism as a bijective mapping or one-to-one and onto mapping that had the property $\phi(a * b) = \phi(a)\phi(b)$ (or similar statements), some students struggled to unpack what "one-to-one" or "onto" meant. For example when B3 was asked what one-to-one meant, she first attempted to give the formal definition but could not recall it. When asked just to state what she thought about one-to-one and onto, she replied that in a one-to-one mapping "one [element] maps to one [element]" as she drew a set diagram illustrating a mapping. However, she still could not explain what onto meant, even in the context of her diagram. When asked to interpret the definition of homomorphism given in question 9, B2 claimed, "It should be abelian….Because you can switch these two, x and y, and then it just, isn't it automatically saying if you say yx, it'll just be y and x?" Additionally, students B2 and B5 attempted to map elements to multiple locations, thus violating the function relationship implicit in the definitions.

Although all participants attempted to use the formal definitions of homomorphism and isomorphism at times, some struggled to move past that point to interpret what they meant. Consider the following exchange after B4 was asked to give the definition of isomorphism.

B4: I don't even know if this is right. [Writes $(a \circ b) = a \circ b$.] I don't know what the circles are, but it's when it's preserved under the same something—I know it but I can't tell you.

I: Ok, well I feel like you're trying to give me the formal definition….Do you have just an intuitive sense of what it is?

B4: It's when two things are multiplied or something under a, say the mapping is α, if you do map of $a \cdot b$ is equal to map of $\alpha(a) \cdot \alpha(b)$ under, yeah, and it's onto and one-to-one, I think.

I: Ok. So you've given me a nice definition. Do you have any sense of, like in practical terms, what that might look like?

B4: No.

I: Ok, so if I asked you for an example you would say…

B4: Would probably give it to you in math terms. I don't know a real example. Yeah.

Some students also struggled to distinguish between the roles and the names of elements. This issue especially arose with the 4x4 Cayley tables in question 10, when students frequently assumed they had to map element a to element a because it was the same letter rather than determining the identity of each group or utilizing other techniques. This tendency to map similarly named elements to each other appeared in later problems as well. For example, in question 13, every participant first tried to map $0 \to 0, \ldots, 4 \to 4$, and all but A1 and B5 concluded that there could not be any homomorphism between the groups because the map matching similarly named elements did not work. Even when presented with the trivial homomorphism as a possible solution to question 13, B3 struggled to accept the mapping because she did not know what to do with the other elements in $\mathbb{Z}_6$ (i.e., 3+4=2 is mapped to 0, but 3+4 = 1 in $\mathbb{Z}_6$ "isn't going anywhere").

Even when students identified the roles of elements in different groups, they did not always know how to create a mapping from this information. For instance, B2, who in response to question 5 had stated that creating Cayley tables could be useful in determining if an isomorphism existed between groups, struggled when presented with the tables of question 10. He successfully located the identity element of each group, but he was unsure what to do with this information until being prompted to consider mapping the identity elements to each other.

Conclusion

In this study, like Larsen et al. (2013), students were more comfortable working with the bijective property than the homomorphism property. This seems plausible given that because the cardinality of a group can be determined rapidly, determining if a bijection exists between two groups is most likely not as difficult as determining if the homomorphism property holds for all pairs of elements of a group. Although the homomorphism property allows specific maps to be tested quickly, students had to rely on trial and error (albeit strategic trial and error) to create reasonable maps to be tested. Additionally, students with limited concept images (Tall & Vinner, 1981) of one-to-one, onto, function, and homomorphism were at a disadvantage when trying to create homomorphisms and isomorphisms. Students A1 and B1, who both attempted and solved the most problems, both utilized the concept of a mapping being invertible if it is an isomorphism and demonstrated the ability to use strategic trial and error to find homomorphisms quickly, indicating a robust concept image of maps, much as the successful doctoral students utilized their knowledge of theorems strategically to write proofs (Weber, 2001).

Like other studies, students considered the cardinalities of the groups to determine if they could be isomorphic (Dubinsky, et al., 1994; Leron, et al., 1995; Weber & Alcock, 2004; Weber, 2002). Despite literature indicating that comparing orders of elements of groups when trying to determine if a map is an isomorphism was a common technique (Leron, et al., 1995), only two participants utilized the technique in this study; however, this may be due to the limited number of questions in which both groups were finite and had the same cardinality.

Future studies should use a larger sample of students who have all been exposed to homomorphism and isomorphism before being interviewed. Additionally, more questions with isomorphic groups should be explored to see if students utilize techniques like considering the orders of elements and creating invertible maps when faced with more groups of the same cardinality. Because of the dearth of studies on homomorphism, it would be illuminating to conduct teaching experiments examining how to enhance students' concept images of these mappings. This might help students consider mapping elements that look different to one another despite elements of similar appearance being present in the other group (e.g., map $1 \to 2$ instead of $1 \to 1$ when generating a homomorphism from $\mathbb{Z}_3 \to \mathbb{Z}_6$). Finally, comparing how other content areas, such as linear algebra and graph theory, create and use homomorphisms and isomorphisms could provide insights into the role of mappings throughout mathematics.

A Success Factor Model for Calculus: The Relative Impact of and Connections between Factors Affecting Student Success in College Calculus

Megan Ryals
North Carolina State University

Karen Keene
North Carolina State University

What factors (in terms of the student) contribute to success in college calculus, and what are the relationships between and relative importance of these factors? This study addresses these questions by building on the Academic Performance Determinants Model (Credé and Kuncel, 2008). A new model called the Success Factor Model for Calculus was developed using semi-structured and task-based interviews with fourteen first-semester college calculus students. The data suggests that creative mathematical reasoning and knowing-why are not required for success on college calculus tests. Alternatively, motivation is a determining factor in success in that students can perform well on exams by being motivated to know how to solve specific types of problems. Motivation is decreased by some course-specific factors, such as lack of structure and accountability, and its effect on success is decreased sometimes by a lack of study skills and habits.

Key words: Calculus, Creative Mathematical Reasoning, Success Factor Model, College Success

Approximately 300,000 students enroll in college calculus in the United States each year (Bressoud, 2015). With calculus being a gateway course to science and engineering disciplines, it is concerning that an estimated 25-30% of these students are not successful in the course and that both student confidence and enjoyment of mathematics decreases significantly between the beginning and end of the college calculus course (Bressoud, Carlson, Mesa, & Rasmussen, 2013). To address the challenges of teaching calculus and determine directions for future research, a comprehensive picture of the factors that lead to or prevent student success in the course is needed. As part of a larger study, this research used a comparative analysis of data from fourteen student interviews to address the following research questions:

1. *What factors contribute to or hinder student success in college calculus?*
2. *What are the relationships between and relative importance of those factors?*

Framework and Review of Literature

The Academic Performance Determinants Model

Student difficulty in calculus may arise from design aspects of the course, such as the types of questions asked on tests and ultimately what type of reasoning is required to be demonstrated on exams. It also may also be impacted by student-specific characteristics such as background knowledge, level of effort or motivation, or knowledge of how to study appropriately. Credé and Kuncel (2008) suggest that some of these factors mediate the effects of others on student performance. Their model of Academic Performance Determinants (see Figure 1) shows relationships between these determinants and illustrates how some affect performance more directly than others. Their model is not specific to mathematics or any other discipline. It was used in this study as a starting point for developing a similar model that is specific to the learning of calculus.

Credé and Kuncel distinguish between study motivation and study skills and habits. Study motivation refers to a student's willingness to study and the "sustained and deliberate effort" they exert in studying (p. 428). In Anthony's (2000) survey of college instructors and students, both groups indicated that a student's level of motivation was the most important factor that contributes to student success. However, there is a discrepancy in the amount of practice that is expected from instructors and the amount that students believe is necessary (Cerrito & Levi, 1999, Bressoud, 2015).

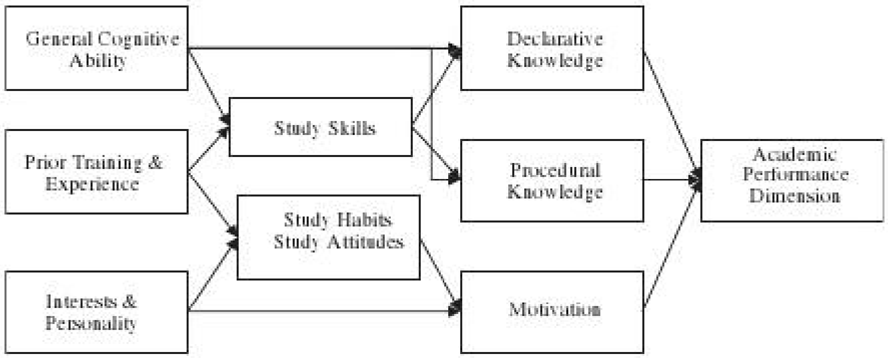

Figure 1. Academic Performance Determinants Model from Credé and Kuncel, 2008.

The Academic Performance Determinants Model suggests that study skills, habits and attitudes impact performance through the acquisition of certain kinds of knowledge. Note that since this model was not developed specifically for mathematical problems, certain types of knowledge or reasoning may not be accounted for in this model. For example, procedural knowledge means something different in mathematics. To aid in the need to consider mathematical knowledge and reasoning, we utilized two additional sets of definitions described next.

Types of Knowing and Reasoning

Building on the work of Ryle (1949) and Skemp (1979), Mason and Spence (1999) distinguish between four types of knowing – knowing-that something is true, knowing-how to do something, knowing-why you do something or why something is true, and knowing-to do something in a particular situation. They explain that while there are certainly connections between the types of knowing, and often one can facilitate another, they are distinct, in that one does not guarantee or precede another. Mason and Spence claim that classroom education focuses on teaching knowing-that, how, and why which amounts to knowing *about* a subject, but that this does not equate to knowing-to. Knowing-to is often a significant barrier in solving non-routine problems.

Lithner and his colleagues (Lithner, 2006; Palm, Boesen, & Lithner, 2006) have developed a conceptual framing that addresses the issue of solving non-routine type problems. They distinguish between creative and imitative mathematical reasoning. Creative mathematical reasoning (CMR) requires learners to produce a solution method they have never seen or have forgotten. Imitative reasoning, in contrast, is devoid of "attempts at originality" (Palm, Boesen, & Lithner, 2006, p. 6). Imitative reasoning can be further categorized as either memorized or algorithmic reasoning. Memorized reasoning (MR) requires simply recalling information to produce a complete solution, such as a facts, definitions, or even proofs. That is, it requires knowing-that. Algorithmic reasoning (AR) requires knowing-to use a particular procedure and knowing-how to use that procedure. Knowing-to in problems that can be solved using algorithmic reasoning is simplified by triggers or surface features from previously studied similar problems. In a problem that requires creative mathematical reasoning, knowing-to is significantly more challenging because of the absence of these surface similarities.

Methods

Participants and Data Collection

This report outlines one piece of a larger study that examined the impact of AP Calculus on students who repeat Calculus 1 in college. Ninety-minute interviews were conducted in the fall semester of 2012 between mid-October and early December. Fourteen interview participants were chosen from two small private and four large public universities in two states in the southeast. These six universities were on the semester system and students were recruited anywhere from 8-14 weeks into the 16-week semester. Participants were first-year students enrolled in a Calculus I course who had taken AP Calculus and taken the AP Calculus exam. Participants were required to have made a C- or lower on a recent exam.

A semi-structured, conversational interview process (Drever, 1995, Smith, 1995) was used for the first 45 minutes. The interview protocol consisted of 17 open-ended questions and was influenced by the Academic Performance Determinants Model. The second portion of the interview was task-based (Kelly & Lesh, 2000) and was diagnostic. Its purpose was to determine whether imitative reasoning (see above for description) could have been used to solve each missed test problem. To make this determination, test problems were compared to problems from other course resources, such as examples from class notes or the textbook or assigned homework problems. Participants were asked to identify whether they were able to solve the similar problems prior to the test and also to attempt the test problem in the interview after reviewing how to solve similar problems from the resources.

Analysis

Analysis of Part I of the interviews led to the emergence of 17 themes relating to students' experiences in calculus. We used open coding to identify experiences among participants and axial coding to group codes into themes (Strauss & Corbin, 1997). A theme was eliminated if it was not mentioned by at least three participants.

Analysis of the second portion of the interviews involved writing summaries for each student's attempts at solving missed test problems and determining what type of reasoning could have been used to solve these problems. After reading each interview transcript, we wrote a 1-2 paragraph description of the student's problem solving process for the attempted test problems and similar problems. These descriptions included the following three items: 1) whether the participant was able to solve the similar problem without assistance, 2) whether the participant was then able to solve the test problem after learning to solve the similar problem, and 3) if not, what barrier(s) the student encountered in solving the test problems (such as insufficient pre-requisite mathematical knowledge). Item 1 spoke to the student's preparation for the test, while item 2 revealed whether imitative reasoning could have been used to solve the problem. Item 3 for each problem was compared across participants and commonalities were noted.

The summaries from the Interview Analysis Part II were combined with some of the results from Interview Analysis Part I to develop a Success Factor Model for College Calculus. The model captured all observed factors affecting success on Calculus exams for the fourteen participants and the relationships between these factors. Themes from Part I were included only if we saw a consistent relationship between the factor and student success. For example, while participants consistently claimed that increased course structure led to greater motivation and subsequently greater performance, smaller class size (while desirable) did not present such a consistent impact.

We initially used certain success factors and terminology while leaving out others that we had no data to support or evaluate. We developed the initial draft of the Success Factor Model after examining individually and comparing the summaries of four participants. As we examined additional transcripts and summaries, we began to change the proximity of some factors to success, add additional factors and remove others, as well as add and remove connections between factors. This was an iterative process that involved going back and forth between the overall model and the individual participants' experiences.

Once the model was complete with its factors and pathways, we set out to determine the relative importance or impact of each factor using a meta matrix and subsequently used the meta matrix to create case-ordered matrices (Miles & Huberman, 1994). That is, we sorted the participants by certain variables and then looked across the other categories for similarities amongst cases with the same characteristic, to determine which variables might be associated with others. We grouped students by their relative success in college calculus. Doing this allowed us to identify which factors were consistent for successful students and which factors varied, or were not essential. This process illuminated the different pathways students could take to success in Calculus (on exams) and the common factors that hindered other students' progress.

Results

The Success Factor Model below depicts the factors of success and the relationships between the factors. Results also include the relative impact of the factors on student success in calculus.

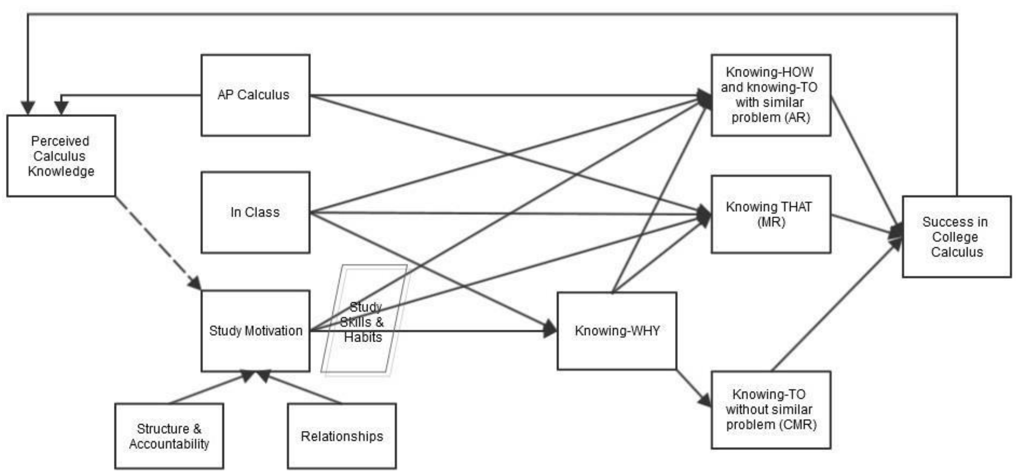

Figure 2. Success Factor Model for College Calculus.

Arrows connecting factors A and B indicate an impact of factor A on factor B. Bold arrows indicate a direct relationship; an increase in the factor A positively impacts factor B. A dashed arrow indicates an inverse relationship; that is, an increase in factor A results in poorer results for factor B. Distance of a factor from success on the diagram does not determine relative impact of that factor; larger distance merely shows that there is a mediating factor that determines how much of an impact that factor will have on success. Due to space restrictions, only selected factors, relationships, and their relative importance will be discussed.

The Relative Impact of the Direct Factors of Success

We first discuss the direct factors of success, displayed on the right-hand side of the Success Factor Model, and their relative importance for students' success on their exams. While any one of these three factors may be required to solve a particular problem, some were more frequently required and/or posed more frequent barriers for the participants than others.

One of the direct factors of success is knowing-to using CMR. Ten of the participants needed to apply some degree of CMR to successfully complete at least one of their discussed test problems, but no student had enough CMR required on his or her test so as to prevent passing the test without it. This result is consistent with that of Bergqvist (2007) who found that 15 of 16 Swedish calculus tests could be passed using only imitative reasoning.

Additionally, very few of the problems required CMR for calculus material; rather, most elements of problems requiring CMR dealt with pre-requisite knowledge or skills. For example, when Blake (all student names are pseudonyms) was asked to find the absolute minimum and maximum of a function, he was able to take a derivative and knew to set it equal to zero, but was then unable to solve the equation. In a limited number of cases, the element requiring CMR came at the beginning of the problem and did prevent the student from being able to continue, thereby costing the students all or most of the points for the problem. These cases were limited, however.

As with knowing-to using CMR, difficulties involving knowing-that were almost all limited to pre-requisite knowledge. While some participants did lose points for not knowing-that on one or two of the discussed problems, this was not a primary issue for any of the participants.

Twelve of the 14 participants were able to make more progress on at least one of their two discussed test problems during the interview than they had made during the test after first learning to solve a similar problem from their resources. Very little variation was found in the directions for the problems from the tests and class resources; therefore, recognizing the problem type did not prove to be problematic for the majority of participants. The implication is that students who missed test problems that could be solved by knowing-to and knowing-how with AR could have improved their grade on the test by having worked similar problems prior to taking their test. For these students, lack of success stemmed from either inadequate study motivation or study habits, both of which will be discussed.

Knowing-why Is Not a Direct Factor of Success

Knowing-why was not essential for solving any of the problems students had missed that were discussed during the interviews and was certainly not essential for passing the test. Knowing-why did prove to be helpful to some students, while other students opted to bypass understanding by using AR. Two students, Frank and Michael, were unable to solve a test problem that asked for the location of a function's horizontal tangent line. When initially reviewing this problem in the interviews, Frank and Michael studied the same similar example from the textbook. Frank focused on the textbook's discussion rather than the solution. After approximately thirty seconds, he quickly attended to the explanation that the derivative is equal to zero when the tangent line is horizontal. He did not proceed to study the provided solution and therefore did not need to use AR. Frank demonstrated an understanding of the connection between the concept of a horizontal tangent line having a slope of zero and the process of setting a derivative equal to zero. He no longer needed an association with a particular type of problem or set of instructions to be able to solve his test question; he now knew-to because he knew-why. In contrast, when Michael looked at the textbook, he focused on the solution rather than the discussion. He explained that in the provided solution, "they would set it equal to zero and get their x values. They then plugged those back into the original equation to get the y's." When asked why they did that, he replied, "I'm not exactly sure why." However, this did not prevent him from being able to then solve the corresponding test question. This finding supports the claim of Mason and Spence (1999); understanding is related to, but not dependent on or necessary for knowing-to. "You can 'understand' but not know-to act,…you can know-to act and yet not fully understand" (p. 140). This finding raises questions about the type of knowing instructors most value and test.

One important distinction mentioned by several participants was that their college calculus course emphasized knowing-why but their AP Calculus course had not. Katelynn described her college course as significantly more challenging because of this knowing-how component. She stated, "I'd definitely say the big difference I've noticed then to now – [in high school] we learned more the how to do things as opposed to why you do them. Like I remember learning like sin x over x equals one, but I had to learn how to derive it this year. That was a lot harder." Other participants made reference to the material in college going more "in depth."

The Impact of Study Motivation is Mediated by Study Skills and Habits

The data suggests that the need for good study motivation and habits may in many cases be circumvented by other factors, but also that having strong study motivation and habits can be the deciding factor in whether some students succeed. Students at four of the six institutions could have been making A's on tests by learning to solve specific problems from their resources prior to the exam and then using AR. Students at the other two institutions were limited somewhat by the presence of multiple problems requiring CMR. However, even these students could have improved their exam scores to at least a B- by making improvements only with AR.

The impact of study motivation on knowledge acquisition for the participants was mediated by their study habits. That is, the effect of a student's willingness or effort to study was either amplified or tempered by the student's ability to study appropriately. Maggie, for example, had very high study motivation, but poor study habits. When asked if she would be able to make at least a C in the course, she declared, "I'll MAKE it happen!" But when she was asked to describe *how* she would do this, she referred only to doing more of the same activities she had already been doing that had not led to success. For example, she said "I will probably read my whole textbook, if I have to." For Maggie, high motivation did not automatically translate into greater knowledge acquisition that produced results.

Structure, Accountability, and Relationships Impact Motivation

The participants' study motivation was impacted by the amount of structure of their course and the amount of accountability provided by their instructors, as well as the relationships they had with their instructors. The most commonly discussed element of course structure was the grading of homework, or lack thereof. Most participants had no regularly graded assignments in high school, but did have this in college, and most claimed it being graded was the only factor that would motivate them to complete it. This was an exception to an important pattern - in most cases, participants described their high school course as much more structured and indicated this was a positive aspect of the high school course. College instructors were not thought to have many expectations of students. Albert explained, "her job is to teach us, not make sure we care about class." Maggie's comments echoed this sentiment. She said, "I think it's like, we're supposed to do it, be responsible for ourselves. It's college, so…" Students seemed to understand

and validate the responsibility put on them in the college environment, but they offered no evidence that it made them more successful. In contrast, Katelynn discussed her AP teacher "staying on top of [the students]" and claimed she would not have passed the course if he hadn't. AP courses tended to provide more regular examination, frequent reminders from teachers, and accessibility of help from teachers.

The relationship between teachers and the participants was one of the most widely discussed differences between high school and college calculus courses. Some participants indicated that their relationship was not just academic but also personal – one student had attended the wedding of his teacher and another described his teacher as "involved and relatable, explaining "I actually went out to dinner with him after I graduated, like me and four friends." Several participants had taken previous courses with their AP Calculus teacher. One explained that "it was almost like we had become a family because everyone had had [this instructor] for so long." The impact of these relationships was significant because the students did not want to "let down" their teachers. Multiple participants increased their amount of studying simply because of their relationship with their teacher. Jeffrey and Frank went so far as to say they would have been content with a B in their AP courses, but they did not want their teachers to think they weren't trying, or that he or she was a bad teacher, so they put it the extra effort to get an A.

There was a glaring void of these kinds of stories from the college courses. Just as the relationship motivated the students in high school, the lack of relationship in the college course was demotivating. Haley explained, "I don't know him as well [as my high school teacher] so I'm not motivated to do as well because I know him. It's terrible to get bad grades, but not because I know him and I'll be embarrassed." When students had a relationship with their teacher, they were motivated to work harder because of how their teacher would perceive them; when the relationship was absent, so was the extra motivation.

Conclusions and Implications

The Success Factor Model presented in this study highlights the need for larger scale studies that assess the relative impact of the success factors and their connections. It also challenges us to ask which of the factors of success are currently being taught or impacted by instructors, and moreover, which *could* be. For example, some have suggested that the best place to teach study skills and habits is in the classroom, rather than divorcing it from content (Taylor & Mander, 2003, Wingate, 2006). This will lead to a discussion of not only what is effective in increasing student success, but how certain recommendations for aspects of course design, such as increased structure or accountability, are perceived by college instructors and how attitudes and resource limitations may challenge such recommendations. Similarly, how do instructors' beliefs about what is important align with how they test students? For example, our findings suggest that students can be successful in college calculus without knowing-why, but this may not be the instructors' intent. The ability or inability to work non-routine problems may have little to do with a strong conceptual understanding, and instructors may be testing for one when desiring the other (Selden & Selden, 2013, Tallman, Carlson, Bressoud, & Pearson, 2016). Finally, we need to know the potential impact of emphasizing and developing each particular factor on students' success in subsequent courses. For example, if calculus courses become more structured, will students find later, less structured courses more challenging, or could the development of CMR in Calculus I lead to greater success in Calculus II?

With this research, we seek to find theoretical constructs that correlate with participants' neural activity that occurs as they are presented slides of mathematical proofs. We first asked three graduate student participants to complete two graduate level proofs (one each of abstract algebra and real analysis) using a LiveScribe pen. We then generated slides of their written work and researcher-generated proofs that we used during electroencephalography (EEG) trials. Having coded the slides along 22 theoretical categories, we used step-wise model selection to determine suitable models for variance in neural activity. Preliminary results indicate that the best code-based models at a given instant can account for between 25 and 50 percent of the variance in electrical activity near the EEG electrode for that model when participants observe their own proofs and between 33 and 75 percent during researchers' proofs.

Keywords: Proof, Electroencephalography, Insight, Mathematical Creativity

Throughout the mathematics education literature, researchers and mathematicians reference moments of insight during problem solving (e.g., Burton, 1999; Hadamard, 1945), which are also described as AHA moments (e.g., Liljedahl, 2004). And, although this notion is a common colloquialism among mathematicians and mathematics educators, little empirical research has focused on evidence beyond self-reported accounts of individuals' moments of insight as they develop formal proofs (Savic, 2015). To investigate and move beyond the self-reported moments of insights, we draw on neuroscience methodologies to provide hard data for exploring insight during proof. Through an experimental methodology using electroencephalography (EEG), coupled with an extended taxonomy created for local proof comprehension (Savic, 2011), we aim to identify and explore neural activity related to proof. Specifically, we seek to identify which theoretical constructs coded for a written proof might be used to model variance in participants' neural activities as they read their own and others' proofs. Ultimately, we are motivated by a broader investigation exploring the possibility of identifying neurological evidence of theoretical constructs related to proving, specifically whether we can identify neural correlates to moments of insight, an aspect of the creative process (Wallas, 1926).

Background Literature/Theoretical Framework

Wallas (1926) outlined four stages of creativity: preparation, incubation, illumination, and verification. Subsequent literature has drawn on these categories and used them to explore the creative process, beginning with mathematicians' reflecting on their own creativity (e.g., Hadamard, 1945; Poincare, 1946; Borwein, Liljedahl, & Zhai, 2014) and moving towards qualitative research relying on participants' subjective recollection of moments of insight (e.g., Burton, 1999; Liljedahl, 2004; 2013). However, Liljedahl (2004) conceded that there might be more that can be done to investigate insight, admitting, "Upon reflection, I now see that the clinical interview is not at all conducive to the fostering of such phenomena [insight]..." (p. 49). With this research, we aim to provide an additional approach exploring moments of insight.

Mathematicians and mathematics educators alike discuss moments during proof production in which a prover gains a clearer sense of why the conjecture they have set out to prove is true (e.g., Burton, 1999; Raman, 2003). Although researchers draw on varying perspectives and language to describe such moments and the psychological processes involved, these moments seem to occur during which the prover develops a sense of a "key idea" of the proof. We use Raman's (2003) definition of key idea as something that "gives a sense of understanding and conviction. Key ideas show why a particular claim is true" (p. 323). Liljedahl (2004) stated that "At the moment of insight, in the flash of understanding when everything seems to make sense and the answer is laid bare before you, you know it, and you call out – AHA!, I GOT IT!" (p. 1).

There have been many neuroscience studies dedicated to insight during problem solving (e.g., Bowden & Jung-Beeman, 2003). Kounios et al. (2006) found that "greater neural activity was observed for insight than for non-insight preparation in bilateral temporal cortex (left more than right, in both experiments)" (p. 887). Finally, insight has been correlated with phenomena such as P300 "positive deflection occurring 300 ms after stimulus presentation," and N200 - "negative deflection 200 ms post stimulus onset" (Dietrich and Kanso, 2010, p. 824). However, the prompts used in these psychology experiments are often remote association tasks, in which three words are given (e.g., electric, high, and wheel) and the participant is supposed to come up with a fourth word (e.g., chair) that can form an association among those three words (i.e., by being able to modify each word). Such tasks, while perhaps generating a moment of insight, may not afford the incubation time that people might need while proving theorems (Savic, 2015).

Researchers from several neuroscience domains – including memory, vision, and motor control – have demonstrated strong evidence supporting the notion that by either remembering or imagining an event or action individuals tend to generate neural activity that is similar to the activity generated during the actual event or action (e.g., Farah, 1988; Stavrinou et al., 2007). Our central hypothesis is that when subjects re-experience their proofs (i.e., see their proofs during the experiment), they might experience similar thinking to that which occurred during the moment of insight that produced a critical step for completing the proof. So, it stands to reason that the neural activity generated during this "re-living" experience will be similar to the brain activity generated during the production of the proof.

Methods

Our experimental methodology combines both theoretical and neuroscience components. We used a modified taxonomy for local proof comprehension (Savic, 2011) to generate codes for each slide of a slideshow that each participant watched during the EEG trial. In the first phase (days 1-2), three graduate mathematics majors (Marshall, Francis, and Buzz) were provided with a Livescribe pen to record his or her proving process, which we call "original" proofs. This pen is able to record the participant's written work and in real-time, allowing each pen stroke to be timestamped (to the second) and synchronized with the participant's verbal utterances during their proof. The pen also allows the participants' work to be saved as digital images. They were provided with two theorem statements (Figure 1), one in abstract algebra and the other in real analysis. We selected theorems that a senior-level abstract algebra and real analysis should reasonably be expected to prove.

Task 1: Prove that no group is the union of two of its proper subgroups.
Task 2: Prove that, if $a \in \mathbb{R}$ and $f: \mathbb{R} \to \mathbb{R}$ and $g: \mathbb{R} \to \mathbb{R}$ are functions continuous at a, then $fg: \mathbb{R} \to \mathbb{R}$ is continuous at a. [Here $(fg)(x) = f(x)g(x)$. Note that $fg \neq f \circ g$.]

Figure 1: Theorem statements to be proven by participants

In the second phase (days 3-4), each participant's digitized proofs were chunked and converted into uniform-sized digital images (700x700 pixels). In addition to the two proofs created by the participants, we generated two pre-written proofs of related, but different, conjectures which we call "canned" proofs. We generated these proofs to be concise, mathematically correct (not misleading) proofs of proximal difficulty as the assigned proofs for the participants to allow us to compare brain activity for a proof generated by the participant with one that was not.

In the third phase (day 5), participants came to the laboratory and were fitted with a 128-channel net, where the EEG data was obtained. Participants were instructed to watch the slideshows of the "canned" proofs and try to follow along with the argument as they would in a lecture or reading a text. For the "original" proofs, we instructed them to try and remember their thought processes as they generated each proof, focusing on their reasons for writing the content of each slide. The canned abstract algebra proof was shown first in its entirety, followed by their own abstract algebra proof, and then the canned real analysis proof, and finally their own real analysis proof. Each slide was shown for three seconds with a subsequent one-second break to blink, and all four groups of slides were shown in one sitting. Following the presentation of the last proof, participants were interviewed, with the entire interview taking between 15 and 45 minutes. This semi-structured interview inquired about academic history (e.g., mathematics courses completed) and demographic data. We also asked each participant to explain what s/he thought it meant to be the key idea of a proof. We then provided each participant with paper copies of their own proofs and the researcher-generated canned proofs, and asked him or her to identify the most important part(s) of the proof.

Variables and analyses

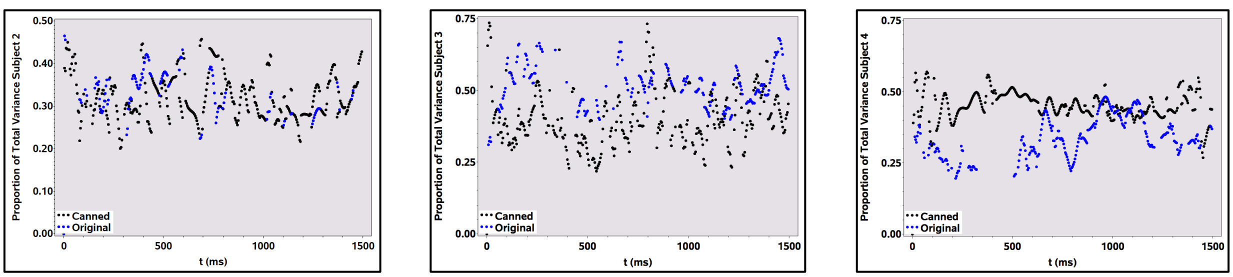
After data collection, at least two researchers from the team separately coded the collections of slides according to the modified proof comprehension taxonomy (Figure 2) and met to compare codes. Discrepancies between codes were resolved through discussion between the coders. We also generated an additional code of "student-reported potential for insight" (SRPFI) based on the slides corresponding to parts of the proof that the participant identified as important during the post-EEG interview. For the EEG data, for each time point (every 4 milliseconds between 0 ms and 1500 ms) in every slide across the four trials, we regressed the measured amplitude of the EEG electrode with the theoretically coded variables, choosing the final model through stepwise regression. In this process, we chose the electrode with greatest predicted total proportion of the variance (R^2) explained using the fewest coded variables. Here, variance in a given electrode is identified as the difference across all slides between the voltage of measured electrical activity by that electrode for a fixed time elapsed after first seeing each slide. We selected these models at each time point to generate a spatial and temporal description of the evolution of the modeled neural activity induced by the slides of the proofs.

Assumption (A), Contradiction statement (CONT), Delimiter (D), Exterior reference (ER), Interior reference (IR), Relabelling (REL), Statement of intent (SI), Similarity in a proof (SIM), Algebra (ALG), Conclusion statement (C), Definition of (DEF), Formal logic (FL), Use of exterior reference (UE), Use of interior reference (UI).

Figure 2: List of Codes from modified local proof comprehension taxonomy (Savic, 2011)

Results

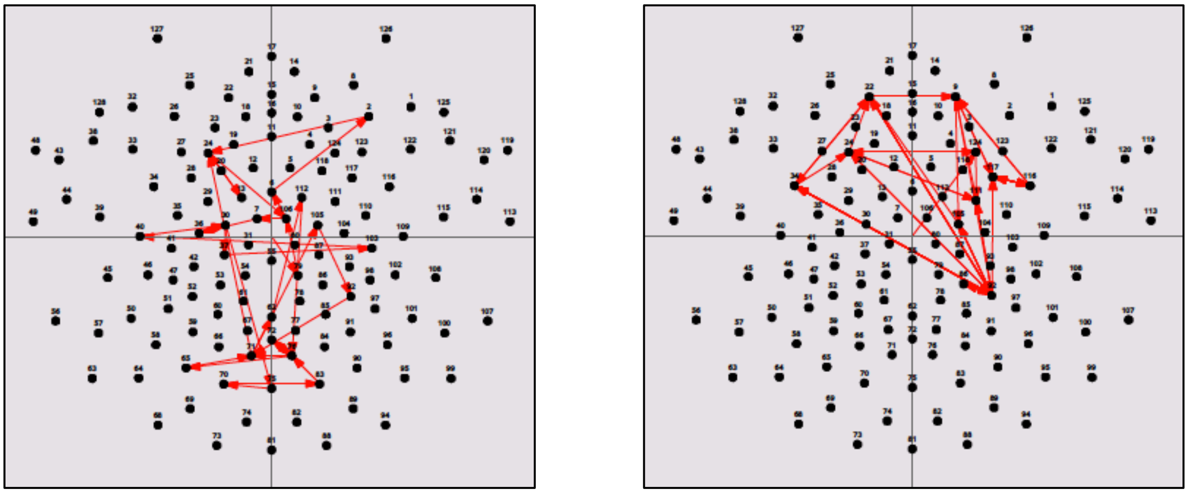
Our preliminary analysis indicates that the theoretical codes are able to account for between 20% and 75% of variance (y-axis in Figure 3) in modeled neural activity, though the codes accounted for around 35% to 50% of variance in neural activity for the majority of the time (x-axis). As one might infer from Figure 3, the current data do not show a conclusive difference between the potential for the theoretical codes to explain (or predict) variance between the canned and original proofs.



(a) Marshall (b) Francis (c) Buzz

Figure 3: Graphs of the proportion of total variance predicted by the model of best fit along time

We have also generated maps of the progression over time of the EEG electrodes with most variance explained (Figure 4). The figures below display the placement of the 128 nodes from the neural net. The highest nodes in quadrants 1 and 2 are located under the eyes. The origin corresponds with the top-most, center part of the participant's head, quadrant I corresponds with the right frontal lobe; quadrant II corresponds with the left frontal lobe, quadrant III corresponds with the left occipital lobe, and quadrant IV corresponds with the right occipital lobe. Initial comparisons between the maps of the participants' responses to the researcher-generated "canned" proofs and their responses to their own proofs indicate that the participants' react to the two types of proofs differently. For instance, the modeled electrodes during Marshall's reaction to the "canned" proof (Figure 4a) initially concentrated in and around the parietal lobe and shift to the temporal and frontal lobes. This implies that Marshall's initial reaction to a slide from the "canned" proofs tended to rely initially on visual processing before shifting to critical processing areas in the brain.

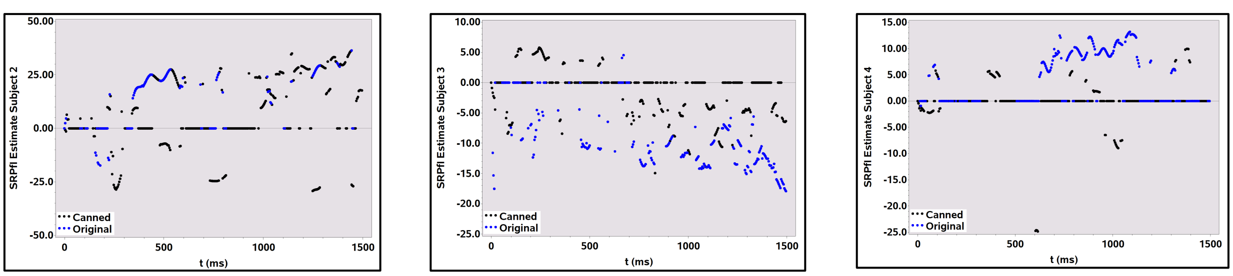


(a) (b)

Figure 4: Progression of neural activity with best model fit for Marshall's canned proofs (a) and original proofs (b).

In contrast, when Marshall was presented with "original" slides, the neural activity modeled in our regression takes place almost entirely in the temporal and frontal lobes (Figure 4b). Since his dominant electrodes were not in the visual processing area (occipital lobe), this supports the notion that Marshall is relying on his prior experiences as he observes the "original" slides. In other words, Marshall is likely engaged in some level of "re-living" his own proof. Finally, we see bilateral movement between left and right hemispheres on both 4a and 4b, which is "essential for complex mathematical reasoning" (Dehaene et al., 1999; cited in Desco et al., 2011, p. 282).

We found that all three participants had the code SRPFI (student-reported potential for insight) included in many of the regression models, seen in Figure 5, where the y-axis is microvolts squared and the x-axis is time. This indicates a potential link between student-reported insight and neural activity. However, due to the preliminary nature of the findings and sample size, we only hope to expand our research on that link.



(a) Marshall (b) Francis (c) Buzz

Figure 5: Graphs of the microvolts^2 of variance influenced by SRPFI

Future Research

We hope to extend our current findings by (1) exploring interpretations of our current data and the theoretical implications this might have on the codes we use to model neural activity, (2) collecting data with more participants, and (3) exploring different neural data collection techniques (e.g., alternative brain-computer interfaces such as fNIRS – functional near-infared spectroscopy). We expect that further analysis of the data collected to this point will help inform future work by raising questions of which theoretical constructs are able to better predict variance in neural activity, in turn narrowing our focus with respect to the existing theoretical codes and also informing our selection of potential codes to use in the future. Can we, with only coding, predict when a person has an insight in his or her proving process? Finally, since the codes considered local proof comprehension, we plan on using other coding schemes for holistic proof comprehension.

Emerging Insights from the Evolving Framework of Structural Abstraction in Knowing and Learning Advanced Mathematics

Thorsten Scheiner
University of Hamburg, Germany

Márcia M. F. Pinto
Federal University of Rio de Janeiro, Brazil

Only recently 'abstraction on objects' has attracted attention in the literature as a form of abstraction that has the potential to take account of the complexity of students' knowing and learning processes compatible with their strategy of giving meaning. This paper draws attention to several emerging insights from the evolving framework of structural abstraction in students' knowing and learning of the limit concept of a sequence. Particular ideas are accentuated that we need to understand from a theoretical point of view since they reveal a new way of understanding knowing and learning advanced mathematical concepts and have significant implications for educational practice.

Keywords: Limit Concept; Mathematical Cognition; Sense-Making; Structural Abstraction

Introduction

Theoretical and empirical research shows the existence of differences in knowing and learning concerning different kinds of knowledge (diSessa, 2002). A general framework on abstraction cannot encompass the whole complexity of knowing and learning processes in mathematics. Rather, in investigating the nature, form, and emergence of knowledge pieces, various micro-genetic learning theories may be developed, which will be quite specific to particular mathematical concepts, individuals, and their underlying sense-making strategies. As a consequence, the complexity of knowing and learning processes in mathematics cannot be described or explained by only one framework. Instead, we acknowledge that comprehensive understanding of cognition and learning in mathematics draws on a variety of theoretical frameworks on abstraction.

The literature demonstrates significant theoretical and empirical advancement in understanding 'abstraction-from-actions' approaches, particularly the cognitive processes of forming a (structural) concept from an (operational) process (Dubinsky, 1991; Gray & Tall, 1994; Sfard, 1991). Abstraction-from-actions approaches take account of a certain sense-making strategy, namely what Pinto (1998) described as 'extracting meaning'. However, only recently 'abstraction on objects' has attracted attention as a form of abstraction that provides a new way of seeing the complex knowing and learning processes compatible with students' strategy of what Pinto (1998) described as 'giving meaning'.

The purpose of this paper is to provide deeper meaning to a recently evolving framework of a particular kind of 'abstraction from objects': structural abstraction. The structural abstraction framework is evolving in the sense that the framework functions both as a tool for research and as an object of research (Scheiner & Pinto, submitted). In more detail, we use the structural abstraction framework retrospectively as a lens through which we reinterpret a set of findings on students' knowing and learning of the limit concept of a sequence. This reinterpretation is an active one in the sense that the framework serves as a tool to analyze a set of data, while the framework is also refined and extended since the reinterpretation produces deeper insights about the framework itself. Especially, these more profound insights are what we need to understand from a theoretical point of view since they have relevance for significant issues in knowing and learning advanced mathematical concepts.

We begin by providing an upshot of our synthesis of the literature on abstraction in knowing and learning mathematics. Our synthesis is to suggest an orientation toward the evolving framework of structural abstraction as an avenue to take account of an important area for consideration – that is, drawing attention to the complex knowing and learning processes compatible with students' 'giving meaning' strategy. The structural abstraction framework constitutes the foundation of the second part of the paper providing emerging insights in knowing and learning the limit concept of a sequence. These insights offer theoretical advancement of the framework and deepen our understanding of knowing and learning advanced mathematics.

Mapping the Terrain of Research on Abstraction in Mathematics Education

Abstraction seems to have gained a bad reputation because of the criticism articulated by the situated cognition (or situated learning) paradigm, and, as a consequence, has almost disappeared. This criticism rests primarily on traditional approaches considering abstraction as decontextualization and often confusing abstraction with generalization. The recent contribution by Fuchs et al. (2003) shows that such classical approaches to abstraction still exist:

> "To abstract a principle is to identify a generic quality or pattern across instances of the principle. In formulating an abstraction, an individual deletes details across exemplars, which are irrelevant to the abstract category […]. These abstractions […] avoid contextual specificity so they can be applied to other instances or across situations." (p. 294)

However, scholars in mathematics education argued against the decontextualization view of abstraction. Van Oers (1998, 2001), for instance, argued that removing context must impoverish a concept rather than enrich it. Several other scholars have reconsidered and advanced our understanding of abstraction in ways that account for the situated nature of knowing and learning in mathematics. Noss and Hoyles (1996) introduced the notion of *situated abstraction* to describe "how learners construct mathematical ideas by drawing on the webbing of a particular setting which, in turn, shapes the way the ideas are expressed" (p. 122). Webbing in this sense means "the presence of a structure that learners can draw up and reconstruct for support – in ways that they can choose as appropriate for their struggle to construct meaning for some mathematics (Noss & Hoyles, 1996, p. 108). Hershkowitz, Schwarz, and Dreyfus (2001) introduced the notion of *abstraction in context* that they presented as "an activity of vertically reorganizing previously constructed mathematics into new mathematical structure" (p. 202). They identify abstraction in context with what Treffers (1987) described as 'vertical mathematization' and propose entire mathematical activity as the unity of analysis. These contributions demonstrate that research on abstraction in knowing and learning mathematics has made significant progress in taking account of the context-sensitivity of knowledge.

Several other contributions shape the territory in mathematics education research on abstraction. Scheiner (2016) proposed a distinction between two forms of abstraction, namely *abstraction on actions* and *abstraction on objects*. This distinction has been further refined in Scheiner and Pinto (2014) arguing that the focus of attention of each form of abstraction takes place on physical objects (referring to the real world) or mental objects (referring to the thought world) (see Fig. 1).

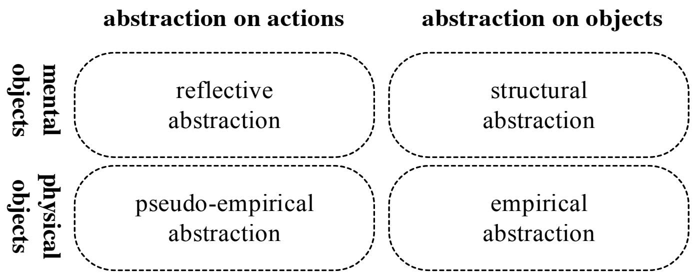

Fig. 1: A frame to capture various kinds of abstraction (reproduced from Scheiner & Pinto, 2014)

We consider this distinction as being productive in trying to capture some of the variety of images of abstraction in mathematics education (for details see Scheiner & Pinto, 2016). It acknowledges Piaget's (1977/2001) three kinds of abstraction, including pseudo-empirical abstraction, empirical abstraction, and reflective abstraction, that served as critical points of departure in thinking about abstraction in learning mathematics. Research on abstraction in mathematics has long moved beyond classifying and categorizing approaches in cognition and learning. For instance, Mitchelmore and White (2007), in going beyond Piaget's empirical abstraction and in drawing on Skemp's (1986) conception of abstraction, described abstraction in learning elementary mathematics concerning seeing the underlying structure rather than the superficial characteristics. Abstraction in learning advanced mathematics, however, is almost always defined in terms of *encapsulation* (or *reification*) of processes into objects, originating in Piaget's (1977/2001) idea of *reflective abstraction*. Reflective abstraction is an abstraction from the subject's actions on objects, particularly from the coordination between these actions. The particular function of reflective abstraction is abstracting properties of an individual's action coordination. That is, reflective abstraction is a mechanism for the isolation of specific properties of a mathematical structure that allows the individual to construct new pieces of knowledge. Taking Piaget's reflective abstraction as a point of departure, Dubinsky and his colleagues (Dubinsky, 1991; Cottrill et al., 1996) developed the APOS theory describing the construction of concepts through the encapsulation of processes. Similar to encapsulation is reification – the central tenet of Sfard's (1991) framework emphasizing the cognitive process of forming a (structural) concept from an (operational) process. In the same way, Gray and Tall (1994) described this issue as an overall progression from procedural thinking to proceptual thinking, whereas proceptual thinking means the ability to flexibly manipulate a mathematical symbol as both a process and a concept. Gray and Tall (1994) termed symbols that may be regarded as being a pivot between a process to compute or manipulate and a concept that may be thought of as a manipulable entity as procepts.

Scheiner (2016) revealed that the literature shows an unyielding bias toward *abstraction on actions* as the driving form of abstraction in knowing and learning advanced mathematics. This almost always exclusive view arises directly from the trajectory of our field's history; originating in Piaget's assumption that only reflective abstraction can be the source of any genuinely new construction of knowledge. While abstraction-on-actions approaches have served many purposes quite well, they cannot track detail of students' knowing and learning processes compatible with the strategy of giving meaning. The recently evolving framework of structural abstraction has attracted attention as a promising tool to shed light into the complexity of students' knowing and learning processes compatible with their strategy of 'giving meaning'.

The Evolving Framework of Structural Abstraction

The evolving framework of structural abstraction (Scheiner, 2016) further elaborates Tall's (2013) conception of this particular kind of abstraction. The crucial aspect lies in the argument that structural abstraction takes account of two processes: (1) complementizing meaningful aspects and structure underlying specific objects falling under a particular concept, and (2) promoting the growth of a complex knowledge system through restructuring various knowledge pieces. Several assumptions guide the evolving framework of structural abstraction assumptions:

Concretizing through Contextualizing

Structural abstraction takes place on mental objects that, in Frege's (1892a) sense, fall under a particular concept. These objects may be either concrete or abstract. Concreteness and abstractness, however, are not considered as properties of an object but rather as properties of an individual's relatedness to an object in the sense of the richness of a person's representations, interactions, and connections with the object (Wilensky, 1991). From this point of view, rather than moving from the concrete to the abstract, individuals, in fact, begin their understanding of (advanced) mathematical concepts with the abstract (Davydov, 1972/1990). The ascending from the abstract to the concrete requires a *concretizing* process where the mathematical structure is particularized by looking at the object in relation with itself or with other objects that fall under the particular concept. The crucial aspect for concretizing is *contextualizing*, that is, setting the object(s) in different specific contexts. Different contexts may provide various senses (Frege, 1892b) of the concept of observation.

Complementizing through Recontextualizing

The central characteristic of the structural abstraction framework is that while, within the empiricist view, conceptual unity relies on the commonality of elements, it is the interrelatedness of diverse elements that creates unity within the approach of structural abstraction. The process of placing objects into different specific contexts allows particularizing essential components. Structural abstraction, then, means attributing the particularized meaningful components of objects to the mathematical concept. Thus, the core of structural abstraction is *complementarity* rather than similarity. The meaning of advanced mathematical concepts is developed by complementizing diverse meaningful components of a variety of specific objects that have been contextualized and recontextualized in multiple situations. This perspective agrees with van Oers' (1998) view on abstraction as related to *re*contextualization instead of *de*contextualization.

Complexifying through Complementizing

The structural abstraction framework takes the view that knowledge is a complex system of many kinds of knowledge elements and structures. Complementizing implies a process of restructuring the system of knowledge pieces. These knowledge pieces have been constructed through the above-mentioned process or are already constructed elements coming from other concept images, which are essential for the new concept construction. The cognitive function of structural abstraction is to facilitate the assembly of more complex and compressed knowledge structures. Taking this perspective, we construe structural abstraction as moving *from simple to complex* knowledge structures, a movement with the aim to build coherence among the various knowledge pieces through restructuring them.

Emerging Insights from the Structural Abstraction Framework

In this section, we summarize emerging insights we gained, and still gain, by using the evolving framework of structural abstraction retrospectively as a lens through which findings on students' (re-)construction of the limit concept of a sequence were reinterpreted. The study by Pinto (1998) provides the context in which she identified mathematics undergraduates' sense-making strategies of formal mathematics. From a cross-sectional analysis of three pairs of students, two prototypical strategies of making sense could be identified, namely 'extracting meaning' and 'giving meaning':

> "*Extracting meaning* involves working within the content, routinizing it, using it, and building its meaning as a formal construct. *Giving meaning* means taking one's personal concept imagery as a starting point to build new knowledge." (Pinto, 1998, pp. 298-299)

The literature on abstraction-from-actions provides several accounts of how students construct a mathematical concept compatible with their strategy of 'extracting meaning'; however, there are almost no accounts of how students construct a concept compatible with their strategy of 'giving meaning'. It is important to note that the evolving framework of structural abstraction is problem driven, that is, addressing the need of bringing light into the complexity of students' knowing and learning processes compatible with their strategy of 'giving meaning', rather than filling a theoretical gap just because it exists. The reinterpretation of empirical data on students' strategies of giving meaning in the light of the theoretical framework of structural abstraction proved to be particular fruitful - not only to provide deeper insights into the strategy of giving meaning but also as a way to deepen our understanding of the phenomenon of structural abstraction that revealed to new theoretical development (Pinto & Scheiner, 2016; Scheiner & Pinto, 2014). In the following pages, we highlight the main theoretical advancements.

The idea of complementizing meaningful components underlying the structural abstraction framework reflects the idea that whether an individual has 'grasped' the meaning of a mathematical concept depends on the specific context where the objects falling under the particular mathematical concept have been placed in. This supports Skemp's (1986) viewpoint that "the subjective nature of understanding […] is not […] an all-or-nothing state" (p. 43). The reanalysis of the data indicates that the object of researchers' observation should be directed to students' *partial constructions* of the limit concept. These partial constructions may be specific and productive to particular contexts but may remain not fully connected and may be unproductive in other contexts (for instance, in making sense of the formal definition). The empirical data shows that, in the case of the students who give meaning, several meaningful elements and relations in understanding the limit concept of a sequence are involved, although a few elements are missing (or distorted). However, some students are able to (re-)construct some meaningful components at need by making use of their partial constructions, while others are not able to do so.

The reanalysis indicates that some students have developed *resources* that enable them to (re-)construct the limit concept of a sequence at need. Scheiner and Pinto (2014) presented a case where a student developed a generic representation of the limit concept of a sequence that operates well in several, although not all, contexts and situations. This particular representation, however, allows the student to (re-)construct the limit concept in other contexts and situations. The reinterpretation of the data sheds light on the phenomenon that individuals may do not 'have' all relevant meaningful components, but, rather, they may have resources to generate some meaningful components and make sense of the context at need. In that sense, the 'completeness' of the complementizing process cannot ever be taken as absolute.

Several scholars suggested exposing learners to multiple contexts and situations. An important insight from using the structural abstraction framework retrospectively is that exposure to multiple contexts is at least important for particularizing meaningful components: various objects falling under a particular mathematical concept have to be set into different specific contexts in order to make visible the meaningful components or mathematical structure of these objects. In so doing, the objects may be 'exemplified' through a variety of representations, in which each representation has the same reference (the mathematical object); however, different representations may express different senses depending on the selected representation system (see Fig. 2). The distinction between *sense* and *reference* has been specified by Frege (1892b) in his work *Über Sinn und Bedeutung*, indicating both the sense and the reference as semantic functions of an expression (a name, sign, or description). In short, the former is the *way* that an expression refers to an object, whereas the latter is the *object* to which the expression refers. According to Frege (1892b), to each representation correspondents a sense; the latter may be connected with an *idea* that can differ within individuals since people might associate different senses with a given representation. Though multiple contexts and situations are needed, a new context that does not provide a new sense will unlikely to be productive for the concept construction. The framework indicates that the *nature of the contexts* the objects are set is determinative of their value toward the complementizing process.

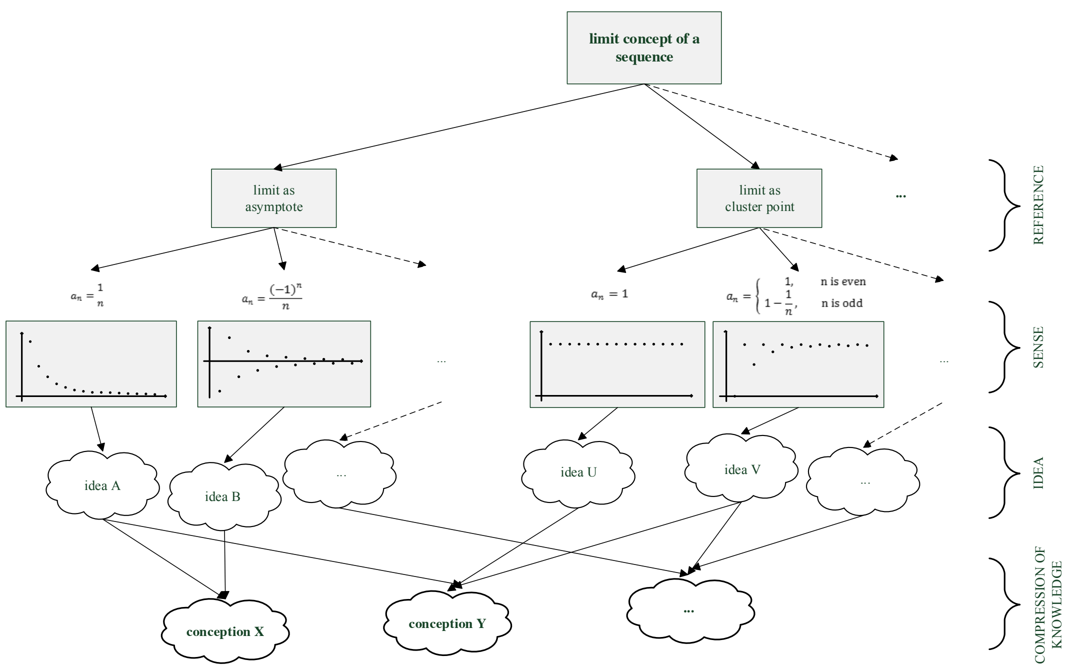

Fig. 2: Reference, sense, and idea

Research also indicates that students may have difficulties with the *relationships* between the sense and the reference as well as difficulties in *maintaining* the reference as the sense changes (Duval, 1995, 2006). Thus, based on the insights we have gained from reanalyzing the data (Pinto & Scheiner, 2016; Scheiner & Pinto, 2014), we can assume that these difficulties may (at least partly) be overcome by providing students a particular resource (such as a generic representation of the mathematical concept) that serves as a guiding tool in complementizing the meaningful components indicated in the different senses. From this perspective, a 'representation for' is a tool that provides theoretical structure in constructing the meaning of the concept of observation. It necessarily reflects essential aspects of a mathematical concept but can have different manifestations (Van den Heuvel-Panhuizen, 2003). Concerning the learning of the limit concept of a sequence, the reinterpretation of the data indicates that a slightly modified version of a student's representation (see Fig. 3) may support the complementizing process when the limit concept is recontextualized.

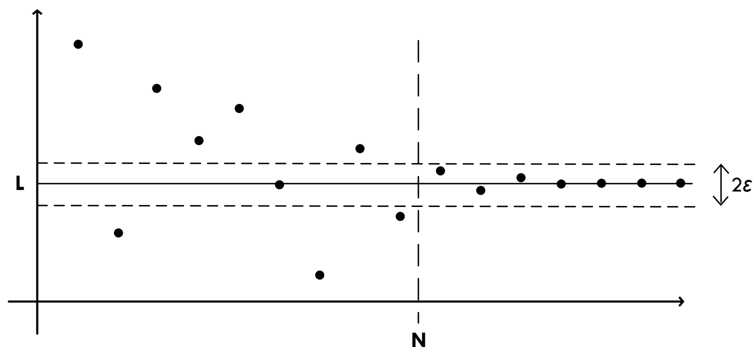

Fig. 3: A generic representation for learning the limit concept of a sequence

Notice that this generic representation for learning the limit concept of a sequence takes account of several students' common conceptions identified in the research literature, including those as (1) the limit is unreachable, (2) the limit has to be approached monotonically, and (3) the limit is a bound that cannot be crossed (see Cornu, 1991; Davis & Vinner, 1986; Przenioslo, 2004; Tall & Vinner, 1981; Williams, 1991).

The reanalysis of the empirical data gained from Pinto's (1998) study has shown that students giving meaning built a representation of the concept and, at the same time, used it as a representation for recognizing and building up knowledge – the reconstruction of the formal concept definition, for instance. The analysis shows that these students consistently used *representations of* mathematical objects to create pieces of knowledge; or, in other words, the representations were actively taken as *representations for* emerging new knowledge and making sense of the context and situation. This shift from constituting a representation of the limit concept to using this representation as a representation for (re-)constructing the limit concept in other contexts can be described in terms of shifting from a *model of* to a *model for* (Streefland, 1985) – a shift from an *after*-image of a piece of given reality to a *pre*-image for a piece of to be created reality. This mental shift from 'after-image' to 'pre-image' indicates a degree of awareness of the meaningful components and the complexity of knowledge structure that allows the transition from a 'representation of' as a result of various representations expressing specific objects set in different contexts to a 'representation for' constructing and reconstructing the limit concept, inter alia, in formal mathematical reasoning. We suggest that a generic representation, as presented in Fig. 3, may provide an instructional tool that supports raising the awareness of meaningful components in learning the limit concept of a sequence. In other words, such a generic representation may direct students' perception of meaningful components.

Physics Students' Use Of Symbolic Forms When Constructing Differential Elements In Multivariable Coordinate Systems

Benjamin P. Schermerhorn
University of Maine

John R. Thompson
University of Maine

Analysis of properties of physical quantities represented by vector fields often involves symmetries and spatial relationships that are best expressed in three dimensional non-Cartesian coordinate systems. Many important quantities, both scalar and vector in nature, are determined by paths, areas, or volume integrals of multivariable functions. The differential quantities in these systems are not trivial for students to understand and implement correctly. As part of an effort to investigate physics students' understanding of the structure of non-Cartesian coordinate systems and the associated differential elements when using vector calculus in Electricity and Magnetism (E&M), we interviewed four pairs of students in the junior-level E&M course. In one particular task, students were asked to construct differential length elements for an unconventional spherical coordinate system. A symbolic forms analysis (Sherin, 2001) of student reasoning revealed both known and novel forms, and found that student difficulties with vector differential quantities were primarily conceptual rather than symbolic.

Key words: Coordinate Systems, Symbolic Forms, Physics, Differential Elements, Vector Calculus

Introduction

The equation is a fundamental construct that appears ubiquitously in physics as a means to provide a mathematical description of physical situations, from the analysis of opposing forces on an object at the introductory level to the use of non-Cartesian vector elements in electricity and magnetism (E&M). The equation becomes a translation across the mathematics-physics interface that students are expected to routinely navigate. The ability to work with mathematical systems, equations, and expressions becomes especially relevant in upper-division coursework, in which the mathematics and physics increase in sophistication. In many cases the use of mathematics includes accounting for underlying physical symmetry, extracting information from physical situations for calculation, or interpreting the results of calculation physically, all of which are cited as areas of student difficulty in upper-division E&M (Pepper *et al.,* 2012).

Our work seeks to address students' understanding of differential vector elements used to solve various vector calculus problems in E&M, specifically answering the following research question: How do students construct differential vector elements in a given coordinate system?

Sherin's (2001) *symbolic* forms is one method of analysis developed to understand how students interpret and construct equations. We use the symbolic forms framework to provide insight into how upper-division students develop the structure of differential vector elements and determine how each component is represented in the final equation.

Background

In upper-division E&M, students reason about physical symmetries of electric and magnetic fields and interpret physical scenarios to construct and implement differential elements into calculation. In the majority of cases, these differential elements begin as vector quantities, having a particular direction, where students are summing up the dot products of various vector fields over specific lines or surfaces. To add complication, field symmetries in E&M often dictate the use of a non-Cartesian coordinate system, meaning the differential elements take on a different form than the traditional dx or $dydz$, a line element and area element both in the $\hat{\imath}$ direction.

In cylindrical and spherical coordinates, motion along curved surfaces results in differential length elements that are arc lengths and include scaling factors ($i.e.,\ dl_\theta = rd\theta\hat{\theta}$ for spherical coordinates in physics). Area elements are constructed by determining which variables are changing and which are constant, and then multiplying the differential length elements associated with the change(s). Therefore an understanding of the differential length vector across each coordinate system emerges as a fundamental mathematical construct in the application of vector calculus in our upper-division electricity and magnetism courses.

Previous studies have assessed student understanding of integration and differentials (Doughty *et al*., 2014; Hu & Rebello, 2013; Nguyen & Rebello, 2011) and have addressed calculation, understanding, and application of gradient, divergence, and curl in both mathematics and physics settings (Astolfi & Baily, 2014; Bollen, *et al*., 2015). Other studies have identified difficulties in applying Gauss's and Ampère's Laws, to common aspects of an E&M course that involve a surface integral and line integral, respectively (Guisasola, *et al*., 2008; Manogue, *et al*., 2006; Pepper *et al*., 2012). However, little work has explored student understanding of the differential vector element as it appears in the non-Cartesian systems used in associated physics problems.

Theoretical Perspective

Based on the knowledge-in-pieces model (diSessa, 1993), a symbolic forms analysis affords the opportunity to investigate students' thinking about equations (Sherin, 2001). Symbolic forms began in a third-semester physics course, where students were provided with several word problems modeling physical situations common to introductory physics. The development of a symbolic forms analysis provided a critical lens for the investigation of students' construction and sense-making of equations at the introductory level.

The specific nature of a symbolic form comes from the combination of a symbol template with a conceptual schema. A symbol template, such as $\square + \square + \square$, is an externalized structure of an equation. Each box contains variables and/or numbers depending on what a student deems fit. A student's conceptual schema is the sum of internalized ideas students use to determine and fill in the template. For example, $\square + \square + \square$ would appear in a students' equation if the student decided they needed to sum multiple quantities. The symbolic form associated with this particular template-schema pair is known as *parts-of-a-whole* (Sherin, 2001). Additionally a student would be able to read information out of an equation, such as relationships between quantities, by interpreting the templates used to construct an equation.

Work with symbolic forms has since expanded into the upper division and to explore integration in mathematics. Meredith and Marrongelle (2008) adapted the conceptual aspects of symbolic forms to describe what features of electrostatics problems cue students to integrate. They found students using the *dependence* form when eliciting the reliance on a particular variable and the *parts-of-a-whole* form when summing up multiple components. The symbolic forms framework has been used to analyze physical chemistry students' use of partial derivatives in thermodynamics (Becker & Towns, 2012). The ideas of symbolic forms were used to address calculus students' ideas when making sense of integrals (Jones, 2015); students' exposed conceptual understandings often included graphical representations of given functions.

$$\vec{dl} = dr\hat{r} + rd\theta\hat{\theta} + rsin\theta d\phi\hat{\phi}$$
$$d\tau = r^2 sin\theta dr d\theta d\phi$$

(d)

$$\vec{dl} = dM\hat{M} + Md\alpha\hat{\alpha} + Mcos\alpha d\beta\hat{\beta}$$
$$d\tau = M^2 cos\alpha dM d\alpha d\beta$$

Figure 1. (a) Conventional (physics) spherical coordinates; (b) an unconventional spherical coordinate system given to students, for which they were to construct differential length and volume elements. The correct elements for each system are in (c) and (d), respectively.

Methods

In order to investigate student construction of differential length vectors, a task was developed in which students were asked to reason about an unconventional spherical coordinate system, which we call “schmerical coordinates” (Figure 1). By developing an unconventional coordinate system, we could determine students’ abilities to work with the underlying conceptual ideas, rather than their ability to recall a memorized answer.

Clinical think-aloud interviews were conducted with four pairs of students (N=8) following the first semester of a two-semester, junior-level E&M sequence. Students were asked whether the given coordinate system was feasible and to determine and verify the differential line and volume elements. Pair interviews facilitated a more authentic interaction between students and minimized the input and influence of the interviewer. Groups are identified as AB, CD, etc., signifying pairings of students A and B, and so on.

Interview data were transcribed and analyzed using open coding to identify common actions and recurring ideas across interview groups. Initial analysis categorized these ideas as aspects of students’ *concept images* (Tall & Vinner, 1981) and building actions. Concept image aspects include *component and direction, dimensionality, differential,* and *projection*. Building actions involved *recall* of and *mapping* to other coordinate systems, as well as *grouping* of specific terms. Subsequently, we addressed the sequence these ideas and actions arose in the construction and checking of the differential vector elements (Schermerhorn & Thompson, 2016).

A secondary, finer-grained analysis investigated how students developed, implemented, and filled known and novel symbol templates as part of a symbolic forms analysis.

Results

Analysis of student work resulted in the identification of symbolic forms related to the construction of non-Cartesian differential length vectors (Table 1). Some invoked symbolic forms match those established by Sherin (2001): *parts-of-a-whole*, *no dependence*, and *coefficient*. In addition, other, novel template-schema combinations were common across all student groups, emerging due to the vector nature of this context and the increased mathematical sophistication of the upper-division content. We labeled these forms *magnitude-direction* and *differential*.

This report focuses on students’ initial attempt at construction before they were asked about the differential volume element. At this stage of construction no group was able to successfully determine the differential length element due to inattention to certain ideas, such as *projection*, or overreliance on recalling spherical coordinates (Schermerhorn & Thompson, 2016).

Table 1. Symbolic forms identified in students' construction of a differential length element.

Symbolic Form	Symbol Template	Conceptual Schema
Parts-of-a-whole	$\square + \square + \square$	Accounts for multiple components that contribute to a larger whole (Sherin, 2001).
No dependence	$[\ldots]$	Indicates an expression is independent of, or not a function of, a specific variable. The expression is therefore absent of the variable (Sherin, 2001).
Coefficient	$[\square\ldots]$	Quantities or variables put in front of an expression; Seen as just numbers or constants, possibly having units (Sherin, 2001).
Magnitude-direction	$\square\hat{\square}$	Used to denote a vector expression including the magnitude of a quantity (having units) paired with a unit vector to indicate a specific direction.
Differential	$d\square$	Represents taking a small amount of or infinitesimal change in a quantity.

Previously identified symbolic forms

Students' attention to the overall structure of the differential length vector led them to recognize the need for multiple components coupled with motion in each of the three spatial directions, consistent with Sherin's *parts-of-a-whole*. Student F demonstrated an appropriate conceptual schema when starting construction:

F: There are three different dl's. There is dl with respect to M, dl with respect to α and dl with respect to β.

Group EF worked on each component independently; student E then summed these components to express their full (incorrect) vector differential:

E: You sum them, so $\overrightarrow{dl}$ is those added together $dM\hat{M} + Md\beta\hat{\beta} + Md\alpha\hat{\alpha}$.

Group CD recognized the need for each part by leaving space to write the components into the expression (Fig. 2).

Students also used language consistent with the *no dependence* symbolic form:

A: [writes $Md\alpha$] For α? [sweeps arm up and down] Yeah, for α, it doesn't have any dependence on this other angle over here.

The arm motion was made by A to trace out how the angle α is changing. Here student A reasoned about the geometrical space to recognize that the differential length element resulting from a change in α is independent of β.

As students made determinations about the scaling factors (*e.g.*, the $M\cos\alpha$ associated with the $M\cos\alpha\, d\beta\hat{\beta}$) they commonly used language associated with Sherin's *coefficient* symbolic form. As the *coefficient* form is typically coupled with additional forms in equation building, the invocation of this form will be discussed later.

Figure 2. Beginning stages of construction for C and D showing the coupling of the *parts-of-a-whole* and *magnitude-direction* symbolic forms.

Newly identified symbolic forms

Given the relevance of mathematics associated with vectors and differentials in this task, this work has identified new template-schema pairings, the *magnitude-direction* and *differential* symbolic forms, emerging from students' constructions.

When constructing differential length vectors, students must attend not only to the magnitude of the length component but also the direction in which the length is taken. All groups recognized the need to include unit vectors in their full expressions. From this we identify the *magnitude-direction* symbolic form, which in a larger context accounts for students recognizing the need to multiply a quantity, representing a magnitude, by a unit vector denoting the direction associated with that particular quantity.

While the *magnitude-direction* symbolic form is similar to the *scaling* and *coefficient* symbolic forms (Sherin, 2001), these existing forms are insufficient to describe the constructed vector expressions. Consider a vector representing a distance of 5 meters north. In two dimensions we could represent this as $(5\text{m})\hat{\jmath}$. The *coefficient* form is not applicable in that the magnitude of a vector expression has specific meaning, especially in physics. The *scaling* form is used to describe unitless or dimensionless quantities that attenuate the size of what follows, and thus contradictory given the emphasis on the vector describing a length. Therefore, the *magnitude-direction* symbolic form is more applicable to describe the choices of our students.

As students determined the expressions for the magnitudes of each component, they discussed the inclusion of differential terms. Student C exemplifies common reasoning:

C: You have a change in your $\widehat{M}$ is going to be your dM, it's your change in your M.

From this and similar statements we identify the *differential* symbolic form, which is used to signify a small change in or small amount of a given quantity, a conceptual schema consistent with students' ideas of differentials as identified in the literature (Artigue *et al.,* 1990; Hu & Rebello, 2013; Roundy *et al.,* 2015; Von Korff & Rebello, 2012). The form itself is similar to what appears in graphically oriented symbolic forms for integration (Jones, 2013) but here, the differential is a standalone quantity with its own attached schemata. Distinction is also made from Sherin's (2001) *base±change* form, where the change is seen as being applied to a quantity or as a correction term dependent upon the base quantity ($i.e.,\ v_o \pm at$).

Student invocation and combination of symbolic forms

Overall, each group invoked and combined symbolic forms in a similar sequence (Fig. 3). At the beginning of construction, there was almost an immediate nesting of the *magnitude-direction* symbolic form into each box of the *parts-of-a-whole* form, specifically accounting for the vector components. Group CD explicitly develops this structure by writing out the three needed units vectors and leaving space to write in the magnitude of each component (Fig. 2).

Students often paired the coefficient and differential terms when the necessity of appropriate dimensions dictated it, as seen in the following two (independent) excerpts:

A: …This doesn't have any units of length, so it needs to have some *M* term.

C: …So, if it's going to be some trig thing but sine of something isn't a length so we're going to have to also have something else in there.

The determinations of the coefficients of each term occurred at multiple stages of construction for a variety of reasons, including recall and mapping to spherical coordinates to a geometric argument that recognized *M* as the radius of a differential arc length. We see the reasoning about dimensionality, in particular, as an abstracted use of the *dependence* symbolic form, where

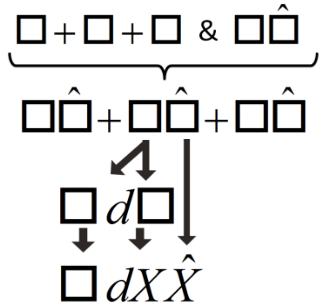

Figure 3. The general flow of students' use and combination of symbol templates during the interview task.

instead of the dependence of the expression being on a specific variable, it is driven by dimensional analysis. C and D paid particular attention to dimensionality and even returned to their expression later in construction with concern about whether the angles carried any units of length. The dependence on units of length sometimes appeared early in construction with the pairing of *magnitude-direction* and *parts-of-a-whole*:

E: So, we're going to have components right... each one has to have units of length.

This often resulted in most students recognizing they did not need to attach a coefficient to dM since it already possessed the necessary units.

As part of students' conceptual schema during construction, many groups paired the differential variable and the corresponding unit vector (*i.e.*, $dM\ \widehat{M}$, $d\alpha\ \hat{\alpha}$, and $d\beta\ \widehat{\beta}$). Groups AB and GH did this automatically during construction (Fig. 4). Other groups initially tried to forcefully insert a differential into their expression. After recognizing $M\cos\alpha$ was a projection into the *xy*-plane, CD wrote a "*d*" in front of the whole expression (Fig. 5). Attempting to insert a trigonometric function into the expression, student F tried to express an infinitesimal arc length as $r\sin d\theta$. After fixing this, group EF focused their construction on having a differential length component in a particular direction containing a differential with that variable:

E: So you're going to have a length component in the β-hat direction…so, basically we're going to need…an M…so it's M times some Δ, I think it's M times $\Delta\beta$, a small β, because it's like if you take r times its small θ then that is the arc length (Fig. 6).

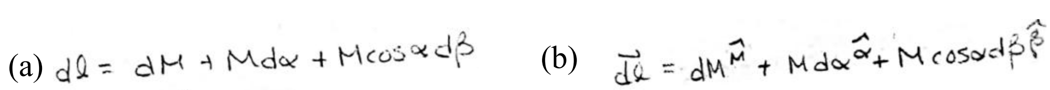

Figure 4. Students G and H before (a) and after (b) recognizing the need to include unit vectors.

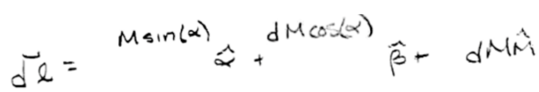

Figure 5. Students C and D incorrectly incorporating the idea of a differential.

Figure 6. Students E and F constructing the beta component of the differential length, initially leaving space to write the needed coefficient and unit vector (a). After discussion they include a coefficient which lacks the needed projection term $\cos\alpha$.

Here we see E and F including the differential element appropriately and using the idea of arc length to fill in the preceding space that was left intentionally blank, similar to C and D with the larger structure (Fig. 3). For E and F, this resolved into the length component, $\overrightarrow{dl}_\beta = Md\beta\hat{\beta}$, which still lacked the needed trigonometric term. As the groups appropriately connected the unit vector with the variable in the *differential* symbolic form, they accounted for the larger pieces of the differential length vector and focused efforts on determining the coefficient terms.

Conclusions

Applying a symbolic forms analysis to student construction of a differential length vector enabled us to see what students think the vector expression should look like as well as what concepts they use to construct the vector elements. The vector context and the increased mathematical sophistication of the upper-division content led to the recognition of existing symbolic forms as well as the identification of new forms. Further analysis identified a typical sequence of invocation of these forms during construction.

Sherin's symbolic forms framework was developed to frame some student difficulties with physics equations as related to the symbol template in addition to or rather than their conceptual understanding. However, our symbolic forms analysis found that students were able to recognize the general structure needed for the equation and invoke the correct template. Difficulties constructing the differential length element were primarily related to conceptual schemata, *e.g.*, students constructed an appropriate expression for the β-component in terms of dimensional and differential considerations, but neglected the projection that introduces the $\cos\alpha$ term.

Results also suggest that attention to dimensionality was significant to students' choices during construction, yet some students struggled to determine the units of certain terms. This is an especially important finding, as previous research on symbolic forms neglects how students' attention to units impacts their problem solving (Sherin, 2001).

Geometric reasoning was prominent in students' construction. In many cases students would attempt to visualize the lengths traced by the vector as small changes were made to individual variables. Students attended to the multiple components needed to express the differential length vector and properly connected the differentials to unit vectors of the same variable. In cases where this proved difficult for students, recall mediated expression construction, similar to upper-division physical chemistry findings dealing with partial derivatives (Becker & Towns, 2012). In our study, however, recall of spherical coordinates during construction led students to expressions that incorrectly included a $\sin(\alpha)$ term (Schermerhorn & Thompson, 2016).

These findings suggest that instructional changes should focus on the concepts associated with the building of the differential, specifically on the determination of the coefficients for the angle components. Subsequent efforts include the development of student-centered instructional materials to be used in E&M and/or mathematical methods of physics courses. In particular, we are developing and piloting a more scaffolded version of the interview task as an instructional activity that guides students through the construction of components of the differential length vector, construction and checking of the volume element, and construction and choice of differential area vectors in schmerical coordinates. Given the importance of the differential area element in E&M calculations (*e.g.*, to determine electric and magnetic flux), current investigations explore how students reason about and construct differential area elements. Additional efforts will investigate the effectiveness of the instructional activity on student understanding of differential length and area vectors.

A Comparison of Calculus, Transition-to-Proof, and Advanced Calculus Student Quantifications in Complex Mathematical Statements

Morgan Sellers, Kyeong Hah Roh, Erika David, and Kody D'Amours
Arizona State University

Abstract: This study investigates Calculus, Transition-to-Proof, and Advanced Calculus students' meanings for quantifiers in conditional statements involving multiple quantifiers. Three students from each course participated in clinical interviews. Students were presented with the Intermediate Value Theorem (IVT) and three other statements whose sentence structure was similar to the IVT except for reordered quantifiers and their attached variables. The results reveal that Advanced Calculus and Transition-to-Proof students made distinctions between the different statements more often than Calculus students. Several student meanings for quantification were found to be necessary for making distinctions between each of the four statements. We also address student quantifications that emerged for the phrase "Suppose f is a function."

Key words: Student Quantification, Undergraduate Students, Comparative Analysis, Intermediate Value Theorem (IVT), Logic

The teaching and learning of Calculus is important for all STEM programs. Many studies have investigated students' meanings for important Calculus concepts such as limits, differentiation, and integration, and how these concepts are presented to students (Carlson et al., 2002; Martin, 2013; Oehrtman, 2009; Orton, 1983; Thompson, 1994; Vinner & Dreyfus, 1989; White & Mitchelmore, 1996; Zandieh, 2000). However, little attention has been paid to the language in which mathematicians express Calculus ideas in textbooks and discourse.

In this paper, we focus on students' meanings for quantifiers in complex mathematical statements. By complex mathematical statements, we mean statements that have both if-then structure and multiple quantifiers. The Intermediate Value Theorem (IVT) is one example of such a statement: "Suppose that f is continuous on the closed interval $[a, b]$ and let N be any number between $f(a)$ and $f(b)$, where $f(a) \neq f(b)$. Then, there exists a real number c in (a, b), such that $f(c)=N$" (Stewart, 2003, p. 131). Similar to the IVT, many Calculus theorems can be classified as complex mathematical statements, even though the topic of quantification is not addressed in popular Calculus textbooks (Bittinger, 1996; Larson, 1998; Stewart, 2003). Quantifier words such as "for all," "there exists," and "unique" may have different student meanings than mathematical ones (Dawkins & Roh, 2016; Dubinsky & Yiparki, 2000; Epp, 1999; Epp, 2003). Students at different mathematical levels, including Calculus, may interpret these words differently than mathematicians. Although some studies have investigated students' and teachers' understandings for quantifiers, many of these studies have dealt with a single quantifier or statements outside of mathematical context (Dubinsky & Yiparaki, 2000; Epp, 2009; Piatek-Jiminez, 2010; Tabach et al., 2010; Tsamir et al., 2009). On the other hand, studies that have dealt with multiple quantifiers in mathematical contexts have placed more emphasis on Transition-to-Proof and Advanced Calculus students' understanding of quantification than Calculus students' understandings of quantification (Dawkins & Roh, 2011; Dawkins & Roh, 2016; Roh & Lee, 2011, 2015, Selden & Selden, 1995). This study explores the following question: *What meanings do students at various mathematical levels have for quantifiers in complex mathematical statements from Calculus?*

Theoretical Perspective

Previous studies show that students often do not problematize the distinction between "for all… there exists" ($\forall\exists$) and "there exists… for all" ($\exists\forall$) statements, and that $\exists\forall$ statements are more frequently misinterpreted than $\forall\exists$ statements (Dubinsky & Yiparaki, 2000; Piatek-Jiminez, 2010). Previous studies also note that students may reorder the variables attached to the quantifiers in their explanation of a complex mathematical statement because they do not necessitate the independence of the first variable and dependence of the second variable (Dawkins & Roh, 2016; Roh & Lee, 2011, 2015). For example, in the IVT, one must consider each value of N before finding the associated c that depends on each N.

Student quantifications[1] for various $\forall\exists$ and $\exists\forall$ statements and relationship between variables attached to the quantifiers may change if we consider different moments. Our goal is to describe our best perception of each student's own meanings for quantifiers at different moments. We thus utilize the phrase "student meaning" throughout this paper the same way in which Piaget views that each individual constructs his own meanings by assimilation to schemes (Thompson, 2013). Students' meanings for quantifiers *in the moment* are preferred because some meanings may be stable, but other meanings may be "meaning(s) in the moment" (Thompson et al., 2014). Thompson et al. (ibid) describe a meaning in the moment as "the space of implications existing at the moment of understanding" (p. 13), so students could be assimilating information in the moment and forming new meanings. A student's thoughts may begin to emerge or different meanings may be elicited in different moments. Thus, we consider several different moments of interaction for each student because different moments of interaction may result in different types of student quantification.

In this study, we identified two types of quantifiers in complex mathematical statements—*explicit* and *implicit quantifiers*, and we seek to understand student meanings for both of these types of quantifiers. *Explicit quantifiers* are directly worded in a mathematical statement. The IVT wording "for all" explicitly states a universal quantification, while "there exists" explicitly states an existential quantification. *Implicit quantifiers* (Durand-Guerrier, 2003) are intended in a mathematical statement but are not conveyed through direct phrasing such as "for all" and "there exists." In the the IVT statement, the hypotheses "Suppose that f is a continuous function" has a hidden universal quantifier because this statement is, in a mathematical convention, a generalized statement and thus f stands *for all* continuous functions.

Methods

Two-hour long clinical interviews (Clement, 2000) were conducted with nine undergraduate students during the spring and summer of 2016 at a large southwestern university in the United States. Students were placed in a category based on the highest course they had already completed. These students had various STEM majors and completed these courses with a variety of different instructors. Three students volunteered from each mathematical level: Calculus I, Transition-to-Proof, and Advanced Calculus. All four authors of this paper participated in data collection (as either interviewer, camera operator, or witness) and analysis.

Interview Tasks. Students were asked to explain their understandings of the four statements shown in Table 1 and to evaluate the truth-values of each of the statements. (Only the statements in the left-hand column of Table 1 were presented to students.) The four statements in Table 1

[1] In this paper, quantification refers to the process by which students quantify variables.

exhaust all combinations for ordering explicit quantifiers and their attached variables. The symbolic representations of the explicit quantifiers found in the conclusion of each statement are also shown beside each statement in Table 1. Three of the statements are false. Statement 2 is the IVT, and the only true statement. The variety of statements allowed us to analyze students' comparisons and contrasts amongst the explicit quantifiers.

Statements	Symbolic Representations
Statement 1: Suppose that f is a continuous function on the closed interval $[a, b]$, where $f(a) \neq f(b)$. Then, for all real numbers c in (a, b), there exists a real number N between $f(a)$ and $f(b)$, such that $f(c)=N$.	$\forall c \exists N$ such that $f(c)=N$
Statement 2: Suppose that f is a continuous function on the closed interval $[a, b]$ where $f(a) \neq f(b)$. Then, for all real numbers N between $f(a)$ and $f(b)$, there exists a real number c in (a, b), such that $f(c)=N$.	$\forall N \exists c$ such that $f(c)=N$
Statement 3: Suppose that f is a continuous function on the closed interval $[a, b]$, where $f(a) \neq f(b)$. Then, there exists a real number N between $f(a)$ and $f(b)$, such that for all real numbers c in (a, b), $f(c)=N$.	$\exists N \forall c$ such that $f(c)=N$
Statement 4: Suppose that f is a continuous function on the closed interval $[a, b]$ where $f(a) \neq f(b)$. Then, there exists a real number c in (a, b), such that for all real numbers N between $f(a)$ and $f(b)$, $f(c)=N$.	$\exists c \forall N$ such that $f(c)=N$

Table 1. Statements presented in the clinical interviews.

Data Analysis. Our analysis was conducted in the spirit of grounded theory (Glaser & Strauss, 1967) using videos of the student interviews as well as the students' written work. Hence, the categories that describe students' meanings for quantifiers emerged from our data and not from previously created categories. Each interview was analyzed moment-by-moment to identify moments where distinctions could be made about a student's meanings for the quantifiers. A new moment began when a student was presented with a new question or task, changed their evaluation of a statement, or if the student provided a new description of the quantifiers in a given statement. Thus, we separated each student interview into moments where we found evidence for his or her quantifier meanings as our unit of analysis. Once the difference in explicit and implicit quantifications was noticed, students' meanings were re-organized and separated into one of these two categories. In the final stage of data analysis, each interview was re-coded moment-by-moment with different types of explicit and implicit quantification. We counted the number of moments that occurred in each category amongst all students. Moments were tagged by the interviewee's mathematical level so that we could make comparisons about student meanings of quantifiers for each group.

Results

The students in this study often provided various truth-values for the statements, and their meanings for the quantifiers also varied. Advanced Calculus students all concluded that the four statements had distinct meanings throughout their interviews, but there were moments with Transition-to-Proof and Calculus students where they said some or all of the statements were equivalent in meaning. Students often had moments where they explained Statements 2-4 in the same ways mathematicians would reason about Statement 1 ($\forall c \exists N$).

Student Meanings for Explicit Quantifiers

Our findings include several meanings for explicit quantification that are necessary for students to have in order for them to interpret the four complex mathematical statements in our task set. We noticed that students with correct truth-values and thorough explanations of the statements were able to distinguish between meanings for different types of quantifiers. These students articulated distinctions for single quantifier words "for all" and "there exists," as well as distinctions for the order of quantifiers "for all… there exists…" and "there exists… for all…" They also recognized and explained the importance of the order of c and N in the statements.

Distinguishing "For all" and "There exists." Some students exhibited distinct meanings that differed for each of the phrases "for all" and "there exists." Some moments involved student specification of the meanings of these phrases in their own words, such as describing "for all," as "for each one of these," or clarifying "there exists" as "I can find at least one." Other student moments were characterized by an interchange or alteration of the meanings for these phrases. Even though the phrases "for all" and "there exists" were used in the statements, students' explanations sometimes included using universal quantifier language such as "every," and "all" for the variable attached to the existential quantifier. Likewise, during some moments, students used phrases such as "I can find an" or "there is a" for the variable attached to the universal quantifier. Such student utterances indicate that in these moments, students did not have distinguishable meanings for the singular universal and existential quantifiers.

Hannah was a Calculus student who did not distinguish between "for all" and "there exists" in some moments. Hannah stated that Statement 4 ($\exists c \forall N$) had the same meaning as another previous statement. She also claimed in this moment, "anywhere you choose c to be, there is a value of N that's a real number because the function is continuous." Hannah said we could choose c-values *anywhere*, which indicates that she was treating the existential quantifier as if it were a universal quantifier. She also said that we could find *a* value of N, even though the statement says that we need to find a c that works for *all* values of N. This dialogue indicates that in this moment she was also treating the universal quantifier as if it were an existential quantifier.

Distinguishing "For all… there exists…" and "There Exists… for all…" Statement 1 ($\forall c \exists N$) and Statement 3 ($\exists N \forall c$) both have "there exists" with N and "for all" with c, but the ordering of these quantifiers is different. Statement 2 ($\forall N \exists c$) and Statement 4 ($\exists c \forall N$) also reorder in a similar fashion. Some student moments included explanations of why each statement in these pairs had a distinct meaning. Other student moments were classified by student views that these pairs were equivalent in meaning. Our findings are similar to those of Dubinsky and Yiparaki (2000), who showed that students may view reordering quantifiers, with variables attached, as inconsequential. Mike, a Transition-to-Proof student, explained why he thought Statement 1 and Statement 3 are similar:

> [Statement 3] and [Statement 1] are saying the same thing and [Statement 2] and [Statement 4] are saying the same thing. These two (*Statements 1 and 3*) are saying that there is only one output for all the inputs. But [for] Statement 1 and 3, I could assume this… for all real numbers c in the interval (a, b) I could assume that's true.

Mike acknowledged that he believed Statement 1 and Statement 3 are equivalent in meaning and Statement 2 and Statement 4 are equivalent in meaning. His classification insinuates that he did not distinguish between these quantifier distinctions. We have further evidence of his lack of distinction because he stated that both Statements 1 and 3 are about *one output* and *all* c's. Mike recognized that these pieces of the quantification are the same. However, since he emphasized the singular quantifiers and concluded that the statements are equivalent, we claim that he did not distinguish the difference in the order of the quantifiers in the statements.

Variable Ordering and Dependence. We also found a difference in how students treated the ordering of the variables c and N in the statements. All but one student mentioned that the ordering of the variables was different in some of the statements. However, during some moments, students claimed that the reordering the variables had no effect on the statement meanings. Zack, a Calculus student, explained why he thought Statement 2 ($\forall N \exists c$) was different, but equivalent, to Statement 1 ($\forall c \exists N$) in this moment:

> Um, so I mean obviously this [*N*] is now flipped with *c*, at least in [Statement 2]. I don't know how this [switch] necessarily affects [the statement]. So, when I explained it on the last one, I thought that *N* was a dependent value depending on what *c* is… Such that *f*(*c*) is equal to *N*… I don't think that, I'm sorry. So it's like that… I'm interpreting [Statement 2] the same, that it's just saying that really for any real value of *N*'s there exists a value of *c*, but *c* is still the value. Like… this (*points to c in f(c) in statement*) is the independent value versus this (*points to an N in the statement*) is the dependent value.

We claim that Zack recognized the variable order in Statement 2 in this moment, but he did not treat the first variable, *N*, as being chosen independently of the *c*-values. Zack mentioned that *c* is an independent variable and *N* is a dependent variable in the function in both statements. Zack appeared to choose *c*-values first because he thought that independent variables should be chosen first. However, he did not seem to connect the variable order in the quantification to his own choice for which variable should be held independent of the other.

Many student moments were different than Zack's moment; in these moments, students noticed the order of the variables and also displayed an understanding of the ramifications of this variable switch in different statements. Jay, an Advanced Calculus student, explained why Statement 1 ($\forall c \exists N$) and Statement 3 ($\exists N \forall c$) are different:

> For this one [Statement 1] all of the... like the values for individual *c*'s can be different. So like given *c,* I give you an *N*, but that doesn't have to be the same *N* as some other *c*. But for here [Statement 3] that's not true. There exists a real... so I give you *N* before you give me *c,* meaning I know what the answer is before I even know what *c* is.

Jay was not only aware of the variable order in this moment, but why the variable ordering affects the statements' meanings. Jay contrasted the order in which the first person gave a *c* or *N* and the other person gave a variable in return. His contrast suggests that he understood that the first variable was to be thought of independently of the second variable. He also used the first variable's information to give information about the second variable, which indicates that he considered that the second variable is dependent on the first.

Explicit Quantifier Distinctions Across Mathematical Levels. The four different meanings in Table 2 were more prevalent amongst the more advanced students interviewed. The results of this comparison of percentages from each of the three groups are shown in Table 2:

Explicit Quantifier Meanings (by % of Relevant Moments[2])	Calculus	Transition-to-Proof	Advanced Calculus
Distinguished "for all" and "there exists"	4/17 (23.53%)	21/22 (95.45%)	17/17 (100%)
Distinguished "for all… there exists…" and "there exists… for all…"	0/8 (0%)	7/12 (58.33%)	6/6 (100%)
Recognized Variable Order	10/13 (76.92%)	4/4 (100%)	5/5 (100%)
First Variable Independent & Second Variable Dependent	4/19 (21.05%)	14/15 (93.75%)	11/11 (100%)

Table 2. Comparison of students' explicit quantifier meanings.

[2] We define a *relevant moment* as any moment where a student explained his meaning for the specified construct.

Table 2 summarizes that higher-level mathematics undergraduates exhibit more moments with distinctive meanings for explicit quantifiers. The Advanced Calculus students had a greater percentage of moments where they exhibited each of these four meanings than Calculus students. Calculus student moments not only showed students' confounded meanings of "for all… there exists…" and "there exists… for all…," but they also revealed Calculus students' tendencies to confound the singular quantifiers "for all" and "there exists" as well. While the Transition-to-Proof students had a higher percentage of moments than Calculus students for distinctions between "for all" and "there exists," there were still several moments where they confounded meanings of "for all… there exists…" and "there exists… for all…" Calculus student moments were most similar to their advanced peers in their comprehension of recognizing variable order, but the variable dependency moments revealed that this recognition was not associated with students' understanding for why variable ordering is important to statement meanings.

Students' Implicit Quantifications

Calculus students had fewer moments where they distinguished between different types of explicit quantifiers and their attached variables than their advanced peers. However, meanings for implicit quantifications varied amongst the groups. The phrase "Suppose f is a continuous function" elicited ambiguity in some student moments. All four statements in Table 1 are written with the intent that readers will apply each statement to *all* continuous functions. We found three ways that these students implicitly quantified f: universally, existentially, or case-by-case.

Universal Implicit Quantification. Some students did quantify the phrase "Suppose f is a continuous function" as intended. Students used words such as "arbitrary" or the phrase "*any* continuous function" to describe their meanings of the statements.

Case-by-case Implicit Quantification. Three students considered that some of the statements that we were giving them were not firmly true or false for some moments. They preferred to evaluate some statements as "sometimes true" or "sometimes false" instead of strictly true or false. Their reasoning for this choice was made apparent when we offered them graphs and they considered that the statement was true for some functions, and false for some functions. Zack claimed in one moment, "No, I still agree that this statement [Statement 1] would be sometimes true… because in my mind this graph (*points to what we would consider the counterexample graph*) proves it… proves that I can't say the statement is true one hundred percent of the time." These students are classified as "Case-by-Case" because they were considering the if-then statement as having a variable truth-value instead of being firmly true or false. Our evidence supports Durand-Guerrier's (2003) finding that students tend to think of a conditional as an open statement which may be true or false, depending on the case at hand.

Existential Implicit Quantification. Ron, a Transition-to-Proof student, interpreted the phrase "Suppose f is a continuous function" with an existential quantification. He described his lack of certainty about the intent of the statement, and described his conclusions in this moment:

> I am not sure if f is limited to there being an existence of a continuous function or it's "suppose that any function." So because the wording is ambiguous in my mind I am not sure. I am just gonna keep it true for now because I am going to assume that "Suppose f is a continuous function" is going to be equivalent to the wording being "Suppose that *there is an existence* of a continuous function f on the closed interval a to b."

Ron's implicit quantification of "Suppose f is a continuous function" affected the rest of his arguments because he believed he only needed one function to make each statement true. He also thought that proving each statement false required exhausting all functions.

Implicit Quantification Across Mathematical Levels. The summary of all the students' meanings in the moment for implicit quantifiers is shown in Table 3:

Implicit Quantifications (by % of Relevant Moments)	Calculus	Transition-to-Proof	Advanced Calculus
Universal	6/8 (75%)	4/8 (50%)	7/8 (87.5%)
Case-by-Case	2/8 (25%)	3/8 (37.5%)	1/8 (12.5%)
Existential	0/8 (0%)	1/8 (12.5%)	0/8 (0%)

Table 3. Comparison of students' quantifications for "Suppose *f* is a continuous function"

As shown in Table 3, the majority of moments when students were implicitly quantifying *f* were distinguished by universal quantification in all three groups of students. However, there were some student moments from all three mathematical levels that exhibited a case-by-case quantification of "Suppose *f* is a continuous function." Universal quantification was more frequent amongst Calculus and Advanced Calculus students than Transition-to-Proof students. This phenomenon is addressed in the discussion. Our only existential implicit quantification moments originated from one Transition-to-Proof student, Ron.

Discussion

This study indicates that students had several different meanings for explicit and implicit quantifiers when reading the IVT. Based on our findings, students need to distinguish the singular quantifiers "for all" and "there exists," and they need to distinguish "there exists… for all…" and "for all… there exists…" They also need to recognize when variables are ordered differently across a set of statements before they focus on how this reordering alters the meanings of the statements. These explicit quantifier meanings are foundational to understanding the explicit quantifiers in complex mathematical statements, and the Calculus students in this study had fewer moments with each of the explicit quantifications necessary for statement coherence than the Transition-to-Proof and Advanced Calculus students. Yet, we teach Calculus theorems with quantifiers that need these meanings for theorem comprehension.

Even though there were more moments where Transition-to-Proof and Advanced Calculus students exhibited distinct meanings for different types of explicit quantifiers, truth-values still varied from student to student. There were moments from students of all three levels who implicitly quantified "Suppose *f* is a continuous function" in different ways than the authors of the statements intended for the statements to be quantified. The quantitative data may seem to indicate that students decrease their abilities in a Transition-to-Proof course. This is not meant to indicate that Transition-to-Proof is harmful for students. This may mean that students are now exposed to new mathematical quantifications, but have yet to reflect on when and how to apply all of these types of quantification.

These results should be considered when making curriculum and instructional decisions for all mathematical courses, but particularly for Calculus and Transition-to-Proof courses. Further research needs to investigate how students come to learn appropriate meanings for both explicit and implicit quantifiers for many different theorems. Our study was limited to the IVT, but was also limited to nine students. Studies that involve a larger number of students in each academic level are suggested to more accurately measure the prevalence of each meaning amongst each group of students.

Beyond the Product Structure for Definite Integrals

Courtney Simmons
Oklahoma State University

Michael Oehrtman
Oklahoma State University

Over the past decade research has shown that a Riemann sum based interpretation of the definite integral supports a robust understanding of the underlying structure of the integrand/differential relationship and facilitates students' ability to make sense of contextual integral models. However, current studies center this understanding on the multiplicative structure $f(x) \cdot \Delta x$ which does not account for many practical uses of integration. In many situations, the Δx is most productively conceived as a component of another quantity which might then be incorporated in any of a variety of quantitative models, such as an inverse square law rather than a simple product. To fill this gap, this study utilized Dewey's theory of inquiry to identify three interpretations of the definite integral which proved productive for students when modeling definite integrals that extend beyond the traditionally studied product structure.

Key words: Definite Integral, Riemann Sum, Adding Up Pieces, Quantitative Reasoning, Physics and Engineering

Introduction and Literature Review

In 2001 Sherin lamented "it seems reasonable to suggest that, prior to physics instruction, students should learn to invent at least some simple types of mathematical models and to express the content of those models." This sentiment is indicative of the general shift in attitude towards the calculus curriculum in recent years proposed by education researchers; that calculus curriculum should focus on an introduction to the concepts of limit, differentiation, and integration in a way that supports students' acclimation of mathematical ideas into their applied STEM fields, simultaneously leveraging that contextualization to support students' interpretation, mathematization, and argumentation (Jones, 2013, 2014, 2015b; Meredith & Marrongelle, 2008; Oehrtman, 2009; Redish & Smith, 2008; Sealey, 2006, 2014; Sealey & Oehrtman, 2005; Thompson, 1994; Thompson & Silverman, 2008).

Although differentiation and limits are both important aspects of the calculus curriculum, special attention should be paid to the definite integral for both its utility within mathematics, as well as its application to modeling in real world contexts (Hibbeler, 2004; Sealey & Oehrtman, 2005; Thompson & Silverman, 2008). Sealey (2014) provided a framework for characterizing student understanding of Riemann sums and definite integrals, decomposing this understanding into five parts; orientation to the constituent quantities, a product layer in which one attends to the quantitative relationship between $f(x_i)$ and Δx, the summation of these products, a limiting process applied to this summation, and a function layer in which ongoing accumulation may be considered. Von Korff and Rebello (2012) further adapted this framework into a physics context promoting the concept of infinitesimal products. Jones (2013) applied Sherins' (2001) symbolic forms to students' interpretations of the definite integral, classifying their reasoning into categories such as area under a curve, function matching, and adding up pieces. Jones (2015) later refined his description of the adding up pieces symbolic form and described a multiplicatively-based summation (MBS) conception that was "highly productive" in engaging students in both the mathematical structure of the definite integral as well as in modeling for physics-based contexts. This Riemann sum interpretation of the definite integral $\int_a^b f(x)\,dx$ focuses on adding up many terms derived from a multiplicative relationship between a (possibly) varying integrand $f(x)$ and small or infinitesimal differential dx. The products in this conception must be abstracted from a parallel multiplicative relationship in what we call a “basic model” between a constant quantity F and a (possibly) larger value X, respectively. Such decompositions to the Riemann sum structure have been stressed by math, engineering, and physics education researchers as essential for STEM student success, including mathematics majors (Doughty, McLoughlin, & van Kampen, 2014; Jones, 2013, 2014; Meredith & Marrongelle, 2008; Redish & Smith, 2008; Sealey, 2014; Sherin, 2001).

Meredith and Marrongelle (2008) made the apt point that a product structure derived from a basic model $F \cdot X$ to generate terms of the form $f(x) \cdot \Delta x$ in a Riemann sum is only adequate for modeling accumulation of a quantity when the integrand is a rate of change or density, yet many contexts do not naturally decompose into this quantitative structure (pp. 575-576). Oehrtman (2015) showed that an MBS interpretation was insufficient for students constructing more complex definite integrals from basic models that are not a simple product. To clarify reasons for students’ success, Oehrtman also analyzed the symbolic forms students applied to the basic model, how they transferred that quantitative reasoning to terms of a Riemann sum or the differential form of a definite integral, and how those symbolic forms interacted with the students’ symbolic forms for the integrals. Thus, only investigating the MBS conception of the definite integral leaves a potentially significant gap in our understanding of the quantitative reasoning required for successful modeling with definite integrals and interpretations of differential forms apart from a generalized product of integrand and differential. Our study seeks to further explore the ways in which students conceptualize definite integrals that do not match the traditional $f(x) \cdot dx$ multiplicative structure and identify key aspects of their reasoning which lead to productive results. Specifically, we pose the research question:

> What interpretations of a definite integral and basic model are productive and unproductive for students as they progress through increasingly complex definite integral modeling tasks?

Theoretical Perspective & Methods

As this study seeks to identify how students engage in and overcome difficulties modeling definite integrals beyond the product structure they typically first learn, we chose to employ John Dewey’s theory of inquiry (Dewey, 1938; Hickman, 1990) to their problem-solving efforts. Dewey characterized knowledge as a product of the activities a student actively engages in when encountering non-routine problems. These activities involve strategically identifying mental tools with which to make sense of the problem, testing that tool in the context of the problem, and utilizing the tool to clarify the problematic situation in some way for the student. New knowledge emerges through the dialectic interplay between application of the tool against the problem and evaluation and refinement of the tool against the perceived progress. With this interpretation of learning in mind, we will classify an interpretation, i.e. tool, of the definite integral as productive if it is perceived by the student in advancing their progress towards resolving a problematic situation. We note that a productive interpretation need only clarify the situation for the student and does not have to be consistent with the researchers’ own views for resolving the problem.

Four pairs of students were selected to participate in an hour and a half long interview focusing on physics applications of the definite integral. The choice to work with pairs rather than individual interviews was made so students could discuss their ideas with each other, rather than an authority figure. The students were encouraged to discuss their thinking aloud while working through problems on a whiteboard until they were satisfied with their solution, after which the interviewers would ask follow-up questions to clarify any notes made during the encounter.

Because our study seeks to understand students' progress beyond an integrand×differential quantitative relationship, it was important to recruit students who were likely already familiar with the MBS conception described by Jones. As such, Group C consisted of a senior undergraduate and second-year masters student who had recently taken an Advanced Calculus course, while the remaining three groups, A, B, and D, were recruited from a second semester calculus course in which the instructor utilized a calculus curriculum emphasizing the Riemann sum approach for definite integrals in classroom labs (Oehrtman, 2016). After our initial round of interviews, Group B was asked back for a second one hour interview due to the strength of their collaboration and quality of data provided. These interviews were video-taped and later transcribed for coding.

Each group was first asked to discuss their general interpretation of a definite integral, followed by a series of tasks chosen to reveal their reasoning while modeling definite integrals as they progressed from simple rate×time contexts to situations that obscure the product structure of a differential form (Figure 1). The intent was to track the students' operative interpretations of the definite integral, the components that comprise the integral, the quantitative relationships involved in the basic physics formulas, and the students' perception of the interconnection between these concepts. We anticipated many students would approach some of the simpler problems heuristically, avoiding reasoning quantitatively, but that the progression of tasks would require an eventual shift to adding up pieces in progressively sophisticated ways in order to be successful.

1. When fully wound, a toy car will travel in a straight line for just over 17 seconds. Its speed t seconds after it is released is $v(t) = 3\sin\left(\frac{t^2}{100}\right) m/s$. Write an integral that gives the distance the fully wound car will travel during the first 10 seconds it travels.

2. Linear density is a measure of an objects mass per unit length. This means for example if an object has length 3.2 ft and **constant** linear density of $.5\ lb/ft$ it will have a total mass of $(3.2)(.5) = 1.6$ lbs.

   King Arthur's lance is 10 feet long and heavier at one end, decreasing from 1.2 lb/ft at the base to 0.2 lb/ft at the tip. That is, the linear density x feet from the base is $\delta(x) = 1.2 - 0.1x$. Write an integral that gives the mass of King Arthur's lance.

3. When pollen from a red cedar tree is released from their cones it travels through the air. Pollen from a mature tree settles on the ground with an estimated density of $\delta(r) = \frac{37}{10+r}\ g/m^2$ a distance r meters from the tree.

   Write an integral that gives the mass of pollen distributed within 100 meters of a mature tree.

4. Coulomb's law says that the force between two electrically charged particles is $F = k_e\frac{q_1q_2}{r^2}$, where k_e is Coulomb's constant ($k_2 = 8.99 \times 10^{21} N \cdot m^2/(\mu C)^2$), q_1 and q_2 are the charges of the particles in microcoulombs (μC), and r is the distance between the charges. Coulomb's law only directly applies to two point charges.

   Write an integral that gives the electrostatic force between a uniformly distributed charge of 29 microcoulombs on a rod of length 7 meters and a particle with charge of 2 microcoulombs 3 meters from the rod along its axis.

5. The energy measured in joules to lift an object straight up h meters is $E = M \cdot g \cdot h$, where M is the mass of the object measured in kg, and g is the gravitational force measured in m/s^2.

   Suppose a 10-meter chain with a total uniform mass of $15kg$ is freely hanging from the roof of a building. Write an integral that represents the total energy required to lift the chain to the top of the building.

Figure 1. Task Sequence.

Group A was only able to progress through task 2, while the remaining three groups were able to advance to the fourth task with varying levels of success. Task 5 was chosen as a supplemental question for Group B to work through during their second interview session and was not presented to any other group.

The video transcriptions were coded using open and axial coding methods of grounded theory (Strauss & Corbin, 1998). Because we were interpreting this data through the lens of Dewey's theory of inquiry, the initial coding pass sought to identify problematic situations for students, in the sense of non-routine engagement and reciprocal influences of their evolving conceptions for definite integrals and basic models with their understanding of the modeling tasks. After these instances were identified, each was broadly coded for all cognitive tools utilized, obvious relationships to previous research, and any specific tools which lead to productive results. Subsequent classifications looked to identify associations between these codes both throughout a specific interview, as well common themes amongst the different groups to develop a narrative regarding students' conceptualizations of these definite integrals. Common problematic situations and tools which led to productive results were identified and the information was synthesized into 3 defining characteristics of productive modeling of the definite integral, Adding up Pieces, Quantitative Reasoning, and Utilization of "nearly constant," which will be discussed in the following section.

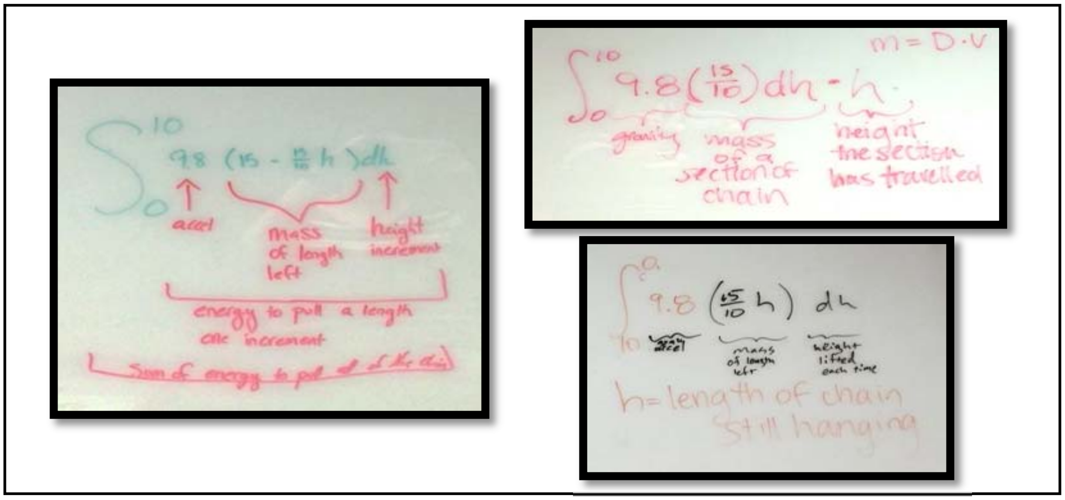
Results

Adding up Pieces

Echoing previous research, our findings suggest that conceptualizing a definite integral as a summation allows for students to model physics equations in a way consistent with both mathematical and physics/engineering constructs. However, our interpretation of adding up pieces differs slightly from that of previous research as we allow for integration of quantitative relationships more complex than the traditional $f(x) \cdot \mathrm{d}x$ structure. Due to the nature in which we recruited our subjects, all pairs demonstrated at least some underlying Riemann sum structure for the definite integral. Group A showed the weakest correlation between Riemann sums and definite integrals, often relying on area under the curve symbolic forms or graphical interpretations, although when pressed they could describe these interpretations in the context of representative rectangles (Jones, 2013, 2015a). This weak connection to adding up pieces played a role in Group A only completing two of the tasks, and only the first completely correctly.

Quantitative Reasoning

Aside from the adding up pieces conceptualization, quantitative reasoning is perhaps the most crucial aspect of modeling definite integrals (Thompson, 1994, 2011; Thompson & Silverman, 2008). Within the construct of a definite integral which is comprised of a non-routine quantity, there are multiple layers of quantitative reasoning a student must navigate. First, the student must attend to the quantitative relationship of the definite integral itself. Within that structure the student must also attend to the relationship between the integrand and differential. Certain contexts lend themselves to obvious relationships, such as Tasks 1 and 2, however, the more complicated structures have yet another quantitative relationship layer; how the differential is situated within a quantitative formula. In Task 3 this extra consideration did not prove overly difficult for most groups, however, in Task 4 it caused numerous problematic encounters for the students and required significant effort to resolve. We note that there are often multiple ways to reason about the basic model within a definite integral quantitatively. Figure 2 displays three



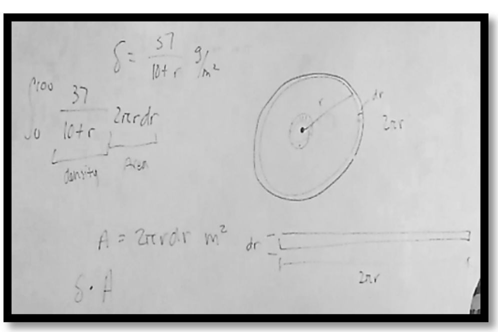
different ways in which group B conceptualized Task 5 during their second interview; the top two were simultaneously modeled by each student individually while discussing the problem relatively fluently with one another. In light of this encounter, we conjecture that students need not conceptualize the quantitative relationship within a basic model in a specific way to be productive in modeling a definite integral. Rather the importance lies in attending to the quantities that comprise a given formula and identifying their relationship to each other in a meaningful way, while simultaneously considering any underlying implications of the basic model, such as the multiplicative structure distance = speed × time is only valid when speed is constant.

Utilization of "Nearly Constant"

In each of the problems presented there is an underlying basic model which holds for

Figure 2. Three quantitative relationships demonstrated by group B in Task 5.

constant values. Every group used these formulas as a part of their final integral structures,



B: So, because the density of pollen is not uniformly distributed you have to find, you have to find what the density is pollen is at every different r. And it's really, it's similar where two r's are really similar. So your dr is your change in that r, and within this range the density is gonna be really similar but if you just say multi, put that plugged in to 100 you'd be assuming uniform density over the whole circle which would be incorrect.

A: Yeah.

I: Alright so earlier you said the $2\pi r$ is the circumference. So why circumference? It has area underneath it, so why circumference?

B: Uh, so you have the circumference because that's the distance around the circle, which when you cut the circle and spread it out and make it into a rectangle that would be the length of the rectangle. But in order to get an area you have to multiply a rectangle length times its width. And your width would be your dr which is your change in r which is a very small number where the density is nearly uniform.

Figure 3. Group C discusses "nearly uniform" density in Task 3.

asserting that the reason you must integrate is that at least one of the quantities in question is varying. Every pair articulated some form of justification for why they use the formula for a "nearly constant" segment, as shown in Figure 3.

For many pairs, inserting the given formula into the integral during the first few tasks was a routine procedure that only became problematic and subsequently justified when questioned by the interviewers. This was especially evident in Task 1, where every group made reference to the relationship that velocity is the derivative of position. However, when pressed, most groups were able to identify that over a small duration of time, speed was basically constant, which allowed for a confident explanation of the role of the differential within the integral. This justification of process, which was evident in early tasks, was not as prevalent in the data for Task 4. Instead there was a shift of focus to "what's changing," which led to many unproductive encounters and in one case led to dividing by the differential (Figure 4).

Group B demonstrated a strong adding up pieces conception and quantitative reasoning skills in all previous tasks, and were fluidly speaking about breaking up the rod in Task 4 into segments and adding forces together to obtain a total force. So in all other aspects they were conceptualizing this definite integral in ways compatible with current research. However, the desire to find the moving part of the equation permeated their reasoning, hindering advancement. Although very problematic for the students, the resolution of this interpretation was only possible through an interviewer's intervention. It is possible that an extra layer of abstraction provided additional difficulties for this pair, as their initial problem contained no specific quantities. Numerical quantities were provided halfway through their encounter with this problem and the task was updated to reflect specific values for future interviews.

J: And then we have 1 over s^2, that's what is changing, s^2?

M: Yeah.

J: So we need to change that to $(s + dl)^2$.

M: Yes, cause s is the distance and the formula just has distance squared. I think that's it, but... that doesn't look like an integral to me.

J: Yeah, dl's down there and it's squared. That's not normal.

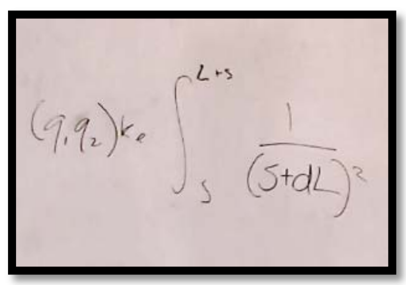


Figure 4. Group B dividing by the differential in Task 4.

Familiarity of context

Although not characterized as productive, and perhaps unsurprising, the unfamiliar context and quantities of electrostatic force proved problematic for the students in this study. Every group that attempted this task required at least some clarification of Coulomb's law. The more troublesome complication arose when the groups tried to conceptualize the adding up process that would need to take place if they were to integrate. Unfamiliar with the principle of superposition, two of the groups envisioned the integral needing to account for forces compounding upon one another as the integrand ranged over its domain. An example of this is shown in Figure 5.

Because students' lack of familiarity with superposition of forces was not intended to introduce complications, one of the interviewers stepped in to provide the supplementary explanation. This finding echoes Meredith and Marrongelle's 2008 assertion that "understanding of the physical situation is necessary, but not sufficient for students to use their mathematical resources".

J: From what I can understand, the function that they gave us, f, like this is just one member that we would get. This is the force between these two parts [points towards a diagram explaining Coulombs Law]. Over here we have a force between these two parts, and then a force between these two parts, and a force between these two parts, and we're adding all of those forces together.

M: Uhhh...

J: It's kind of like the other ones we were doing, it's like, the thing that's changing is the forces and that's what we're adding together.

M: Yeah...[laughs] but... I don't know. It doesn't make sense to me that it doesn't like compound, you know?

J: Compound?

M: Well cause wouldn't the charge of this be like, like right here have that plus all of this [points to the far end and then motions across the full length of the rod]. Wouldn't that have...

J: Ohhhh

M: That's why I was saying if it was moving it would be easier. Because then you're looking at this and then nothing but space. But you're looking at this [points to the third subsection] and then like that little part [motions to the two subsections preceding the third subsection].

J: I get what you're saying. So is it like a double integral?

M: [whispers] I don't know.

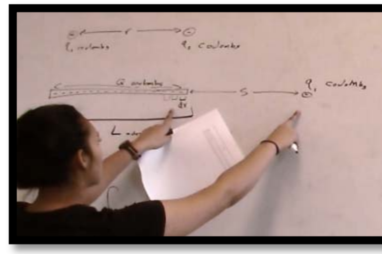

Figure 5. Group B discussing compounding force.

Discussion

The results of this study illustrate three key interpretations of the definite integral, adding up pieces, quantitative reasoning, and attention to the quantity which is nearly constant, which we have identified as crucial for successful modeling of not only multiplicative basic models but also more general basic models found in many physics and engineering contexts. While discussed separately, these different themes are often interrelated and require the student to coordinate subtle interplay between them. For example, the decision to break a situation into multiple pieces to create a Riemann sum interacts with their conception of variable and constant quantities in the basic model and with their conceptions of the definite integral. As in previous research, we found the adding up pieces conception of the definite integral highly productive for students, however, when paired with the more complex basic model there are additional layers of this construct for the student to work though. It may be clear that the integral will add up small chunks of the basic model to obtain the desired total, while the quantitative reasoning behind breaking up the physical (or abstract) situation to obtain these small chunks can remain problematic for students. To overcome this difficulty, students must be able to attend to how the concept of a small chuck being "nearly constant" allows for the use of integration of the basic model, which can support their decision of how and why they are breaking up the situation into smaller constructs.

Based on the data collected in this paper, and the call for modeling of definite integrals in the other STEM fields, it is our contention that Jones' (2015a) MBS conception of the definite integral can be productively extended to a Quantitatively Based Summation conception (QBS) for the definite integral, of which the MBS conception would be an often utilized subset. Similar to the MBS conception, this interpretation of the definite integral in a QBS is incorporated into a Riemann sum approach to the definite integral, but requires focus on the rich quantitative reasoning about the basic model and transferred in flexible ways to the differential form for the definite integral.

Exploring Undergraduates' Experience of the Transition to Proof

John P. Smith III
Michigan State University

Mariana Levin

V. Rani Satyam
Michigan State University

Younggon Bae
Michigan State University

We report a qualitative analysis of 14 undergraduate students' experience in a semester long introduction to proof course. Half were mathematics majors. Our research aims to characterize, conceptually and empirically, students' transition from a focus on computation to proof in mathematics. Our analysis focused on how students saw the course as different from prior courses, how they described their work in it, and whether being successful in the course required new or different learning activity of them. This approach—targeting students' overall experience of the course—differs from prior research that has tracked students' challenges, focused on their work on specific proof problems, and explored how to support and improve their work (e.g., Selden & Selden, 2003). Our work has promise for informing the design of transition to proof courses and how those courses are organized and taught.

Key words: transition to proof, proof reasoning, students' experience, qualitative analysis

The Transition to Proof and Proving

Many undergraduates experience difficulty in learning to prove mathematical propositions, including those who major in mathematics (Baker & Campbell, 2004; Moore, 1994; Selden, 2012). For many, experience with proof prior to college is quite limited (Anderson, 1994; Jones, 2000). Students' prior competence (and interest) in mathematics is typically centered on producing accurate answers to easily recognized tasks—"exercises" in Schoenfeld's terms (1992). That work involves recognizing specific types of such "problems" quickly and applying well-practiced procedures to solve them. These abilities do not support, and may interfere with students' work to conceptualize, write, or evaluate proofs. In addition to differences in the didactical contract between computation-heavy courses like calculus and proof-intensive courses, Selden (2012) reports that students encounter many difficulties, including mastering logic and definition, generating and using examples and counterexamples, understanding concepts and theorems, and evaluating the arguments of others. In short, the transition to proof is complex and challenging, and much of students' prior ability appears inadequate, if not problematic for addressing these challenges.

Many mathematics departments have recognized this problem and experimented with different curricular and instructional approaches to support students' entry into proof, including dedicated "transition to proof" courses. These typically focus on precision of language and notation, reasoning, and proof and sample accessible statements from numerous content domains to prove or disprove. But designing these courses is not a trivial task, and they have often shown limited positive effects (Selden & Selden, 2003; 2014). A crucial limitation effecting course design is that research has not systematically focused on the experience of students. Instead, course design and instructional decisions have often been shaped by assumptions about students, the kinds of challenges they face, and structures that support their learning. To begin to address this limitation, we explored how students describe their experiences in one such “transition to proof” course.

Conceptual Framework

To explore students’ experience of the shift in mathematics work from producing answers to composing proofs, we drew on prior work in conceptualizing “experience” and “transition.” Smith and Star (2007) proposed that precollege students’ mathematical experience could be composed into four dimensions: Achievement, disposition, differences between prior and current mathematics work, and learning activity. Assessing change on these dimensions in turn supported grounded judgments of the significance/depth of students’ transitions. The present study built on this work in its focus on the following dimensions of students’ experience of the introduction to proof course: (1) The nature of the course and how it differed from prior courses, (2) the reasoning involved in proving, and (4) the learning activities that support success. The first and third dimensions correspond closely to Smith and Star’s (2007) dimensions of differences and learning activity. It also drew on that study’s use of student-constructed graphs to assess changes in students’ confidence.

In analyzing the data we collected, we also found the constructivist focus on how prior resources are recruited to cope with new challenges productive, whether those resources prove effective or not (e.g., Smith, diSessa, & Roschelle, 1994). This perspective provided a frame for understanding how components of students’ experience and skill developed in more computationally-oriented mathematics work may be applied and reworked or adapted in the efforts to succeed in the quite different mathematical work of proof and proving.

The Course & The Participants

The 14 participants in the study were all graduates of a multi-section semester course designed to introduce them—both mathematics majors and not—to proof and proving. The mathematics department hoped that the course would support the success of both groups of students in upper-division courses that emphasize proof. The course introduces appropriate syntax and notation, basic concepts, and proof techniques before proof of “entry-level” statements from various content domains (e.g., linear algebra, real analysis, and number theory). The course pedagogy is not lecture-based. Instead instructors give short presentations and present proofs (or parts of proofs) before students spend substantial time working on proof tasks themselves, often in small groups. The course also includes elements of “flipped classrooms;” students read and answer basic comprehension questions prior to working on problems in class that draw on that content. Evaluation was primarily based on homework and exam grades ($n = 3$ before the final). Students were required to use LaTeX to post their solutions to homework tasks, but their solutions on all exams were hand-written.

We interviewed students in the summer after they completed the course. We invited all 110 enrolled students from the prior semester to participate; 17 (~15%) responded positively, and 14 (~13%) completed an hour-long interview about their experience, which were audiotaped for analysis. Nine students were male and five were female; three were international students. The sample was diverse by major. Six were mathematics majors; two others were majoring in actuarial science. In addition, we interviewed mechanical engineering, chemistry, packaging, biology, and economics majors. Two of those were pursuing dual majors. Most of the other "non-math" majors were pursuing minors in mathematics where the course was a requirement. Table 1 provides an overview of the sample, including their final grades.

Table 1. *Overview of Participants*

Student	Gender	Home	Major(s)	Standing[a]	Minor[b]	Grade
1	F	US	Mathematics	1		3.0
2	M	US	Actuarial Science	2		3.5
3	M	US	Mechanical Engineering	4	Math	4.0
4	M	US	Chemistry	3	Math	3.0
5	M	US	Actuarial Science	1	Math	4.0
6	M	Intl	Mechanical Engineering	3	Math	4.0
7	M	Intl	Computational Mathematics	3		4.0
8	F	US	Mathematics	1		3.0
9	F	US	Packaging	2	Math	2.5
10	F	US	Mathematics	2	Act Sci	3.0
11	M	US	Human Biology	3	Math	3.5
12	M	Intl	Mathematics	3		4.0
13	F	US	Economics & Statistics	2		4.0
14	M	US	Economics & Mathematics	2		4.0

[a]"Standing" reflects the amount of university coursework; in some cases, standing exceeds the number of years at the university. [b]S5 and S9 were strongly considering a mathematics minor but had not decided.

We focused our interview questions on understanding students' experience of the course in their terms, relative to their prior work in high school and college mathematics. We first secured basic information about them (e.g., major, standing, section/instructor, minor, and prior and intended math courses). Then we asked about their sense of the nature of the course (in contrast to their prior courses), their sense of success (or not) in it, what they did to be/become successful, and specifically how their view of and work on proof tasks may have changed in the course. As complement to seeking their verbal responses, we also asked them to graph their confidence in the course across the semester. These Confidence Graphs (Figure 1) often surfaced new information about our focal issues, as students explained the shape and location of their graphs.

We also asked about their sense of their instructor's view of the course, whether the course experience influenced their understanding of calculus, and whether they expected to be successful in any subsequent math courses. Finally, we asked what they would tell incoming students about the course. We also regularly observed (about twice per week) the classroom teaching and interactions in one section of the course for most of the semester—the section taught by the course coordinator. Observers took field notes in an observation template. These observations proved essential in preparing for the interviews, interpreting and responding to student responses, and in the analysis of the resulting data.

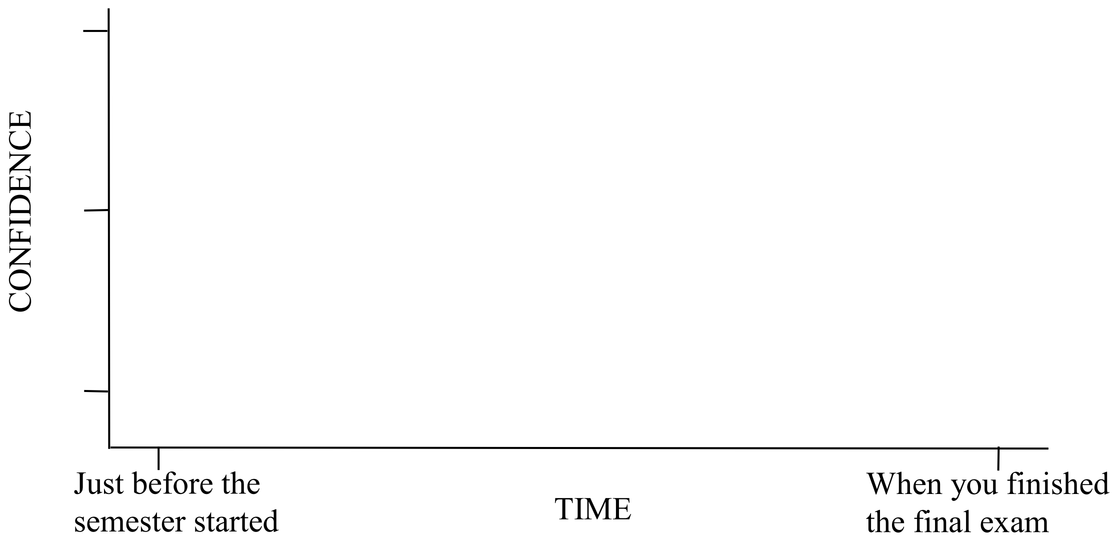

Figure 1. Confidence Graph (reduced in size). Each participant drew a graph of confidence over the course of the semester. The X-axis represents time, from just before the course began through the final exam. The Y-axis represents their confidence in doing well in the course.

Analysis of the Interviews

Our analysis was qualitative, “bottom-up” (though guided by our foci), and cyclical in nature. The results of initial analyses led to more detailed and focused rounds of analysis around specific issues. First, immediately after each interview, interviewers posted detailed summary descriptions of their interviewee’s responses. All members of the research team then read carefully and discussed the similarities and differences evident in those summaries. Next, the audio records were transcribed verbatim, and particular passages were examined to check our summary descriptions and provide exact wordings. We analyzed the Confidence Graphs for their general graphical properties (e.g., initial sense of confidence and where slopes of the graphs were greatest, positively and negatively) and particularly for points in the semester when students’ confidence dropped. Many students described the reasons for these drops and actions they took in response. In response to our questions about activities in their classrooms, students described some differences in instructors’ teaching methods. But because we observed in only one section, we could not assess the accuracy of their claims or the magnitude of instructional differences across sections. This is an important issue that we have to address in our on-going work.

Results

We report results in four main components. First, we present our summary of how the students described the course in comparison to prior mathematics courses. Second, we discuss one aspect of that comparison—how students used the terms “problem” and “answer” in describing their course work. Third, we characterize how students described their reasoning in solving proof tasks. Finally, we describe how the students viewed and evaluated their success in the course and the learning activities that they engaged in.

The Different Nature of the Course

Students were quite articulate about how the course differed from their prior mathematics course experiences, but their focus and emphasis varied. We found three main characterizations of difference: (1) Work in the transition to proof course explained why mathematics worked the way it did, where prior work had focused mainly on producing answers, (2) the course valued process over answers, and (3) the course changed students' conceptions about proof and writing in mathematics. Very few students reported substantial prior experience with proof, in either high school or college. Those who cited two-column proof in high school geometry were largely dismissive of that work as irrelevant.

Most frequently, the students stated that the course *explained* mathematics, "why things are the way they are," much more than prior courses. More than half of the students said it explained "the rules" or "where things come from." S14 and S6 cited derivatives and operations with matrices, respectively, as examples of learning why procedures from prior courses actually worked. This result indicates that the course served an explanatory purpose for students, providing conceptual understanding over and above their learning about language, notation, and proof techniques. This is a central function of proof in mathematics (e.g., Thurston, 1994), but it was pleasing to hear students articulate it.

Second, students contrasted the computational, answer-focused nature of their work in prior courses (e.g., calculus) to the process- or argument-focused work in the transition to proof course. As we note below, numerous students described the course in terms of what it was not: Writing proofs was not straightforward or step-by-step (S2, S11) and did not involve applying formulas or solving equations (S6, S12, S14). About a quarter of the sample stated that the course valued the process of reasoning more than the result.

Third, about half of the students talked explicitly about the new focus on proof and the dramatically increased focus on writing. They commented on changes in how they perceived mathematical writing and noted how much more writing was required in the course. Some realized that proofs can include words, not just symbols (S12, S13); others came to new understandings about the importance of accurate grammar in writing compelling proofs (S2, S3). They saw that mathematical terms have much more specific meanings than do words in everyday language and communication and that that specificity was important.

New Meanings for "Problem" and "Answer"

In characterizing their work in the course, students often used terms that typically describe work in more computationally-oriented courses, particularly "problem" and "answer." Most participants used the term "problem" to describe the proof tasks they were assigned, in class and for homework. More standard mathematical terms (i.e., "statement" and "proposition") were rarely used; only one subject did so consistently. In part, this use of "problem" reflected the language of the classroom; the course assigned "homework problems," and the instructor we observed also used this term to refer to the proof tasks he presented. But it also represents a strong connection with students' prior work in mathematics. We found a similar pattern for "answer." There was no consistent pattern in how students described the form of successful solutions to proof tasks. References to "proofs" were relatively common, but so were references to "answers." S1 spontaneously used that term to describe her solution to "problems," but then sounded embarrassed when the interviewer asked her how "answers" fit with proof problems. S10 indicated that an important difference in the course was that problems now often led to "a whole set of answers, not just one." We interpret students' use of these terms as indicating that their meanings for task and solution were in the process of change yet still retained some connection to the computationally-focused past.

Reasoning in Proof

A central objective of our work has been to characterize how students saw and carried out the reasoning required to produce acceptable proofs. By reasoning, we include: (1) Their thinking and notating prior to writing any well-formed statements, (2) their proof composing on paper, and (3) their final expression of their proofs in LaTeX. Though students saw and described their work in the course as different from their prior experience, many struggled to describe their reasoning on proof tasks and how it was different from prior work of applying procedures and computing answers.

Students' responses to questions about the nature of their proof reasoning fell into four main patterns. One set of student responses focused on what their reasoning was <u>not</u> like—that is, that the prior pattern of first recognizing the task, applying the appropriate procedure or approach, and then completing it step by step did not work. Most (S3, S6, S8, S11) recognized that they could not use their instructors' proofs as model solutions for other problems and that no general procedures for "solving" a wide variety of proof tasks existed. But one student (S7) did report that he tried to adapt his instructor's proofs to new problems, and another (S13) inspected model solutions to make sure that her proofs included relevant features and details she saw in them. A second set of students emphasized the first phase of "reasoning" above—that they could not begin their proof without first understanding the concepts involved and how they were related. One student (S12) emphasized the importance of conceptual understanding in terms of knowing how to use concepts in proof writing beyond just memorizing definitions of those concepts. A third set offered some characterization of reasoning common to proof tasks, but their descriptions were difficult to follow. For example, S11 described the work of proving as looking forward across a large number of steps (not just one) to assess if the approach looks as if it would work. S10 characterized that proof writing involved "working backwards," from the consequent back to the premises. A smaller fourth set described their reasoning in more standard terms as the search for a proof technique (e.g., proof by contradiction, induction, or contrapositive) that would "work" on the task at hand.

For the final step in their proof reasoning, most students spoke about the mandated use of LaTeX on assigned homework, either positively or negatively. Those who were more positive indicated that LaTeX forced them to be more careful and explicit with the mathematical language in their proofs. They seemed to accept the positive effect of that coercion. Those who were more negative cited the additional time required to submit via LaTeX or questioned the importance of or the need to improve the "neatness" of their work.

Specific Challenges, Sense of Success and Learning Activities

When we asked about students' sense of success in the course, most responded in terms of their final grade. Less frequently, they assessed their satisfaction with understanding the content or their sense of having mastered that content. For example, S7 stated that he felt he mastered "90% of the course content." As Table 1 indicates, half of the students received final grades of 4.0, and only one student received a 2.5. S1 reported that her 3.0 grade missed being a 3.5 by a single point. So overall, despite the new demands of the course, most of the students were successful by the traditional measure of final grades.

Most students described the work required to be successful in the course as more demanding than prior courses. Some were primed for challenge by characterizations offered by friends who had already taken it. Once in the course, they found that the homework carried substantial value in the grading scheme and that completing it took more than it did in prior courses—often much more time. Most students offered estimates of 7 to 10 hours for each weekly homework set, compared to 1 to 2 hours in prior courses. For students who composed their proofs completely on paper, translation into LaTeX added significantly to the time required.

All but two students explained that they employed different practices in completing their homework than they had in prior courses. In response to the demands of frequent and challenging homework, most indicated that they responded by starting earlier in the week and/or distributing the work across days. Four communicated with peers via e-mail, worked with a classmate, or asked questions in class for the first time in mathematics. Twelve described the importance of using the university's math learning centers—many for the first time—in interesting and diverse ways. Some cited the availability of tutors to answer their questions; others simply sought a physical space to go and work alone; others emphasized collaborative work with other students in the space designated for this course. For some (e.g., S10), productive discussion and community building happened with students from other sections of the course. That said, the use of social and peer resources was not universal; some students (e.g., S5) simply worked on their own, even as they worked harder and longer.

Conclusions, Limitations, & Next Steps

Our research is on-going, and subsequent steps will help refine our characterization of students' experience of the course. But this first round of research has been revealing, in expected and unexpected ways. First, we have found that successful graduates of the course are developmentally "in motion" between the prior focus on computation and the new focus on proof. Second, how they describe their learning in the course is also significant. Some offered relatively argument-focused descriptions that cited language, notation, and proof techniques, but others described their focus on learning why the mathematics they had learned before worked the way it did. These students described how proving made them focus on concepts and relationships and thereby explained mathematics in much more precise ways than before.

This study complements prior work that has focused on students' reasoning on specific problem-based tasks—typically proof construction and evaluation. In targeting students' experience, we have focused on broader and more general themes, especially what is different in elementary proof work and how students reorganize their learning to meet the challenge. These issues are important foci for all efforts to assist students in understanding the new challenges and supporting their own in addressing them.

Our next steps are two-fold. First, we plan to recruit and interview students who are currently taking the course in the early weeks of the semester to refine our view of the difference and challenge in the course and reach some students who are or will soon struggle. Second, we intend to interview course graduates who are enrolled in their first semester of proof-intensive coursework to learn whether and how their experience in the transition to proof course is supporting their work and success in those courses (or not).

Researchers have demonstrated the importance of covariational reasoning for students' development of various mathematical ideas. Several researchers have also argued that creating and sustaining multiplicative objects is a necessary mental action to reason covariationally. In this report, we describe task-design principles we have found to be productive for investigating and supporting students' construction of multiplicative objects and their covariational reasoning. Drawing on our research investigating students' covariational reasoning, we include data that highlights how these principles have been productive in our research and teaching.

Key words: Task Design, Covariational Reasoning, Multiplicative Objects

Researchers have identified that quantitative and covariational reasoning are important to the development of mathematical ideas such as rate of change and function (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Confrey & Smith, 1995; P. W. Thompson, 1994), with students' abilities to develop images of quantities' magnitudes being critical to their reasoning covariationally (Carlson et al., 2002; Saldanha & Thompson, 1998). Specifically, these images afford students opportunities to construct multiplicative objects; this notion of covariation involves an individual sustaining an image of two quantities' magnitudes such that the two quantities are coupled so that she "tracks either quantity's value with the immediate, explicit, and persistent realization that, at every moment, the other quantity also has a value" (Saldanha & Thompson, 1998, p. 299). Researchers examining students' covariational reasoning have designed tasks to provide students opportunities to reason covariationally—*City Travels* (Saldanha & Thompson, 1998), *Power Tower* (Moore, Silverman, Paoletti, & LaForest, 2014), *Over and Back* (A. G. Thompson & Thompson, 1996; P. W. Thompson, 1994), and adaptations of the *Bottle Problem* (Carlson et al., 2002; Johnson, 2015; Zeytun, Cetinkaya, & Erbas, 2010). From our ongoing work in developing models of students' thinking and our interpretations of these researchers' works, we describe task-design principles that we have found productive in investigating and supporting students' construction of multiplicative objects and their covariational reasoning in small group and whole-class research and teaching settings. Our task-design principles are (a) avoid using quantities that are time or monotonic in the situation, (b) use shapes strategically to match or not match the graphical shape, (c) use different representational systems or orientations, and (d) use varying segment magnitudes to represent a quantity's magnitude in a situation.

Background

In this paper, we draw on P. W. Thompson's (2011) and Thompson, Hatfield, Yoon, Joshua, and Byerley's (2016) extension of the definition of covariational reasoning offered by Saldanha and Thompson (1998). We note that covariation is not an inherent feature of a situation, graph, table, etc.; a student must conceive of a situation, graph, table, etc. as constituted by covarying quantities (P. W. Thompson, 2011). Thompson (2011) characterized covariational reasoning in terms of an individual conceiving two quantities' magnitudes (or values), x and y, each varying (by intervals of size ε) over conceptual time, t. He used ordered pair notation, $(x(t_\varepsilon), y(t_\varepsilon))$, to denote the cognitive uniting of these two magnitudes, the result of which is a multiplicative object. Thompson's use of multiplicative object stems from Piaget's notion of "and" as a multiplicative operator (Inhelder & Piaget, 1958). The creation of such a multiplicative object is essential for conceiving displayed graphs as constituted by covarying quantities, and Thompson et al. (2016) explained that an individual's conception of a multiplicative object is not restricted to or contained in a displayed graph. Instead, a graph is one way to represent a constructed multiplicative object. Thus, as we present our task-design principles, we focus on students' construction of multiplicative objects primarily, but not exclusively, in the context of graphing.

With regard to previous recommendations on task-design principles, our tasks follow Gravemeijer and Doorman's (1999) recommendation that tasks be experientially real—tasks involve a situation that students can imagine and understand in order to support conceptions of varying quantities. Additionally, our tasks include simplified versions of common situations, often in the form of dynamic videos or applets (Johnson, 2013, 2015; Saldanha & Thompson, 1998; P. W. Thompson, 1994). Both aforementioned principles are mentioned in Carlson, Larsen, and Lesh's (2003) list of principles they used to structure covariational reasoning within a model-eliciting task. Lastly, although Johnson (2015) recommended sequencing tasks that support students in progressing from numerical to non-numerical reasoning, we avoid providing numbers in our tasks because quantitative reasoning is fundamentally non-numeric in nature (Smith III & Thompson, 2008). Moreover, we do not explicitly include non-numeracy in our task design principles because quantitative reasoning is principally non-numeric.

Task Background

Because of space limitations, we illustrate the task-design principles using two tasks: *Going Around Gainesville* (*GAG*) and *Which One? (WO?)*. *GAG* is a modification of Saldanha and Thompson's (1998) *City Travels* task. A student watches an animation of a car traveling around Gainesville on the way from Atlanta to Tampa (Figure 1). After we ask the student to describe the situation, we ask her to create a graph relating the car's total distance traveled and distance from Gainesville during the trip (Part I). After the student addresses Part I, in which she chooses her axes orientation, we request a graph relating the car's distance from Gainesville and distance from Atlanta on a given set of axes (Part II) (see Figure 1 for a normative solution to Part II).

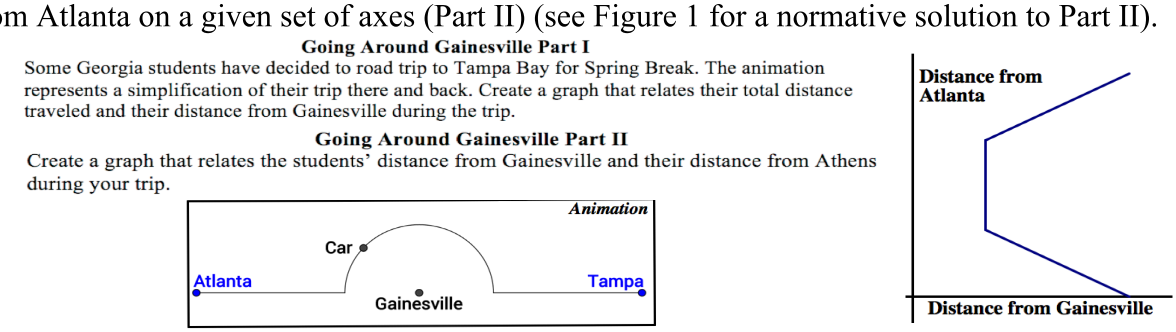

Figure 1: The *Going Around Gainesville* task and animation.

The *WO?* task (Figure 2) is an adaption of the *Ferris Wheel* task (Moore & Carlson, 2012). In this task, we present a student with an animation of a Ferris wheel rotating counterclockwise at a constant speed with a rider starting at the three o'clock position (see screenshot of animation in Figure 2a). We ask the student to describe the relationship between the height above the horizontal diameter of the wheel and the arc length the rider has traversed. We then present the student with a simplified version of the Ferris wheel situation with the position of a single rider indicated by a dynamic point on a circle. Beside the situation, there are seven directed horizontal line segments. We inform the student that the topmost line segment (shown in blue) represents the arc length the rider has traveled counterclockwise from the initial three o'clock position. Students can change the length of this topmost segment by dragging point B or by clicking the 'Vary' button. As the position of the point on the circle (i.e., the rider) moves, the length of the topmost segment varies appropriately. We then ask the student to determine which of the six red segments (labeled in Figure 2b for the reader), if any, accurately represent the rider's height above the horizontal diameter of the Ferris wheel as the rider's arc length traveled varies. The design of these six segments is in Table 1; segment 1 is a normative solution to the task.

Table 1
Behavior of red magnitudes with respect to B, the arc length traveled; all values relative to radius.

Seg.	$0 \le B \le \pi/2$	$\pi/2 \le B \le \pi$	$\pi \le B \le (3\pi)/2$	$(3\pi)/2 \le B \le 2\pi$
1	Increasing from 0 to 1 at a decreasing rate	Decreasing from 1 to 0 at a decreasing rate	Decreasing from 0 to –1 at an increasing rate	Increasing from –1 to 0 at an increasing rate
2	Increasing from 0 to 1 at a decreasing rate	Decreasing from 1 to 0 at a decreasing rate	Increasing from 0 to 1 at a decreasing rate	Decreasing from 1 to 0 at a decreasing rate
3	Decreasing from 1 to 0 at a decreasing rate	Decreasing from 0 to –1 at an increasing rate	Increasing from –1 to 0 at an increasing rate	Increasing from 0 to 1 at a decreasing rate
4	Decreasing from 1 to 0 at a decreasing rate	Increasing from 0 to 1 at an increasing rate	Decreasing from 1 to 0 at a decreasing rate	Increasing from 0 to 1 at a decreasing rate
5	Increasing from 0 to 1 at a constant rate	Decreasing from 1 to 0 at a constant rate	Decreasing from 0 to –1 at a constant rate	Increasing from –1 to 0 at a constant rate
6	Increasing from 0 to 1 at a constant rate	Decreasing from 1 to 0 at a constant rate	Increasing from 0 to 1 at a constant rate	Decreasing from 1 to 0 at a constant rate

Task-Design Principles and Illustrations

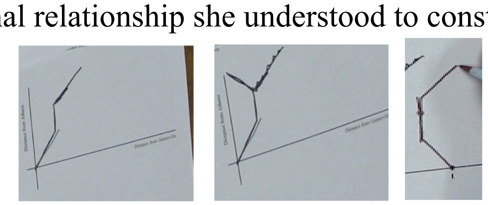
In this section we provide a description of each of the design principles and examples of student activity highlighting the productivity of these principles. The students were pre-service secondary mathematics teachers at a large university in the southeastern U.S. and were enrolled in or had completed a content course in a secondary mathematics education program. All students had completed a calculus sequence and at least two additional mathematics courses (e.g., linear algebra, differential equations, etc.) with at least C letter grades. We collected data using semi-structured task-based clinical interviews (Clement, 2000; Goldin, 2000) and teaching experiments (Steffe & Thompson, 2000), a methodology in which task design is critical and rooted in developing models of student thinking and seeking to engender shifts in student thinking based on those models; one's hypothetical models of student thinking and shifts in student thinking drives her or his design of tasks. The purpose of this paper is to report on our task-design decisions, and thus we point the reader to our other works for more information about our methods in the context of particular studies (e.g., Moore, Paoletti, & Musgrave, 2013; Moore, Paoletti, Stevens, & Hobson, 2016).

Avoid using quantities that are time or monotonic in the situation

One of the key features of considering a graph as representing a multiplicative object is to understand a coordinate point *simultaneously* represents *two* magnitudes (oriented orthogonally in the normative Cartesian system); this construction is non-trivial (Thompson et al., 2016). Complicating the matter, researchers (Carlson, Larsen, & Lesh, 2003; Johnson, 2015; Leinhardt, Zaslavsky, & Stein, 1990) have argued that students often reason uni-variationally when creating graphs, particularly if time is one of the quantities under consideration (i.e., students consider changes in one quantity without explicitly coordinating a second quantity). In our work, we have identified that students have a propensity to reason about a quantity varying with respect to experiential time if the second quantity under consideration varies monotonically (Paoletti, 2015), especially if this quantity is represented on the Cartesian horizontal axis; due to the monotonic variation of the second quantity, the student need not maintain explicit attention to its variation. Hence, our first task-design principle is to prompt students to consider quantity pairs such that neither quantity is time or varies monotonically.

In *GAG* Part II, we ask the student to create a graph using distance from Gainesville on the horizontal axis and distance from Atlanta on the vertical axis; distance from Atlanta is equivalent to total distance traveled until the car reaches Tampa, at which point distance from Atlanta begins to decrease as the car travels back towards Atlanta. This part of the task asks students to represent two quantities that are not varying monotonically, which has enabled us to determine the extent to which students sustain an explicit coordination of the two quantities under consideration (i.e., the extent to which students maintain understanding their graph as a multiplicative object) or if they (tacitly) represent another quantity (i.e., total distance traveled or time) during their construction of the graph in Part II.

To illustrate, throughout her activity in *GAG* Part II, Alicia accurately described the relationship between distances from the two cities. However, as she graphed the relationship she accurately described, she drew a graph that monotonically increased with respect to both axes (Figure 3a); we infer Alicia *tacitly* imagined the quantity on the horizontal axis as increasing. With respect to the situation Alicia understood that neither quantity varies monotonically, but to represent graphically the relationship she perceived in the Cartesian coordinate system, Alicia needed to create and sustain a multiplicative object of *both* distances. Alicia eventually did conceive her graph as representing a multiplicative object, evidenced by when she pointed to the bottom-left segment in Figure 3a and stated, "our distance from Gainesville should be getting smaller instead of bigger", and she was eventually able to adjust her graph (Figure 3b-3c) so that it represented the covariational relationship she understood to constitute the situation.



(a) (b) (c)

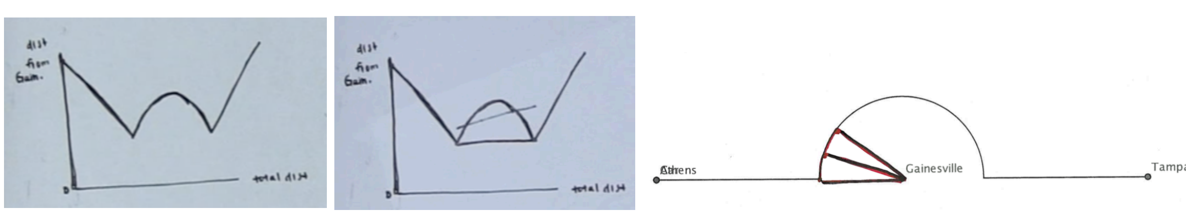
Figure 3: (a)-(c) Three stages of Alicia's solution to GAG Part II.

Use shapes strategically to match or not match the graphical shape

Several researchers (Clement, 1989; Leinhardt et al., 1990; Monk, 1992) have reported on students incorporating conceived iconic elements (i.e., visual features) of a task situation into graphical representations. We highlight that, in that moment, a student is not constructing and sustaining a multiplicative object of the form we discuss. Rather, the student is forming figurative associations between a perceived situation and graph (P. W. Thompson, 2016). Hence, as a second task-design principle, we design tasks such that perceived shapes in the situation do match perceived shapes of normative graphs, do not match perceived shapes of normative graphs, and a combination of the two.

For instance, in *GAG*, the simplified road is composed of linear segments and a semicircle. While the car travels on the straight paths, the car's distances from the two cities changes at a constant rate resulting in straight segments in the graph; while the car travels on the semicircular arc, however, the car's distance from Atlanta is changing while the distance from Gainesville remains constant, resulting in another linear segment in the graph. Including these different components in the situation allows us to gain insights into whether a student is reasoning with quantitative relationships or engaging in iconic translations. Further, we incorporate the aforementioned combination to examine whether students generalize such associations (e.g., "shapes always match graph" or "shapes never match graph").

To highlight the utility of this task-design principle, consider Alicia's activity in *GAG* Part I. After accurately describing the relationship between the car's distances from the two cities when drawing the segment from the vertical axis, Alicia engaged in an iconic translation as she drew a semicircular arc in her graph (Figure 4a). It was *after* creating the graph that Alicia thought about the result of that activity as a multiplicative object; she indicated that, to her, there was an increase and decrease in the distance from Gainesville while traveling along the semicircular path. Alicia then put concerted effort into justifying this part of her graph by comparing this claim with her image of the situation. Only when carefully attending to the car's distance from Gainesville in the situation, measuring it with a ruler (Figure 4c), did she conceive that this quantity did not change on the semicircle and replaced the arc in her graph with a straight segment (Figure 4b). She stated, "They're all the same! Why did I think it was changing? That's the radius…. So, we should be the same distance from Gainesville". Thus, Alicia compared the relationship she conceived her graph as representing to the relationship she constructed in her image of the situation, which resulted in her conceiving the same relationship as constituting both the graph and situation.



(a) (b) (c)

Figure 4: Two stages of Alicia's solution to *GAG* Part I (a-b) and her measurement work (c).

Use different representational systems or orientations

Previous researchers (e.g., Moore et al., 2016; Moore et al., 2014; P. W. Thompson, 2016) have illustrated that students' ways of thinking for graphs are often dominated by figurative activity (e.g., graphs "pass the vertical line test" or graphs are drawn left-to-right). This outcome can be explained by students having infrequent opportunities to construct images of covarying quantities and their having repeated, and possibly exclusive, experiences with graphs that have those figurative attributes (Carlson et al., 2002; Moore et al., 2016; Smith III & Thompson, 2008). Thus, for our third task-design principle, we suggest having students use various orientations of coordinate systems (e.g., changing axes orientations) or entirely different representational systems (e.g., alternative coordinate systems and representational systems like the ones described in the next principle). This design principle has supported us in gaining insights into the extent that students' actions are dominated by figurative activity or coordinating quantities. Moreover, we have been able to gain insights into the extent that students construct and sustain multiplicative objects across a variety of representational systems.

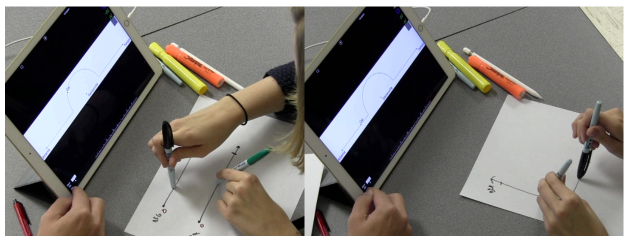
To illustrate, students may, from our perspective, be reasoning covariationally about two quantities in *GAG* Part I, but when given *GAG* Part II, they hesitate to draw a vertical line (see Figure 1) because they claim graphs cannot "look" like that. Other examples from *GAG* included students having difficulty constructing a relationship that is represented by a graph drawn "right-to-left". We have shown such issues to be problematic for students as they create graphs, particularly if the students do not persistently focus on covarying quantities (Moore et al., 2016). Further, we have found that using a multitude of coordinate systems supports students in reasoning covariationally in order to conceive graphs in different coordinate systems as representing an invariant relationship between quantities (Moore, Paoletti, & Musgrave, 2013). Hence, like the other principles, using different coordinate systems or orientations supports us in differentiating students who are conceiving of graphs as representing a multiplicative object versus those whose thinking is dominated by figurative thought; when changing coordinate systems or orientations, figurative aspects of a function's graph typically change.

Use varying segment magnitudes to represent a quantity's magnitude in a situation

The three preceding task-design principles have been helpful in allowing us to have a sense of the students who are reasoning covariationally within and across situations and graphical representations. As previously mentioned, constructing a multiplicative object does not require a coordinate system (P. W. Thompson et al., 2016). By working with varying magnitudes instead of prompting a student to create a graph (e.g., *WO?)*, we gain insights into students' reasoning while minimizing the influence of the ways of thinking they have developed for graphs (e.g., iconic translations, issues of function/dependency, ways of thinking based in figurative thought). Specifically, we are able to gain insights into the extent that a student constructs and sustains a multiplicative object with respect to a situation and the displayed magnitudes. Moreover, we are able to gain related insights into students' ways of reasoning about graphs by scaffolding tasks to support students in orienting the segments orthogonally, constructing a coordinate point, and imagining a trace representing all instantiated pairs of the covarying magnitudes (as seen in the "finger tool" explained in Lima, McClain, Castillo-Garsow, and P. W. Thompson (2009); P. W. Thompson (2002)).

Consider Lydia's reasoning in the *WO?* task. When referencing the first quarter rotation of the Ferris wheel (Figure 2a), she explained, "[A]s the arc length is increasing… [the] vertical distance from the center is increasing… but the value that we're increasing by is decreasing." After providing this accurate description of the situation, Lydia moved to select the appropriate segment in the *WO?* task (Figure 2b). She eliminated all segments except 1 and 5 (Figure 2b). Focused on the top of the Ferris wheel, Lydia said, "I think it is [segment 5], because it is decreasing at the same rate that I am increasing [referring to her moving the blue segment]." Despite having potential constraints from a graphing task removed, Lydia reasoned about the segments in a way that was not consistent (from the researchers' perspective) with her reasoning about the quantities in the situation. Lydia's contradictory statements in this task illustrate students' difficulties with constructing and sustaining a covariational relationship across representational systems that do not necessitate also constructing a coordinate point.

As Lydia continued in her teaching experiment, having repeated opportunities to reason about magnitudes in non-graphical situations was beneficial in her coming to understand graphs as representations of multiplicative objects. For instance, on *GAG* Part II, Lydia could not initially construct a graph as requested. However, she then imagined horizontal segments representing the varying magnitudes of each of the distances. As the animation played, Lydia used her pen tips, both oriented horizontally, to indicate how each quantity's magnitude varied (Figure 5a). Then, she engaged in the same activity but with her pen tips oriented orthogonally (Figure 5b); this activity supported her imagining and drawing a trace of the graph that she understood as uniting the two magnitudes into a point and trace (i.e., a multiplicative object) à la the "finger tool").



(a) (b)

Figure 5: Lydia reasoning with (a) horizontal magnitudes and (b) orthogonal magnitudes on *GAG* Part II.

Discussion

We presented several task-design principles intended to afford students opportunities to reason covariationally as they construct, maintain, and represent multiplicative objects in various representational systems. We have found that tasks designed with these principles provides students repeated opportunities to construct and compare relationships between quantities across a multitude of representational activities. Moreover, these design principles afford teachers opportunities to gain insights into their students' propensities to reason covariationally as well as to perturb students who engage in reasoning that is not attentive to covariational relationships. Hence, we believe that tasks designed using these principles will provide students with intellectual need (Harel, 2007); students will find covariational reasoning to be productive when engaging in these tasks. We conclude by emphasizing that we have found the last design principle most productive in our work with undergraduate students, particularly because of students' propensity to reason about graphing in ways that do not entail quantitative or covariational reasoning.

Common Algebraic Errors in Calculus Courses

Sepideh Stewart
University of Oklahoma

Stacy Reeder
University of Oklahoma

College mathematics instructors often view the final problem solving steps in their respective disciplines as "just Algebra", but in reality, a weak foundation in Algebra may be the cause of failure for many college students. The purpose of this paper is to identify common algebraic errors students make in college level mathematics courses that plague their ability to succeed in higher level courses. The identification of these common errors will aid in the creation of a model for intervention.

Keywords: algebra, common errors, calculus

Introduction

As early as 1910 common errors related to arithmetic and rational number computation and the difficulties students were facing in learning mathematics were noted by De Morgan. Since then other researchers have catalogued common errors in computation and algebra (Ashlock, 2010; Benander & Clement, 1985; Booth, Barbieri, Eyer & Paré-Blagoev, 2014). Benander and Clement (1985) catalogued errors students made in basic arithmetic and algebra courses. Their work involved classroom observations and resulted in 11 categories of common errors including, basic problem solving skills, averages, whole numbers, fractions, decimals, percents, integers, exponents, simple equations, ratios and proportions, geometry, and graphing. Ashlock (2010) focused on the mathematics work of school-aged children and on helping instructors thoughtfully analyze their students' work in order to discover patterns in their errors for the purpose of improving instruction. Ashlock suggests that as students learn about mathematical operations and methods of computation, they often develop and adopt misconceptions and procedural errors. Teachers who understand that this occurs and are able to identify these problems in their students' work can develop strategies to help students. In a more recent study, Booth, et al. (2014) focused on the errors in algebra with school-aged students and identified errors that were "persistent and pernicious" given their predictive ability for student difficulty on standardized test items. Their study involved an in-depth analysis of students' errors during problem solving at different points during the year and resulted in the classification of these errors which include: *variable* errors, *negative sign* errors, *equality/inequality* errors, *operation* errors, *mathematical properties* errors, and *fraction* errors.

Drouhard and Teppo's (2004) work presented the idea of *denotation* and suggests that it is a developed sense about what one is writing and a lack of sense regarding denotation creates significant problems for students. They note "that students with poor capabilities to recognize this aspect of the meaning of an expression often make endless calculations because they do not know in what direction to go and when to stop" (p. 235). Harel, Fuller, and Rabin (2008) further comment on the idea of meaning and denotation indicating that students often cancel within problems without attending to the quantitative meaning of their action. For example, Harel et al. (2008) states "it is not uncommon for students to manipulate symbols without a meaningful basis that is grounded in the context in which the symbols arise; for instance, a student might write: $(\log a + \log b)/\log c = (a + b)/c$" (p. 116). In this case, students may be overgeneralizing their use of the distributive property and cancel "log" without considering the quantitative meaning of their action. Harel (2007) suggests that the lack of emphasis on mathematical meaning that students, and perhaps their teachers, apply to mathematical symbols creates what is referred to as a *non-referential symbolic* way of thinking and that this way of thinking can be tied to a myriad of algebra errors. Sfard and Linchevski (1994) believe that students must be motivated "to actively struggle for meaning at every stage of learning" (p. 225). They are concerned that "if not challenged, the pupil may soon reach the point of no return, beyond which what is acceptable only as a temporary way of looking at things will freeze into a permanent perspective" (p. 225). Mason (2002) in his framework: *Manipulating-Getting-a-sense-of-Articulating*, emphasizes that students must be given opportunities to make sense of situations. He believes that "students want, indeed need, confidence-inspiring familiar objects to manipulate and on which to try out new ideas so that they can literally 'make sense' of them" (p. 187). In Harel and Sowder's (2005) opinion "instruction (or curriculum) that ignores sense-making, for example, can scarcely be expected to produce sense-making students" (p. 46).

Although, research on students' difficulties with algebra in school has been well documented (e.g. Kieran, 1992; Hoch & Dreyfus, 2004; Stacey, Chick, & Kendal, 2004), studies on occurrence of these errors in college level mathematics courses is scarce. In response to this need a pilot study conducted by Stewart and Reeder (2017) revealed how the unresolved high school algebra misconceptions and shortcomings may create major complications in college mathematics courses. Figure 1 demonstrates the progress and complexities of mathematical ideas as students approach the calculus courses (Stewart, 2017, p. vii).

$$\frac{1}{2} + \frac{1}{16}$$
$$\frac{1}{x^2} + \frac{1}{x^4} = 50$$
$$\frac{\mathrm{d}}{\mathrm{dx}}\left(\frac{x^2}{16}\right)$$
$$\lim_{x \to 0} \frac{\sqrt{1 + x^2} - \sqrt{1 - x^2}}{x}$$

Figure 1. The unresolved issues with fractions compound as students confront limits in calculus.

While it appears that many students follow the theories that are introduced in calculus courses, in many cases not having a rich algebra background prevents students from completing basic tasks. Many students become particularly frustrated as they realize that the fast pace of college mathematics lectures and new material are not going to wait for them to catch up. On the other

hand, the instructors become disappointed with students' performances as they note instances of algebra errors that should have been resolved years ago in high school.
The aim of this study was to identify and categorize students' common algebra errors in entry university mathematics courses. This paper does not deal with the question of why students are making such errors and continue to make them, but rather seeks to identify the type of errors that are most commonly made.

Method

Our research team included two mathematics educators working with three graduate students and a cognitive psychologist who specializes in children's algebra thinking process as our consultant. Informed by the previous work and findings from their pilot study, this research team collected data from entry level college mathematics courses from a university in the Southwest United States. Data were gathered from approximately 600 students' final exams and tests from the following mathematics courses: College Algebra; Pre-Calculus for Business, and Calculus and Analytical Geometry I during a single semester. For the purposes of this study, only the results from the Pre-Calculus for Business course will be discussed. Given the data for this research project were exams for actual college mathematics courses, the data had ecological validity. While the use of actual test and exam questions provided validity to the study in that participants were doing the mathematics they are and will be asked to do in their college level mathematics courses rather than working through problems developed for the purpose of the study that might invoke or invite certain errors, this created challenges for coding and predicting the kinds of errors students might make. The ecological nature of the data called for a process of open coding and examination of codes and coding again.

As in the case of Booth et al. (2014) we anticipated that the errors would be concept driven. For example, certain errors were present at the beginning of the semester and did not appear again until near the end of the semester. However, we were interested to see if the errors persisted and showed up again in the final exam. Hence, we collected data from students' tests 1, 2, 3 and the final examination, de-identified students' names and gave each student a number as well as their instructor's name in order to monitor their progress. For example, Jane Smith from Mr. Thomas's class was coded as: "SP16 Course Number Thom 1".

The data were scanned, and organized in a shared Dropbox for easy access by the members of the research team. The team met to review the findings of the pilot study and to discuss possible codes for common errors in student work. In order to ensure that the research team could work effectively to identify student errors, one set of exam questions was assigned to the group to analyze independently. The research team met the following week to discuss the coding categories and themes that emerged in an effort to determine an initial list of codes. This resulted in a list of the first nine codes Table 1. Further, the team agreed that beyond the initial nine codes, each person would add codes as needed. The data were then assigned to five members of the research team such that each set of test questions were analyzed independently by two researchers. Each exam question was analyzed independently and coded using the nine pre-established codes combined with a process of open-coding. Following this analysis and coding, the team met to discuss the codes and establish what word would represent the kinds of errors that were emergent in the data (Rossman & Rallis, 2012) and what was collectively understood when that code was used. This discussion resulted in the addition of several new codes and the further definition of some of the codes already in use. Following this discussion, the team once again analyzed the data to re-code where necessary and open code as needed. This process resulted in the coding list presented in Table 1. When the coding process was complete, 4,328 test and final exam questions had been analyzed from students (N=163) in two instructors' sections of Pre-Calculus for Business. Table 1 represents the percentage of each of those identified errors by code or error type. The results revealed that *Simplifying*, *Sign Errors*, *Log Properties* followed by *Distributing*, *Isolating Variable* and *Exponents* were the six highest percentages of the errors.

Table 1. Percentage of errors by coding type.

Code and Description	**%**	**Code and Description**	**%**
1. Isolating Variable (Balance point) - Students are unable to correctly work with variables on both sides of an equation.	9.09	11. Substitution - Students substitute variables or values incorrectly,	1.67
2. Simplifying - Students are unable to simplify or do not simplify when needed.	12.86	12. Absolute Value - Student do not interpret absolute value correctly.	0.12
3. Exponents - Mistakes are made with exponents.	9.03	13. Function Notation - Students do not interpret function notation correctly.	4.08
4. Sign Errors - An error made with signs.	10.76	14. Mystery Zero - Students replace a variable with zero.	1.61
5. Fractions - Mistakes with computations with fractions or with working with variables within fraction notation.	1.55	15. Quadratic Equation - Unable to solve a problem using the quadratic equation.	1.55
6. Distributing - Misuse of or ignoring the distributive property.	9.96	16. Computational Error - Simple addition or other computation mistake.	1.36
7. Cancelling - Cancelling when it is not appropriate.	3.83	17. ln/e Conversion - Students convert between logarithmic and exponential forms of an equation incorrectly.	2.97
8. Radicals - Misuse of the radical sign or inability to convert the radical sign to an exponent representation.	8.97	18. Log properties - Students incorrectly combine or expand logarithmic properties.	10.95

9. Factoring - Incorrect factoring by not removing the greatest common factor or only factoring from some but not all terms.	3.53	19. Miscellaneous	6.00
10. Inequalities - Mistake with inequality or with changing signs when dividing or multiplying across an inequality.	0.12	20. DNS-Student did not sit the exam (maybe T1, maybe T2, T3 and Final; maybe T3 and Final; maybe just Final).	

The followings (see Table 2) are a sample of questions from tests 1, 2, 3 and the final exam. The questions were unified across all the sections and designed by the course coordinator. The tests and final exams contained multi-choice questions as well as long-answer questions. For the purpose of finding the algebraic errors, we only considered the long-answer questions.

Table 2. Sample Questions from Tests/Finals.

Tests & Final	**Sample Questions**
T1	1) Solve the formula: $Y = \frac{T - m\,x}{k} - 12$ for the variable x. 2) Factor completely: $2a^2x^3 - 3a^2x^2 - 18x + 27$ 4) Find the complete solution set for: $\frac{1}{x^4} + \frac{1}{x^2} = 90$
T2	1) If the average rate of change of $f(x) = x^2 + 3x + 7$ from $x = 2$ to $x = k$ is equal to 13, then find the value of k 2) If $f(x) = 8 - 9x - 10x^2$, then find and simplify $\frac{f(x+h) - f(x)}{h}$
T3	1) If you place $100,000 into an account drawing 7.5% interest compounded continuously, then how many years would it take to have $350,000 in that account? [round to the nearest year] $[A = P(1 + \frac{r}{n})^{nt}]$ $[A = Pe^{rt}]$
Final	**8) Find the complete solution set for this equation:** $\log_3(x - 5) + \log_3(x + 3) = 2$

Results

The result of this research show that college students carry with them misunderstandings and challenges related to algebra from their high school years into their entry level college mathematics courses. The types of errors they made varied and yet making errors was persistent and plagued the students' abilities to learn new mathematics concepts throughout the semester from Test 1 to the Final examination. This study revealed that while algebra related errors are evident in student work throughout the semester, the type of errors made are often dependent on the type of mathematics problems they are asked to solve. For example, errors with fractions may appear to be resolved as the semester moves along but it may well be that students are simply not asked to work problems that involve fractions near the end of the semester. Figures 2 and 3 below are examples of some of the error types resultant from this study. Figure 2 highlights the kind of error that was coded as Isolating Variable given that the student struggled to isolate the variable on one side of the equation. Nearly 10% of the errors found in this study were of this type. Figure 3 below provides an example of a students' error with function notation.

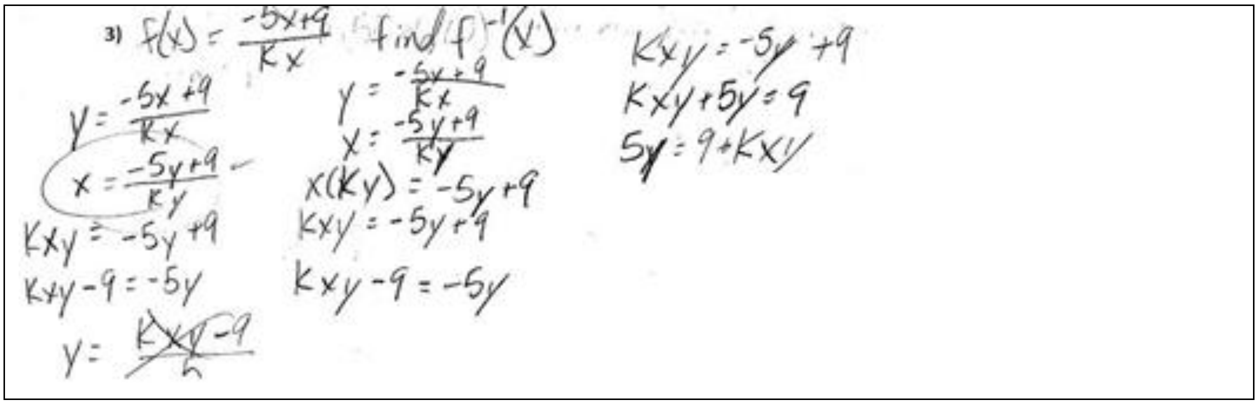

Figure 2. Isolating Variables (Balance Point).

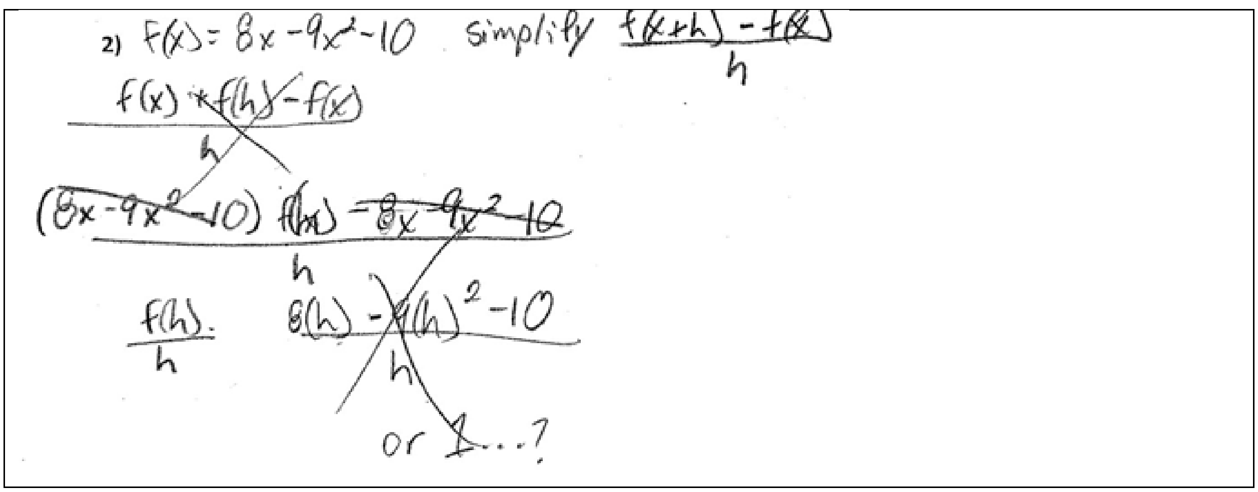

Figure 3. Function Notation.

Discussion and Concluding Remarks

This study investigated test and exam questions performed by 163 Pre-Calculus for Business students, and examined more than 4000 problems, in order to categorize the most common types of algebraic errors that college mathematics students make. Although, it is perceived that the type of exam questions posed, invited certain types of errors, the frequency of errors is persistent throughout the semester regardless of problem type. The students consistently make mistakes and errors with algebra from Test 1 to the final examination.

While analyzing the data, we witnessed over and over again how algebra errors rapidly terminated the flow of the problem solving sequence for many students and resulted in incorrect solutions or no solutions. Many mathematics instructors believe that it is not our responsibility to teach or re-teach school algebra in college level courses. Realistically, going over algebra misconceptions is not a possibility and we have no time to repair them. Many of the errors found in this study reflect Drouhard et al.'s (2004) finding that students make endless calculations when they do not know what direction to go and Harel's (2007) point about non-referential symbolic way of thinking. Booth et al. (2014) suggests that "the misconceptions underlying specific persistent errors are not corrected through typical instruction and may require additional intervention in order for students to learn correct strategies." (p. 21).

Future research

Although, it is believed among many instructors that these types of algebraic errors should have been resolved years ago in high school and maybe nothing can be done at this stage, we believe that pinpointing the type of errors will help in creating interventions that remedy the algebraic errors. We continue to refine our common error types as more data become available from College Algebra and Calculus and Analytical Geometry I courses. Our next steps are to interview the instructors who taught these courses and seek more information from them in order to create the most effective interventions to help future calculus students.

Completeness and Sequence Convergence: Interdependent Development in the Context of Proving the Intermediate Value Theorem

Steve Strand
CSU Chico

As a part of a larger RME-based instructional design project for advanced calculus, this paper reports on two students' reinventions of formal conceptions of sequence convergence and the completeness property of the real numbers in the context of developing a proof of the Intermediate Value Theorem (IVT). Over the course of ten, hour-long sessions I worked with two students in a clinical setting, as these students collaborated on a sequence of tasks designed to support them in producing a proof of the IVT. Along the way, these students conjectured and developed a proof of the Monotone Convergence Theorem. Through this development I found that student conceptions of completeness were based on the geometric representation of the real numbers as a number line, and that the development of formal conceptions of sequence convergence and completeness were inextricably intertwined.

Key Words: RME, instructional design, real analysis, limit, completeness

Introduction

The transition from lower-division mathematics courses, where the emphasis is often on calculational approaches, to upper-division courses, primarily concerned with proof and more abstract mathematics, is a challenging one for many undergraduate students. There has been growing interest in developing research-based, student-centered curricula for undergraduate mathematics to support students in making this transition in the areas of abstract algebra (TAAFU: Larsen, 2013; Larsen & Lockwood, 2013), differential equations (IO-DE: Rasmussen & Kwon, 2007), geometry (Zandieh & Rasmussen, 2010), and linear algebra (IOLA: Wawro, et al., 2012). The data presented in this paper comes from early efforts at similarly-motivated instructional design efforts for advanced calculus. One of the central ideas underpinning all areas of advanced calculus is that of limits and convergence. One of the features of the real numbers that makes limits and convergence so important (indeed, possible) is that of completeness. While a large body of research exists about how students think about limits and how that thinking develops in formality, there is a dearth of research dealing directly with students' conceptions of the completeness of the real numbers.

This paper reports on student strategies that anticipated the concept of completeness, as those strategies emerged in the context of a teaching experiment. This experiment was part of an instructional design effort to develop the proof of the Intermediate Value Theorem (IVT) as a starting point for inquiry-oriented advanced calculus. The students in the teaching experiment began by approximating the (irrational) root of a polynomial using the principles behind the IVT. They developed a sequence of approximations by looking for the sign change of the function on smaller and smaller intervals. As the IVT (and many other facets of convergence) implicitly depend on the completeness of the real numbers, I expected that investigations of these kind would give insight into students' informal conceptions of completeness, as well as insight into how students might be supported in reinventing formal characterizations of completeness.

In this paper I will detail how early student justifications anticipated the Monotone

Convergence Theorem (MCT)[1], and how the proof of that theorem became a powerful context for the interdependent development of more formal conceptions of sequence convergence and completeness.

Literature Review

A great deal of research has investigated student understanding of the concept of limit. The focus of these investigations has shifted over the last few decades. Initially, a large number of studies sought to describe the difficulties students encountered when trying to work with limits (Bezuidenhout, 2001; Cornu, 1991; Davis & Vinner, 1986; Moru, 2009; Sierpińska, 1987; Szydlik, 2000; Tall, 1980; Tall & Schwarzenberger, 1978; Williams, 1991). Gradually, more and more studies have investigated how student conceptions might develop in formality (Cottrill, et al., 1996; Oehrtman, 2009; Oehrtman, Swinyard, & Martin, 2014; Swinyard & Larsen, 2012). One important feature of formal work with limits, first given prominence by Swinyard & Larsen (2012), is the shift from *finding limits* to *verifying limit candidates.* While limit problems in calculus are often centered around the use of algebra to *find* limits, formal activity with limits is usually centered around using formal definitions to prove that a limit exists or to prove general properties about limits. What has received almost no study is what the process of developing such formal definitions of limits looks like in the context of proving, or what role completeness plays in this process of formalization. While the research reported here informs both of these topics, this proposal will focus on the latter.

While Cauchy is widely recognized as one of the fathers of real analysis, his proofs conspicuously lack any mention of the completeness of the real numbers (Grabiner, 1981; Lützen, 2003). In fact, one of the first explicit treatments of the completeness[2] of the real numbers was Dedekind's "Continuity and Irrational Number" essay, originally published in 1872 (1901), over fifty years after Cauchy's *Cours d'Analyse*. However, it is a critical component of the proof of the Intermediate Value Theorem, and so identifying student strategies that anticipate formal conceptions of completeness in this context will be critical in developing instruction for advanced calculus using this context as a starting point.

As such, the specific questions that guided this component of this design research project were the following:

1. *In the context of proving the IVT, what student strategies anticipate the concept of completeness?*
2. *In what ways do the developments of completeness and sequence convergence support one another?*

Theoretical Framework

The instructional design heuristics of RME have guided the development and implementation of this design project. They have also been indispensable as tools for analyzing student thinking and activity. In particular the heuristic of *emergent models* provides language and tools for describing students' activity at the informal level and also for describing the development of their activity toward greater formality and rigor. In RME, these models emerge from student activity, in the sense that the models provide a way for a teacher/researcher to describe student activity (Larsen & Lockwood, 2013).

---

1 MCT: *If $\{a_n\}$ is a bounded, monotonic sequence, then it converges.*

2 The German word that Dedekind used was the word for "continuity", but it is clear that he was describing the modern concept of the completeness of the real numbers.

In emergent models, the model-of/model-for transition captures large, significant developments in student activity and thinking (Gravemeijer, 1999). For describing more local development of these models, Rasmussen and Marrongelle described the construct of a *transformational record* (2006). Such a record is an inscription or notation recorded by the students, or used by the teacher to capture student thinking, that later is used by the students for further mathematical development. This construct can be particularly useful for teachers in supporting the development of emergent models. In the Results section I will illustrate how I used a transformational record to support students in developing a more formal understanding of sequence convergence.

Transformational records can also be described using the RME construct of record-of/tool-for (Johnson, 2014; Larsen, 2004; Larsen, 2013). A record-of student activity generally refers to an inscription or notation that represents one form of the larger emergent model. This record-of becomes a tool-for when students use it for further mathematical development. This *transformation* of the record at a local level represents a development of the larger emergent model. A model-of students' activity can be evidenced by many different forms. One way to describe the development of this model toward a model-for is through "students' increasing ability to reason with various forms of the model" (Johnson, 2014). While not as significant as a model-of/model-for transition, which represents the students becoming aware of and using the model as a whole, these record-of/tool-for transitions nonetheless represent important developments in student activity.

In the study reported here, we will see how the concept of completeness emerged as a global model-of student reasoning about the convergence of an approximation algorithm. Later least-upper bounds, as one form of that global model, emerged as a record-of student thinking. This form of the model then developed into a tool-for more formal activity as student used least-upper bounds in two important developments: 1) formally defining a specific mode of sequence convergence, and 2) completing a proof of the Monotone Convergence Theorem. After describing the structure and implementation of the teaching experiment, as well as the manner in which I analyzed the data, I will briefly describe how completeness emerged as a model-of student activity, and how that model developed through the course of the teaching experiment.

Methods

As a part of the early stages of an instructional design project, I ran two separate teaching experiments over the course of a year, a little more than six months apart. Each teaching experiment consisted of 10, hour-long sessions with myself as teacher/researcher and a pair of students working at a chalkboard at the front of the room. These students were volunteers selected from courses that were direct prerequisites to advanced calculus/elementary real analysis courses, and who had expressed an intention to take advanced calculus in the near future. All four participants had completed the calculus sequence, differential equations, and at least one proofs-based course, prior to participating in the teaching experiment.

The data for this paper comes from the second teaching experiment, with students who will hereafter be referred to as Dylan and Jay. With the first teaching experiment, my attention was primarily focused on issues of convergence. It was not until retrospective analysis that I discerned the importance of the role that completeness could play in this context. For this reason I modified the task sequence for the second teaching experiment, which resulted in an abundance of data relating to student understanding of completeness. For these reasons this paper focuses on the experiences of Dylan and Jay.

During the implementation of the teaching experiment there were anywhere from three days to an entire week between sessions. During that time I watched the videos of the previous session, creating written session summaries, and tried to identify student statements and strategies that begged for further investigation. For example, Dylan and Jay justified the convergence of a particular sequence by appealing to the fact that the sequence was increasing and was bounded. But it was not clear from their statements whether they thought such a sequence *had* to converge to the given bound. To start the next session I gave them exactly this conjecture and observed their discussion.

After the conclusion of each of the teaching experiments, I performed a retrospective analysis of the data as a whole. I watched all of the videos again, transcribing segments I had flagged during the ongoing analysis, looking for student strategies that anticipated the completeness of the real numbers. For each of these I sought to explain what elicited these strategies. Finally, I followed these strategies through the data and using the design heuristics of RME I sought to explain how these strategies were leveraged to support the development of more formal ideas, or how they might be leveraged in future implementations of the LIT.

Results

In the context of developing their own proof of the IVT, I found that characterizations of the completeness of the real numbers emerged from Dylan and Jay's activity. This suggested to me that completeness, as a collection of varied but equivalent characterizations, could be seen as a model-of students' activity. Using primarily the emergent models design heuristic, I will describe how completeness emerged as a model-of their thinking, and how aspects of this model became a tool-for more formal reasoning about convergence.

Justifying Convergence

When tasked with approximating the root of a polynomial, Dylan and Jay used the sign-change of the function over successively smaller intervals to construct a sequence of approximations to that root. The transcript excerpt below came from a conversation in which Dylan, Jay, and I were discussing how they knew that their algorithm would find a root of the function in question. They had recently established that, if the root were irrational, their Decimal-Expansion algorithm would *never* give them the exact root.

I: So how do you know that there is such a number?

D: As long as we can recursively show that every time we step our function forward it gets a little bit closer to zero. This is how you do the limit in general: every time you step it forward, every time you know you move forward a little bit, you get closer to the number you think the limit is.

There are a few problems with Dylan's characterization of a "limit in general". For one, he is a describing convergence in a monotonic fashion, and so is not truly giving a general description. Second he is characterizing the convergence of their sequence of approximations using the monotonicity of the *outputs* of the function. This held true of the specific polynomial with which their investigations had started, but it was not necessary in general for their algorithm to work.

While there were many details to be worked out, Dylan's statement represented very promising reasoning. Here we can see that the concept of completeness, taking the form of the Monotone Convergence Theorem, served as a model-of Dylan and Jay's explicit justifications for the convergence of their sequence of approximations. More specifically, his statement suggested that he believed an increasing sequence, that was bounded above, should converge. Whether or not he really believed that this characterized limits in general was immaterial at that moment. This emergent model suggested that codifying and analyzing Dylan's justification could be very fruitful.

On the board Dylan had written:

$$f(x_i) < f(x_{i+1}) < 0 \qquad (1)$$

In an attempt to draw their attention away from the outputs for a moment, I asked Dylan and Jay whether a similar statement could be made about the inputs. I did this because I wanted to have them analyze Dylan's statement, but I did *not* want considerations about the behavior of the function to muddy the water. Without any discussion, Dylan wrote:

$$x_i < x_{i+1} < \overline{x} \qquad (2)$$

(where $\overline{x}$ was the conjectured root). Then he and Jay explained why the second compound inequality might be preferable.

Jay: We're controlling this [gestures at (2)] more than we're controlling this [gestures at (1)]. We can't control the outputs, but we can control the inputs.

Dylan: Right. I guess we just observe this [gestures at (1)] for this particular function.

With Dylan and Jay in agreement with the statement about the monotonicity and boundedness of the *inputs*, we were ready to consider their justification as a conjecture. Completeness, manifested as the Monotone Convergence Theorem, was an even clearer model-of their thinking about the convergence of their sequence of approximations. In order to support the development of their thinking, I set Dylan and Jay tasks that would have them engage in vertical mathematizing, by having them reflect on and analyze their own reasoning about convergence.

Least-upper Bounds

Another important development arose when Dylan and Jay considered conditions under which a bounded, monotonic sequence would converge to an upper bound. Dylan put forth the following explanation:

> "Because if you can pick a value, some a, between x_{i+1} and b...and...x_{i+1} passes every value of a...like every possible value of a...and passes b...wait, if this is true, so it doesn't pass b. So worst case scenario it converges to b."

It appeared that what Dylan described was essentially a characterization of b as the least-upper bound of the sequence. He seemed to suggest that if we could choose a to be any arbitrary value less than b, and then we knew that a value of the sequence $\{x_i\}$ passed that value of a, then the sequence would have to converge to b. So there was no value of a less than b that was also an upper bound for the sequence.

This condition, that the sequence passes every value of a less than b, but never passes b, proved to be pivotal in Dylan and Jay's developments of both completeness and convergence. A short while after this, I incorporated this condition as an added hypothesis to their MCT and had them consider it; in this way it became a record-of their thinking, and also represented one form of the larger completeness model. Subsequent to that discussion Dylan explicitly leveraged the condition to define "decreases to zero".

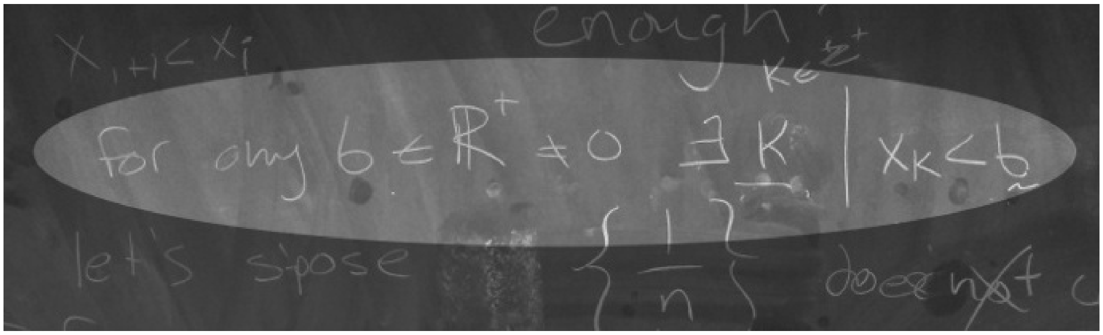

Figure 1: Students' definition of a sequence "decreasing to zero"

A Transformational Record

A little later Dylan and Jay set about to define formally what it meant for a sequence to "decrease to zero" (Figure 1).

In the following exchange Dylan explained the genesis of their definition.

Jay: How'd you get that?

Dylan: Basically going from our last idea that if a number converges to...to b, I guess. So, ...this is kind of formally writing out that...for every b that's less than a, or- which is zero in this case, I guess- is between where we're starting and the boundary.

Dylan made a connection back to their work with a previous conjecture: that if a monotonically increasing sequence was bounded by b, but passed every a less than b, then it must converge to b. Though the roles of the variables have been reversed, Dylan has described adapting their idea of "passes every a less than b" to this case of a sequence monotonically decreasing to zero.

Dylan went on to explain his definition in more detail.

> "So the boundary we know we want is zero. So we're going to talk about all the numbers that aren't zero, above zero...So we know this [sequence] is always getting smaller. Down to some...you know, whatever. It goes off to somewhere. But do you know it goes to zero? And you do as long as you can pick any of these [positive real] numbers and just keep going through until you find some k [sic] that's smaller than it."

Here we see the results of the students successfully leveraging a transformational record. Earlier in the experiment, when reasoning about the conditions under which a monotonic sequence might converge to its bound, Dylan's made the statement "passes every a less than b". A little later I recorded this reasoning, presenting it back to the students as an additional hypothesis to their MCT; in this way this characterization of least-upper bounds served as a record-of their thinking. And above we saw how this record became a tool-for solving the problem of defining the convergence of a sequence decreasing to zero. In this way an informal strategy of the students developed into a tool-for reasoning more formally about limits. More specifically, my presentation of their strategy as a conjecture acted as a *transformational record*, which they used to solve the problem of defining a sequence decreasing to zero.

Discussion

In the context of developing a proof of the Intermediate Value Theorem, the informal strategies of two students anticipated formal characterizations of completeness. The Monotone Convergence Theorem (MCT) emerged as the students considered the convergence of their (monotonically increasing, bounded) sequence of approximations to a root. Initially the convergence of such a sequence was intuitively clear to them. Digging deeper into *why* that might be the case led to the investigation and development of a proof of this idea. Least-upper bounds also emerged from their activity, for the first time as they tried to identify what conditions would guarantee that a monotonically increasing sequence would converge to an upper bound. Dylan and Jay subsequently utilized this idea to define what it meant for a sequence to converge to zero. Finally, though not detailed in this proposal, in constructing a proof of the MCT Dylan and Jay debated the existence of least-upper bounds, ultimately accepting their existence as a consequence of the real number line. The existence and properties of least-upper bounds were the key ideas in the ultimate completion of their proof of the MCT.

One way to frame this development is using the RME construct of emergent models. In justifying the convergence of their sequence of approximations, the students' thinking could be modeled by the larger concept of the completeness of the real numbers. Dylan and Jay were eventually able to use aspects of this model as a tool-for reasoning more formally about convergence. The development of this model was inextricably tied up with the development of their understanding of convergence. It was in the process of defining sequence convergence that least-upper bounds emerged as a record-of their thinking. Through the process of reflecting on and formally defining "maximum" (which helped them solidify their definition of sequence convergence), completeness, specifically as signified with least-upper bounds, began to transition to a tool-for the students to reason more formally about convergence *and* to complete a proof of the MCT. In this way the development of their understanding of completeness supported and was supported by the development of their understanding of sequence convergence.

Future research will investigate further the nature of this interdependent concept development in this context. For example, in my first teaching experiment, the pair of students considered a sequence of nested, shrinking intervals, rather than a sequence of approximations to a root. This thinking could also be modeled by the larger concept of the completeness of the real numbers, as it is essentially the Nested Interval Property. From an instructional design perspective, it will be important to investigate the constraints and affordances of developing a proof of alternative characterizations of completeness. This research suggests a promising instructional design approach, and knowing more about how these two concepts develop together would be invaluable for these efforts.

This proposal contributes to our understanding of how students think about the completeness of the real numbers. Specifically in the context of the Intermediate Value Theorem, there is strong evidence that completeness can be a powerful model, first as a record-of student thinking about convergence, and then for use by the students as a tool-for developing more formal conceptions of sequence convergence and completeness itself. This further suggests that intuitive notions of completeness could support students in developing their understanding of sequence convergence and completeness in other contexts, as well; for example, in an IBL (Inquiry-Based Learning) or even a traditional lecture-based advanced calculus course. There is also evidence that these informal student characterizations of completeness are rooted in representations of the real numbers as a number line; the historical development of completeness lends credence to this idea (Dedekind, 1901). While there is still much to uncover about how students think about completeness and how that thinking might progress, it is evident that there are important connections between completeness and convergence in students' minds.

Angle Measure, Quantitative Reasoning, and Instructional Coherence: The Case of David

Michael A. Tallman
Oklahoma State University

This paper reports findings from a study that explored the effect of a secondary mathematics teacher's level of attention to quantitative reasoning on the quality and coherence of his instruction of angle measure. I analyzed 37 videos of an experienced teacher's instruction to characterize the extent to which he attended to supporting students in reasoning quantitatively, and to examine the consequences of this attention (or lack thereof) on the quality and coherence of the meanings the teacher's instruction supported. My analysis revealed that the incoherencies in the teacher's instruction were occasioned by his inattention to quantitative reasoning. This study therefore demonstrates that when teachers do not possess a disposition to attend to quantities and their relationships, the circumstances are ripe for instruction that emphasizes inconsistent, incoherent, and sometimes incompatible, mathematical meanings.

Key words: Mathematical Knowledge for Teaching, Quantitative Reasoning, Angle Measure, Radical Constructivism, Pre-Service Teacher Preparation

Introduction

Thompson (2013) argued that the quality of mathematics instruction in the United States suffers from "a systemic, cultural inattention to mathematical meaning and coherence" (p. 57). While a number of empirical studies demonstrate that Thompson's accusation applies to a spectrum of mathematics courses and topics (e.g., Ma, 1999; Stigler & Hiebert, 1999), several researchers have noted that pre- and in-service teachers' personal understandings of trigonometry, as well as their instruction, tend to be particularly lacking in coherence and conceptual meaning (Akkoc, 2008; Moore et al., in press; Tallman, 2015; Thompson, 2008; Thompson, Carlson, & Silverman, 2007). Others have observed that trigonometry is a notoriously difficult subject for students (Moore, 2012, 2014; Weber, 2005). Identifying the factors that contribute to widespread incoherent instruction of trigonometry is therefore a priority for improving students' learning of the subject.

A growing body of research (e.g., Castillo-Garsow, 2010; Confrey & Smith, 1995; Ellis, 2007; Moore, 2012, 2014; Moore & Carlson, 2012; Oehrtman, Carlson, & Thompson, 2008; Thompson 1994) has identified *quantitative reasoning* (Smith & Thompson, 2007; Thompson, 1990, 2011) as a powerful way of thinking that supports students in constructing a meaningful understanding of a wide variety of mathematics concepts. Several researchers have noted that quantitative reasoning is especially foundational for supporting students' conceptual learning of angle measure and trigonometric functions (Hertel & Cullen, 2011; Moore, 2012, 2014; Tallman, 2015; Thompson, 2008). However, the instructional consequences of teachers' attention to quantitative reasoning (or lack thereof) are less frequently documented. By *instructional consequences*, I do not mean the understandings students construct while engaged in instructional experiences that emphasize (or fail to emphasize) quantitative reasoning. I am instead referring to the characteristics of the instruction itself, namely the nature of the understandings it promotes as well as its coherence.

Discerning how teachers' attention to quantitative reasoning affects the quality and coherence of their trigonometry instruction has the potential to inform instructional and curricular innovations that seek to improve the quality of this instruction, both in the United States and internationally. For this reason, I designed the present study to achieve such discernment. Specifically, I explored the effect of a secondary mathematics teacher's level of attention to quantitative reasoning on the coherence of the meanings of angle measure his instruction supported.

Quantitative Reasoning

I leveraged Smith and Thompson's (2007) and Thompson's (1990, 2011) explicit formalizations of *quantitative reasoning* in the design of this study and in my analysis of its data. Quantitative reasoning is a characterization of the mental actions involved in conceptualizing situations in terms of *quantities* and *quantitative relationships*. A *quantity* is an attribute, or quality, of an object that admits a measurement process (Thompson, 1990). One has conceptualized a quantity when she has identified a particular quality of an object and has in mind a process by which she might assign a numerical value to this quality in an appropriate unit (Thompson, 1994). It is important to emphasize that quantities do not reside in objects or situations, but are instead constructed in the mind of an individual perceiving and interpreting an object or situation. Quantities are therefore conceptual entities (Thompson, 2011; Thompson et al., 2014).

Conceptualizing a quantity does not require one to assign a numerical value to a particular attribute of an object. Instead, it is sufficient to have a measurement process in mind and to have conceived, either implicitly or explicitly, an appropriate unit of measure. *Quantification* refers to the mental actions involved in conceptualizing an appropriate unit of measure as well as a measurement process, and results in an understanding of "what it means to measure a quantity, what one measures to do so, and what a measure means after getting one" (Thompson, 2011, p. 38). I emphasize that one need not measure an attribute of an object to have quantified it, but must have in mind a process by which she might do so (Thompson, 1994).

The quantities one might construct upon analyzing a situation are not limited to those whose numerical values are attainable from direct measurements. Defining a process by which one might measure a quantity often involves an operation on two or more previously defined quantities. In such situations, we say that the new quantity results from a *quantitative operation*—its conception involved an operation on other quantities. Quantitative operations result in a conception of a single quantity while also defining the relationship between the quantity produced and the quantities operated upon to produce it (Thompson, 1990, p. 12). It is important to draw attention to the distinction between a quantitative operation and a numerical or arithmetic operation. Arithmetic operations are used to calculate a quantity's value whereas quantitative operations define the relationship between a new quantity and the quantities operated upon to conceive it (Thompson, 1990).

Methods

The sole participant for this study was an experienced secondary mathematics teacher, David, who taught Honors Algebra II at a large suburban high school in the Southwestern United States. David used the *Pathways Algebra II* (Carlson, O'Bryan, & Joyner, 2013) curriculum materials in this course. The *Pathways Algebra II* materials are organized into modules, each of which contains a number of investigations that students are expected to work on in small groups during class sessions.

I collected data throughout David's instruction of Module 8 of the *Pathways Algebra II* curriculum. This module focuses on a variety of ideas related to trigonometric functions including angle measure, the output quantities and graphical representations of various periodic functions, periodic function transformations, and inverse trigonometric functions. In this paper, I present only the results of my analysis of David's instruction of angle measure. I do not discuss in detail my analysis of David's instruction of other topics addressed in Module 8 of the *Pathways Algebra II* curriculum since the conclusions I drew therefrom are consistent with those I present below.

David taught two sections of Honors Algebra II every weekday during the spring semester of 2014. I video recorded both classroom sessions over a seven-and-a-half-week period of this semester, which resulted in 37 videos of David's instruction. The only class sessions that I did not videotape were those during which students were testing or those in which David was teaching content unrelated to trigonometric functions. In addition to the video recordings of David's instruction, I generated field notes during the class sessions that focused on characterizing the extent to which David supported students in reasoning quantitatively, and on documenting the mathematical meanings David's instruction promoted.

The procedures I used to analyze the video data are consistent with Strauss and Corbin's (1990) and Corbin and Strauss's (2008) grounded theory approach. I began my analysis of these videos by making an initial pass of open coding during which I identified instances that David conveyed some way of understanding. I coded these occasions for the specific category of understanding David communicated. I then made a pass of axial coding in which I verified and refined my initial codes. After having coded the 37 videos of David's classroom teaching, I produced a 57-page document entitled, "Post-Analysis Memos" wherein I summarized each coded instance of the videos and included selective transcriptions of what appeared to be particularly revealing moments of David's instruction. These memos also focused on characterizing for each coded instance the extent to which David supported his students in reasoning quantitatively. In particular, I documented the degree to which David's instruction supported students in: (1) identifying quantities, (2) attending to units of measure, (3) constructing quantitative relationships, and (4) interpreting mathematical symbols and expressions as representing the values of quantities. I carefully read through these memos and organized the coded segments of video into themes. I then examined the data within each theme and characterized the extent to which the quality and coherence of the meanings David's instruction promoted was facilitated/impeded by his level of attention to supporting students in reasoning quantitatively.

Results

Meaningfully assigning numerical values to the "openness" of an angle requires that one has identified a quantity to measure and has specified a unit with which to measure it. David's instruction was often inconsistent with regard to the quantity one measures when assigning numerical values to the "openness" of an angle. On some occasions David supported students in conceptualizing angle measure as the length of an arc the angle subtends, while on other occasions he explained that measuring an angle involves determining the fraction of the circle's circumference subtended by the angle. These meanings are not the same. Understanding the fraction of a circle's circumference that an angle subtends as a measure of subtended arc length involves conceptualizing the circle's circumference as a unit of measure for the length of the subtended arc. Specifically, one must recognize that the resulting fraction represents a multiplicative comparison of the quantity being measured (subtended arc length) and the unit of measure (circumference). For example, to say an angle subtends 59/360ths of the circumference of a circle centered at its vertex is to say that the length of the subtended arc has a measure of 59/360 in units of one circumference. The two meanings of angle measure David conveyed were distinct since he did not support students in conceptualizing the circumference of the circle centered at the angle's vertex as a unit of measure for the length of the subtended arc. Due to space limitations, the following paragraphs illustrate only two occasions in which David's instruction supported inconsistent meanings of angle measure (from my perspective). I emphasize that the events discussed here are representative of several instances from David's teaching in which he promoted discrepant meanings.

Lessons 1 and 2

David began the first lesson of Module 8 by asking a student to draw two angles on the whiteboard. The student drew one angle above the other. David then explained that the measure of the angle on top is larger than the measure of the angle on bottom because, if one were to construct two circles of equal radii respectively centered at the vertex of each angle, the angle on top would subtend an arc that is longer than the arc subtended by the angle on bottom. Immediately following this explanation, David asked the question in Line 1 of Excerpt 1.

Excerpt 1

1. *David*: When we measure an angle what are we really measuring? I mean it's not like we're measuring a length, right? How would we describe the thing that I'm measuring when I just look at these two angles? …
2. *Student*: The openness of the angle.
3. *David*: Yeah. Which is weird. How do you measure openness? … I'm not measuring length. … We have to think about what we are actually measuring.

While David previously compared the openness of two angles by attending to the respective arc lengths these angles subtend, he claimed in Lines 1 and 3 of Excerpt 1 that quantifying the openness of an angle does *not* involve measuring a length. Following the dialogue in Excerpt 1, David explained that two angles have the same measure if "the length of the [subtended] arc is the same, as long as I made the circle have the same radius and it was centered at the vertex." David therefore supported contradictory meanings of angle measure during the first lesson; he pronounced that measuring an angle is not a process of measuring a length and then proceeded to compare the openness of two angles, as well as define what it means for two angles to have the same measure, by attending to the arc lengths the two angles respectively subtend. In other words, when speaking of angle measure David did not consistently reference the same quantity being measured.[1]

A few minutes after David's remark in Line 3 of Excerpt 1, he projected the image displayed in Figure 1 on the whiteboard and asked his students the question in Line 1 of Excerpt 2.

[1] Understanding angle measure quantitatively involves conceptualizing a specific attribute to measure as well as identifying an appropriate unit with which to measure it. When measuring an angle, the attribute one measures is the length of the arc the angle subtends. This subtended arc length must be measured in units that are proportionally related to the circumference of the circle that contains the subtended arc so as to make the size of this circle inconsequential to the measure of the angle. It is important to note that this condition on the unit of measure does *not* change the quantity being measured: *subtended arc length*.

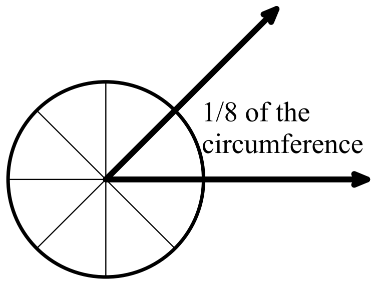

Figure 1. Angle measure as a fraction of the circle's circumference

Excerpt 2

1. *David*: So the angle subtends 1/8th of the circumference of the circle. (*Pause*) Now do units matter here? … Why do units not matter here?
2. *Student*: 'Cause you're using a proportion.
3. *David*: Why does that matter? …
4. *Student*: Because even though you're making the radius larger you're also making the whole circle larger.
5. *David*: So what happens when you do your proportion? Think in science class. (*Long pause*) 'Cause we're comparing it to our circumference, right? We're comparing arc length to circumference? What would happen to the units then? (*Long pause*) So lets just say for the sake of argument 1/8th could be a circumference of, uh, a circumference of 16, that would mean that the arc length would be two, if it's an eighth. So two inches divided by 16 inches is?
6. *Student*: One-eighth.
7. *David*: One-eighth. What are the units now? (*Long pause*) What happens when you put—and again think in terms of science class—what happens when you put two inches divided by 16 inches (*writes* "2in/16in"), your science teacher would say that's 1/8th. What are the units?
8. *Student*: It doesn't matter.
9. *David*: It does matter. What are the units?
10. *Student*: Inches.
11. *David*: Inches divided by inches give you inches?
12. *Student*: No.
13. *David*: What does it give you?
14. *Student*: One-eighth.
15. *David*: What are the units?
16. *Student*: It doesn't have units.
17. *David*: It doesn't have units? Why not?
18. *Student*: Because the inches cancel.
19. *David*: 'Cause inches cancel inches! … 'Cause I'm not just measuring arc length. What am I measuring? I'm measuring arc length and comparing it to what?
20. *Student*: Circumference.
21. *David*: Circumference! How am I comparing them?
22. *Student*: By length.
23. *David*: By length? What operation is going on here? Am I subtracting the circumference? (*Pause*) It's division! We're creating a ratio! Then do the units matter?
24. *Student*: No. …

25. *David*: What happens when we do the ratio? The units stop mattering, right? Because the units end up canceling. We're interested in the ratio. We're not interested in the units from the ratio because the units are going to reduce.

After acknowledging in Line 1 of Excerpt 2 that the angle in Figure 1 "subtends 1/8th of the circumference of the circle," David exclaimed that the measure of the angle is a value without units. In particular, David explained that if one measured the subtended arc length and circumference in inches, the ratio of these quantities is unit-less because the inches "cancel" as a result of the division. Moreover, by claiming, "I'm not just measuring arc length. What am I measuring? I'm measuring arc length and comparing it to what? … Circumference!" David did not support his students in seeing the ratio of subtended arc length to circumference as the length of the subtended arc measured *in units of the circumference*. Generally speaking, David's statements and questions in Excerpt 2 did not provide students with an opportunity to interpret the ratio of subtended arc length to circumference as a quantitative operation but rather as an arithmetic operation; that is, he did not communicate the division of these quantities as a measure of subtended arc length in units of circumference but simply as the ratio of two lengths. Such an emphasis is necessary if one is to support students in conceptualizing angle measure quantitatively (i.e., as a measure of some attribute in some unit). Therefore, while David's instruction during the first lesson overtly emphasized angle measure as a fraction of the circle's circumference subtended by the angle—and implicitly conveyed angle measure as the length of the subtended arc—he did not encourage students to see the former meaning as an application of the latter by failing to support them in conceptualizing the ratio of subtended arc length to circumference as a quantity that represents the length of the subtended arc measured in units of the circumference. In fact, David suggested that these meanings were incompatible by continually asserting that the process of measuring an angle is not one of measuring length.

David's instruction of angle measure did not consistently support students in conceptualizing the quantity one measures when assigning numerical values to the openness of an angle. On some occasions David conveyed that the process of measuring an angle is one of determining the length of the arc an angle subtends, while on other occasions he explained that measuring an angle involves determining the fraction of a circle's circumference subtended by the angle. While in certain circumstances one of these ways of understanding might be more natural than the other, David did not support his students in making the connection between these ways of understanding. In other words, David did not provide opportunities for students to see these meanings as two instantiations of the same quantification process (measuring the length of the subtended arc in units proportional to the circumference of the circle containing the subtended arc) because he did not support students in conceptualizing the circumference of the circle centered at the angle's vertex as a unit of measure for the length of the subtended arc.

Summary of Lessons 1-9

While David's instruction during the first lesson emphasized the understanding of angle measure as the fraction of the circle's circumference subtended by the angle, he also discussed angle measure as the length of the arc an angle subtends, but then suggested that these two meanings are incompatible by explaining that the process of measuring an angle is not one of measuring a length. The majority of David's instruction during Lessons 2 and 3 emphasized angle measure as the fraction of the circle's circumference subtended by the angle. Specifically, David's teaching promoted the mental imagery of imagining the circumference of the circle centered at the vertex of the angle being split into a number of equal pieces, and then attending to the ratio of the number of these pieces subtended by the angle to the number of these pieces contained in the circumference of the circle. However, on several occasions during Lessons 4-9, David discussed angle measure as the length of the subtended arc measured in units of the radius of the circle containing the subtended arc. Moreover, David's instruction throughout Lessons 4-9 was often contradictory in that he encouraged meanings that on other occasions he did not accept and devalued meanings that he elsewhere endorsed.

Discussion

The results of this study demonstrate that a secondary mathematics teacher's (David) inattention to quantitative reasoning contributed to his conveying incoherent meanings of angle measure and trigonometric functions. In particular, by not maintaining a consistent emphasis on supporting students in: (1) identifying quantities, (2) attending to units of measure, (3) constructing quantitative relationships, (4) interpreting mathematical symbols and expressions as representing the values of quantities, and (5) performing quantitative—rather than arithmetic—operations, the ways of understanding David's instruction promoted were often inconsistent and even incompatible. Moreover, the meanings David supported varied by context because they were not consistently governed by, or in the service of promoting, a particular way reasoning. These findings suggest implications for secondary mathematics teacher preparation.

While the well-documented affordances of quantitative reasoning on students' conceptual mathematics learning are enough to justify its emphasis in pre- and in-service teacher education, the results of the present study provide an additional incentive for mathematics educators to engage teachers in experiences that advance their ability to reason quantitatively, as well as support them in leveraging quantitative reasoning in their teaching of specific concepts. Specifically, the results of this study suggest that teacher educators should design instructional experiences that allow pre- and in-service teachers to develop the disposition to support students' identification of quantities and quantitative relationships, and their interpretation of mathematical symbols and expressions as representations of a measure of an attribute of some object in some unit, particularly in the difficult context of trigonometry. Equipped with such a disposition, teachers' instructional actions may consistently be in the service of leveraging a powerful way of reasoning to support students' learning of various mathematical ideas while simultaneously promoting the way of reasoning itself. The results of the present study demonstrate that when teachers do not possess a disposition to attend to quantitative reasoning, the circumstances are ripe for instruction that emphasizes inconsistent, incoherent, and sometimes incompatible, mathematical meanings.

Virtual Manipulatives, Vertical Number Lines, and Taylor Series Convergence: The Case of Cody

Matthew Thomas
Ithaca College

Jason Martin
University of Central Arkansas

Evidence from recent Taylor series studies suggests that well-designed virtual manipulatives can support calculus students in developing an understanding of Taylor series convergence consistent with the formal pointwise convergence definition. In particular, virtual manipulatives depicting convergence along vertical number lines (VNLs) provide graphical representations of quantities necessary for pointwise convergence. We detail one student's reasoning about Taylor series convergence before and after a VNL was revealed in a Taylor series graph. Prior to the VNL the student had produced very accurate Taylor polynomial graphs based on visually perceptual clues but had omitted notions of pointwise convergence. After a VNL was revealed, the student's reasoning now included quantities along the vertical as he responded to approximation tasks. We believe that such reasoning can later support the student in developing an understanding of pointwise convergence.

Keywords: Taylor series, virtual manipulatives, quantitative reasoning, calculus, approximation

A recent survey collected from 225 students suggests that well-designed virtual manipulatives (VMs) can help students in developing an understanding of Taylor series convergence consistent with notions from pointwise convergence (Martin, Thomas, & Oehrtman, 2016). In particular, survey results found that students from classes using VMs were significantly more likely than students from classes not using VMs to draw Taylor polynomial graphs with the correct shape, observing general trends indicative of Taylor polynomials becoming better approximations for increasing degrees and Taylor polynomials drawn tangent to the function being approximated. Furthermore, this study observed gains in the number of students mentioning convergent behavior for particular values of the independent variable, x. It is the attention to convergence for particular values of x that is especially important when considering the formal pointwise convergence definition. Graphically, Taylor series convergence for particular values of x can be conceived along vertical number lines (VNLs) to indicate attributes, such as "estimates" and "error," of pointwise convergence. In particular, these attributes are quantities (Thompson, 1994, 2011) of a VNL that the student can anticipate as having values (magnitudes) that can be compared using approximation and error analysis. We ask the question, just because students from VM classes were drawing more accurate graphs depicting Taylor series convergence, does this mean that they were reasoning about Taylor series convergence in a way that was consistent with pointwise convergence, such as reasoning about needed quantities?

In this paper, we expand upon the analysis of the survey and detail one student's reasoning as he interacted with multiple images of Taylor series convergence, including images containing a VNL and a VM. While not necessarily representative of all calculus students, we found that that this student demonstrated similar patterns of understanding displayed by many students from our small sample of interviewed students. His story provides an example of a possible progression of reasoning as he interacted with a VNL and subsequently identified quantities related to pointwise convergence in the context of Taylor series convergence. We use this student to detail possible ways that VNLs might support students in conceiving of and relating relevant quantities related to pointwise convergence and identify how a VM might further support such reasoning.

Taylor Series Literature

A Taylor series for an infinitely differentiable function, f, centered at $x = a$ is given by $\sum_{k=0}^{\infty} \frac{f^{(k)}(a)}{k!}(x-a)^k$. If f is real analytic, then $f(x) = \sum_{k=0}^{\infty} \frac{f^{(k)}(a)}{k!}(x-a)^k$ for all x within the interval of convergence. Taylor series convergence is an example of pointwise convergence where a Taylor series converges to f over an interval of convergence I iff $\forall x \in I$, $\forall \varepsilon > 0$, there is some natural number $N > 0$ such that for all natural numbers $n > N, |f(x) - T_n(x)| < \varepsilon$. While we do not see a need for a calculus student to be able to quote the formal definition of pointwise convergence, our ideal first-year calculus student is a student who can meaningfully discusses Taylor series convergence in a way that exemplifies both symbolically and graphically the quantities and relationships seen within the formal pointwise convergence definition.

Studies investigating students' reasoning about Taylor series repeatedly document student struggles to comprehend this topic (e.g. Champney & Kuo, 2012; Kidron & Zehava, 2002; Kung & Speer, 2010; Martin, 2013; Martin & Oehrtman, 2010). Lack of attending to particular values of the independent variable distinguishes student understanding from expert understanding (Martin, 2013). In addition, students tend to focus on isolated facts and formulaic procedure when reasoning about Taylor series (Martin, 2013). When viewing graphical representations, students often attend to general behavior indicated by the most salient of visually perceptual clues lacking reference to quantities necessary for pointwise convergence (Habre, 2009; Kidron, 2004; Kidron & Zehavi, 2002; Martin, 2013). For example, students might describe Taylor polynomials as "getting closer" to the approximated function without alluding to any meaning of "close" as a measurable distance. In some cases, these perceived attributes are inconsistent with pointwise convergence. For example, while viewing Taylor series graphs, students have been observed noting that a Taylor polynomial and the approximated function were identical over an interval since the two graphs were visually "touching," Oehrtman (2009) referred to this perception as a collapse of error. Instead, a model of limit where Taylor polynomials evaluated at particular values of the independent variable, $T_n(x)$, are viewed as approximations to $f(x)$ with an associated error, $|f(x) - T_n(x)|$, and bound on the error can focus student reasoning on those quantities related to pointwise convergence (Martin & Oehrtman, 2010; Martin, Oehrtman, Roh, Swinyard, & Hart-Weber, 2011; Oehrtman, 2009).

Virtual Manipulatives (VMs) and Taylor Series

Creating Taylor series graphs can be especially time consuming during class. We believe that interactive computer representations, which we call VMs, show potential for not only supporting first-year calculus students in making sense of Taylor series but VMs might also alleviate some of the time constraints felt by instructors attempting to provide their students a much needed graphical understanding of Taylor series.

VMs have already been shown to provide students with a tool to explore and develop mathematical understanding (Moyer-Packingham & Westenskow, 2013). In particular, it has already been demonstrated that VMs can reinforce quantitative relationships that students can recall months later (Cory & Garofalo, 2011). Yet, as already noted concerning graphical images of Taylor series, VMs not using VNLs seem to have little impact on and may reinforce students' persistence in using visually perceptual clues ungrounded in quantitative reasoning (Habre, 2009; Kidron, 2004; Kidron & Zehavi, 2002). We hypothesize that well-designed VMs with VNLs coordinated with approximation tasks can move students away from merely attending to perceptual clues and include reasoning about quantities along the vertical.

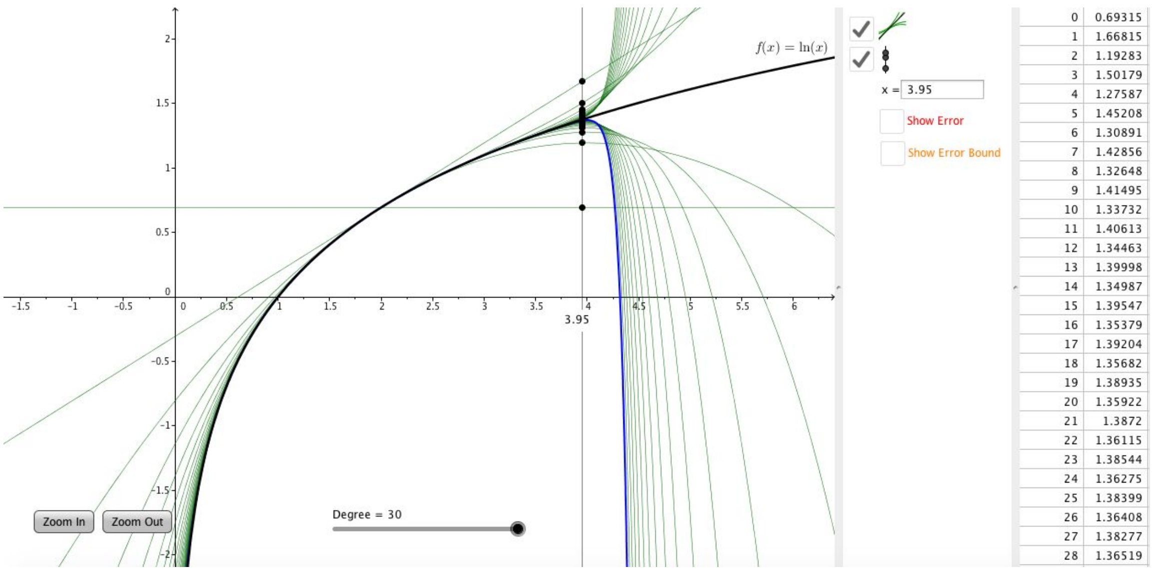

Figure 1. Screenshot of Taylor series VM

Since very little has been done to investigate the effects of VMs on student learning beyond 6th grade (Moyer-Packingham and Westenskow, 2013), research into video lectures provides additional detail that can inform on how to design VMs well. For example, irrelevant details should be removed (Harp & Mayer; 1998; Mayer, Griffith, Jurkowitz, & Rothman, 2008), conceptual difficulties can be explicitly addressed (Boesdorfer, Lorsbach, & Morey, 2011; Muller, 2008; Muller, Bewes, Sharma, & Reimann, 2007), and a series of still frames are preferable over animations in certain situations (Mayer, Hegarty, Mayer, & Campbell, 2005). The VM's provides the student control to show and hide relevant and irrelevant details, to progress through "still frames," and the zoom ability of the VMs was included to explicitly combat a collapse notion of error.

Methods

Cody was one of 225 students who participated in a Taylor series survey (Martin, Thomas, & Oehrtman, 2016), and one of five students who participated in two task-based individual interviews lasting around 60 minutes each. Cody was from a class using VMs to investigate Taylor series convergence during group (referred to as labs) and individual homework approximation exercices (Oehrtman, 2008). Our analysis revealed that in many cases, Cody's reasoning typified the group of interviewed students. For the purpose of this report, we focus exclusively on Cody's evolution of ideas as he progressed through the interview tasks (Figure 2) during the first interview.

1) Using the graph of sin(x) below, on the same axes sketch three different Taylor polynomials for sine. [included a graph of y=sin(x) over the interval [-4π,4π]]
2) Using the graph of sin(x) below, on the same axes sketch the Taylor series for sine. [included a graph of y=sin(x) over the interval [-4π,4π]]
3) The following graph represents a function $f(x)$. [see bottom graph in Figure 4] Graph the first, second, and third degree Taylor polynomials of $f(x)$ centered at x=2. If n is the degree of the polynomial you are graphing, label it $T_n(x)$. (E.g. $T_1(x)$ is the degree one polynomial).
4) What might $T_{1000}(x)$ look like? Add this to the graph above and label correctly. [used same graph as Task 3]
5) What if the series was centered at x=0? On the graph below, graph three Taylor polynomials for the Taylor series centered at x=0 and label correctly. [included a reproduction of the graph seen in Task 3]
6) Explain in detail what it means for a Taylor series to converge.
7) List all the ways in which Taylor series convergence is related to sequence convergence and series convergence if at all. Make sure your explanations reference a. Formulas when appropriate and b. Includes a graphical explanation that highlights sequences and/or series on your graph. (That is, add to the graph to appropriately highlight sequences and/or series convergence as it relates to Taylor series convergence.)
8) [Given graphs including a sequence of Taylor polynomials] The Taylor series for $g(x) = ln\, x$ centered at x=2 is given by $ln\ 2 + \sum_{k=1}^{\infty} \frac{(-1)^{k+1}}{k \cdot 2^k}(x-2)^k = ln\ 2 + \frac{1}{1\cdot 2}(x-2) - \frac{1}{2\cdot 4}(x-2)^2 + \frac{1}{3\cdot 8}(x-2)^3 \mp \cdots$ and the degree n Taylor polynomial is given by $T_n(x) = ln\ 2 + \sum_{k=1}^{n} \frac{(-1)^{k+1}}{k \cdot 2^k}(x-2)^k = ln\ 2 + \frac{1}{1\cdot 2}(x-2) - \frac{1}{2\cdot 4}(x-2)^2 \pm \cdots + \frac{(-1)^{n+1}}{n \cdot 2^n}(x-2)^n$ a. The radius of convergence of this Taylor series is (0,4]. Speculate on why it diverges beyond this radius. b. Use the graph to explain $T_n(3.98)$. c. Use the graph to approximate ln (3.98).

Figure 2. Sample interview tasks.

Question 1.	What are you approximating?
Question 2.	What are your approximations? Which are overestimates? Which are underestimates?
Question 3.	What is the error for any one approximation?
Question 4.	What is error bound?
Question 5.	Can you find an approximation accurate to within 0.04 of what you are approximating?

Figure 3. Common approximation question repeated throughout images.

Prior to Task 8, Cody only produced graphs, but during Task 8, Cody was provided graphs as he advanced through static, animated, and VM depictions of Taylor series convergence while responding to approximation questions adopted from Oehrtman (2008) (Figure 3). In addition, Cody first viewed three static images, starting with a standard Taylor series graph and progressed through two more images with VNLs (one without error and one image with error depicted). Likewise, the VM did not initially show a VNL but Cody had the option to make a VNL visible. While viewing each depiction, Cody was repeatedly asked to "show" the interviewer on the image his responses to the approximation questions. The data was coded for indicators of quantitative reasoning and changes in how Cody was reasoning were tracked relative to the type of depiction (e.g., VNL or no VNL) he was viewing. In addition, commonalities and differences in reasoning employed by Cody between the VNL depicted on the sequence convergence VM and the any VNL depicted in Taylor series convergence was noted.

Results

Thinking Prior to VNL and VM

When first encountering the Taylor series' tasks, Cody's actions were dominated by often unfruitful attempts to remember facts and relationships from class. His remembrances were frequently peppered with comments expressing uncertainty, such "I guess" or "I'm not really sure." When graphing Taylor polynomials, Cody consistently produced linear, quadratic and polynomial shapes (Figure 4). He noted general trends, such as even and odd degree Taylor polynomials alternate between being "above" and "below" the the approximated function or that as "as you go further on in the exponents [while making a rightward chopping motion gesture with right hand] you start to, you add a curve each time [...]"

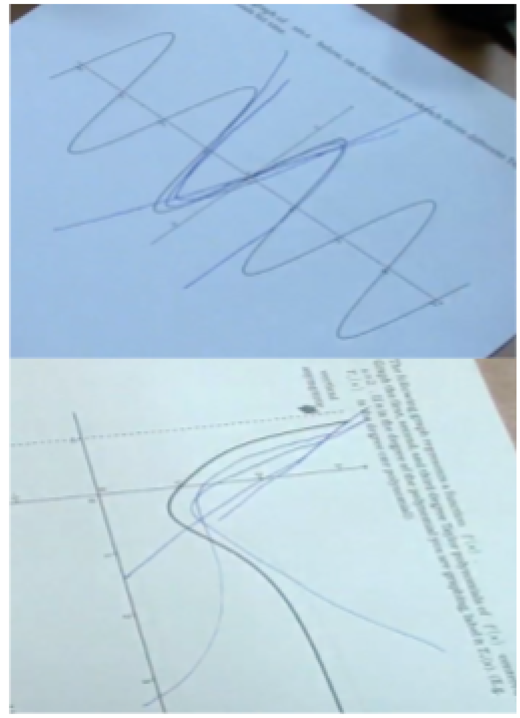

Figure 4. Images of Task 1 (top) and Task 3 (bottom)

For Cody, convergence was achieved by Taylor polynomials "approaching" the approximated function via two methods: a vertical transformation and an increasing interval over which polynomials become more accurate. Thus, small degree Taylor polynomials need not be tangent to the approximated function (note the Task 3 Image in Figure 4) but as degree increases, a vertical transformation causes the the larger degree polynomials to better approximate the given function. For example, for T_{1000} Cody drew a polynomial that traced the approximated function over a large interval. It should be noted that throughout the early interview tasks, Cody did not attend to convergent behavior for particular values of x. When explicitly asked to explain what it meant for a Taylor series to converge, he expressed confusion about the object to which the Taylor series converges, "Taylor series converging is, I guess, when it's approaching one certain...not a point...but it's approaching a number." Although he seemed to indicate convergence to a point, at no moment were his references explicitly coordinated with particular values for x, and his later choice to use "line" as a reference to the function instead of "point" or "number" suggests that his uses of "point" and "number" were purely metonymic. "As you go further and further, you go up to infinite number, or infinite powers you would start approaching that number that you're ideally trying to estimate, or the line that you're trying to estimate." Without any vertical number line visible, he continued to describe Taylor series convergence using general graphical trends.

Introducing the VNL in a Static Image

Once a VNL was visible, Cody's reasoning became structured by the vertical as evidenced by his gestures becoming almost entirely restricted to either points or quantities contained within the VNL. When presented with the first static image displaying a VNL, Cody immediately identified the VNL as providing vertical distances from the graph of ln(x). He then began to indicate points as answers to previous tasks. For example, “I guess this is, this point right here [pointing to where ln(x) and the vertical number line intersected] is ln(3.98). I guess we are approximating just that point.” When asked how to determine numerical values for the approximations, he connected the formula to the graphical representation by first gesturing vertically between the appropriate points on the VNL and saying “as you have more of these terms involved [points to the formula] it becomes closer and closer, you’d eventually will get pretty damn close, but I can’t tell exactly what the point is here [gesturing horizontally from the point (2, ln 2) to the location of ln 2 on the y-axis].” He continued with his horizontal gestures as he indicated approximations as points on the vertical number line paired with values on the y-axis.

When prompted to discuss error, he immediately stated that error was the “distance between the approximation and the actual” and then included a graphical quantity by pointing at the point (3.98, ln(3.98)) on the graph and described error as the distance between that point and “any of these points,” gesturing towards all the other points on the VNL. When asked whether it would be possible to approximate the value of ln(3.98) to within 0.04, Cody responded that one could “keep adding” terms, gesturing to the right to indicate a formula growing as if he were appending terms, causing the Taylor polynomials to “get closer and closer” while gesturing vertically over the vertical number line. While tracing a curve, Cody said “I guess, for it to converge it would have to approach the equation you are trying to estimate or for the point to approach, [now focusing on the vertical number line] the point you’re, so yeah, to approach the point you’re trying to estimate. So as these get closer and closer, [waving over the approximation points on the VNL] and that would be the convergence for the series as it opposed to that [referring to his previous answers on Tasks 5 and 6].”

Introducing the VM

Once Cody was interacting with the VM, he began exploring by clicking through the check boxes and then changing the degree of the Taylor Polynomial. He changed the x-value for the VNL to 3.98 and changed the value for the error bound (but not initially to 0.04). He later zoomed in on the graph at $x = 3.98$, and then changed the value for the error bound again, this time to 0.2. He expressed concern about the error bound, saying that he didn’t “know how you determine...the length of the orange line.” After more investigation, he became more comfortable with the orange line, noting “that it helps gage how far apart some of these are,” essentially describing an error bound despite his discomfort with the notion of an error bound as anything other than a difference between an overestimate and an underestimate. When asked whether he could find an approximation to within 0.04, without hesitation he changed the value in the error bound to 0.04, and pointed to the points within the boundaries set by the value of the error bound.

Earlier in the interview while looking at a static image containing a VNL, Cody’s language seemed indicative of a collapse of error, but when explicitly asked by the interviewer if the Taylor polynomial ever became the approximated function, Cody clearly stated that approximations “never fully reach” the exact value and that nonzero error remained. Later, Cody used Geogebra ability to zoom with images of large degree Taylor polynomials to visually justify that error remained.

Revision of Definition of Convergence

On his own initiative, Cody revisited his explanation to what it meant for a Taylor series to converge, Task 6. Cody now attempted to reconcile function convergence with his emerging notion of VNL convergence.

> "I guess, for it [tracing over $y = \ln(x)$] to converge, it would have to approach the equation you are trying to estimate, or for the point to approach [focusing on the VNL] [...], to approach the point you're trying to estimate. So as these get closer and closer [waving over the approximation points on the VNL], and that would be the convergence for the series, as it opposed to that [Taylor series]. [Cody added a VNL to a Taylor series graph he produced when first responding to Task 6.]"

Instead of repeating prior explanations, Cody indicated function convergence as approaching "the point you're trying to estimate" and made a change from a horizontal gesture of tracing over $y = \ln(x)$ to a vertical gesture for convergence at a point by waving over approximation points on the VNL. In addition, his use of "the point you're trying to estimate" might be indicative of a recognition that different values of the independent variable, x, would influence convergence. Furthermore, Cody related convergence to a point with merely a "series" and not a Taylor series, indicating that he was conceiving of graphical, and not merely symbolic, connections between series and Taylor series.

Discussion

After seeing the VNL, Cody framed his thinking in terms of the visible "dots" on the VNL. Even when his gestures included horizontal movements to the y-axis, his gestures began with the approximating "dots." While Cody was indicating the corresponding y-values for these "dots," there was no evidence that he was thinking of these locations as quantities in the sense of being a vertical distance from the x-axis. Vertical distances appeared in the context of error and error bound as Cody described "distances" from the graph of $y = \ln(x)$ to the "dots" on the VNL. And although Cody had not indicated these "dots" as vertical distances, the "dots" served a references for establishing quantities.

In addition to using the zoom feature to combat collapse, the impact of the VM on Cody's conception of convergence became clear in the second interview when Cody was asked to find an approximation to within 0.04 of the actual value while viewing a static image. Cody responded that he could, if he had a "slider." While his description of Taylor series convergence had clearly improved, in that moment, the VM was a part of his mental image of convergence.

Cody's experiences with the VNL and VM provide complementary evidence to that presented previously by Martin, Thomas, & Oehrtman (2016). While this work indicated that students in classrooms with VMs were more likely to answer questions about Taylor series convergence correctly, Cody's experiences give us some notions of how these VMs may be transforming the students' conceptions of convergence. While Cody's reasoning has room to grow, he provides insight into the kinds of positive learning experiences that can be fostered using these VMs.

Developing Students' Reasoning about the Derivative of Complex-Valued Functions with the Aid of *Geometer's Sketchpad (GSP)*

Jonathan Troup
University of Oklahoma

In this paper, I share results of a case study describing the development of two undergraduate students' geometric reasoning about the derivative of a complex-valued function with the aid of Geometer's Sketchpad (GSP). My participants initially had difficulty reasoning about the derivative as a rotation and dilation. Without the aid of GSP, they could describe the rotation and dilation aspect of the derivative for linear complex-valued functions, but were unable to generalize this to non-linear complex-valued functions. Participants' use of GSP, speech, and gesture assisted with discovering function behavior, generalizing how the derivative describes the rotation and dilation of an image with respect to its pre-image for non-linear complex-valued functions, and recognizing that the derivative is a local property.

Introduction

In the calculus reform era, a main goal was to develop students' conceptual understanding of calculus by integrating algebraic and geometric reasoning (Asiala, Cottrill, Dubinsky, & Schwingendorf, 1997; Lauten, Graham, & Ferrini-Mundy, 1994; Meel, 1998). While similar research has been conducted in other mathematical content domains, there is less research in complex analysis, which allows potential for geometric reasoning. The purpose of this research was thus to address two research questions: What is the nature of students' reasoning about the derivative of complex-valued functions, and what role does *GSP* play in developing students' geometric reasoning about the derivative of complex-valued functions (i.e., the *amplitwist*)?
For my work, I adopted the National Council of Teachers of Mathematics' (NCTM, 2009) *reasoning* definition, which is "the process of drawing conclusions on the basis of evidence or stated assumptions" (p. 4), and is categorized as algebraic or geometric. *Algebraic reasoning* involves symbolic manipulation, and *geometric reasoning* involves spatial elements. I also refer to inscriptions, which Roth and McGinn (1998) define as "signs that are materially embodied … and because of their material embodiment, inscriptions (in contrast to mental representations) are publicly and directly available, so that they are primarily social objects" (p. 37).

Literature Review

In this section, I summarize literature on students' reasoning in the realm of complex analysis, and the benefits of DGEs on students' reasoning. As these domains draw on gesture as evidence for reasoning, I conclude this section by synthesizing related gesture research.

The Teaching and Learning of Complex Numbers

There has been a recent increase in educational studies focusing on complex numbers (Danenhower, 2006; Harel, 2013; Karakok, Soto-Johnson, & Anderson-Dyben, 2014;

Nemirovsky, Rasmussen, Sweeney, & Wawro, 2012; Panaoura, Elia, Gagatsis, & Giatilis; 2006; Soto-Johnson, 2014; Soto-Johnson & Troup, 2014). The results of these studies show that participants struggle to reason geometrically about complex numbers. In brief, Panaoura et al. found that high school students had difficulty transitioning between algebraic and geometric reasoning, while Danenhower showed undergraduate mathematics majors could not convert $\frac{a+ib}{c+id}$ to exponential or Cartesian form. Applying Sfard's (1991) duality principle. Karakok et al. saw that teachers displayed a process/object duality of the Cartesian form, but only an operational level of the exponential form. Harel (2013) noted that teachers were unable to attach a geometric meaning to the addition and multiplication complex numbers.
However, reasoning via embodied cognition may help students reason geometrically about complex analysis. Nemirovsky et al. (2012) observed that through the usage of a "floor tile" representation of the complex plane and stick-on dots and string to represent complex numbers, pre-service teachers discovered multiplying by i corresponds to a rigid 90° rotation. Soto-Johnson and Troup (2014) also found that undergraduates integrated their algebraic and geometric reasoning while drawing a representative diagram.

Dynamic Geometric Environments

In contrast with complex analysis research, research on educational technology is abundant. Some suggest that technology can cause harm by promoting overgeneralizations (Clements & Battista, 1992; Olive, 2000) or an over-reliance on technology (Salomon, 1990). Alternatively, technology can help students and teachers refine mathematical ideas (Arcavi & Hadas, 2000; Barrera-Mora & Reyes-Rodríguez, 2013; Heid & Blume, 2008; Hollebrands, 2007; Jones, 2000; Olive, 2000; Tabaghi & Sinclair, 2013; Vitale, Swart, & Black, 2014) without relying on mathematical authorities such as teachers or textbooks. DGEs such as *Geogebra* have been shown to help develop concepts related to real-valued differentiation (Hohenwarter, Hohenwarter, Kreis, and Lavicza, 2008; Ndlovu, Wessels, and De Villiers, 2010). Salomon (1990) suggested that DGEs may help students by providing multiple representations of mathematical objects. Hollebrands (2007) and Olive (2000) contend that *GSP* makes abstract ideas appear more concrete, which could help students ground reasoning in the physical environment. For example, Tabaghi and Sinclair (2013) found that while interacting with an eigenvector sketch in *Sketchpad*, students reasoned via gesture.

Gesture

Many (Alibali & Nathan, 2012; Goldin-Meadow, 2003; Keene, Rasmussen, & Stephan, 2012; Roth, 2001) believe "gestures can be used as a window into what students in a classroom are thinking" (Keene et. al., p.367). Others suggest diagrams and gestures inform each other (Châtelet, 2000; Chen and Herbst, 2013). For example, a vector could express the result of the multiplication of two complex numbers and a flick of the wrist could convey the associated rotation and dilation (Soto-Johnson & Troup, 2014). Some also state gesture and speech form a single, integrated system to support both visual and verbal content (Alibali & Nathan, 2012; Goldin-Meadow, 2003; Keene et al., 2012; Roth, 2001). For example, Goldin-Meadows found gesture aids memory and the ability to describe it, while restricting gesture hampers this ability. Some literature suggests gesture can transform over time from primarily representative to primarily pointing as students become more familiar with mathematical procedures (Alibali & DiRusso, 1999; Soto-Johnson & Troup, 2014; Garcia & Engelke, 2012; Marrongelle, 2007; Soto-Johnson and Troup, 2014). Garcia and Engelke (2012) also noticed that their undergraduate participants gestured more frequently when they were stuck on a task. Vitale et al.'s (2014) participants initially gestured to remind themselves of a geometric concept, but transitioned into using gesture as a validation tool. The students additionally interacted with virtual representations of spatial gestures, which resembled their "real" gestures.

Given that gesture may result from explorations with technology (Tabaghi & Sinclair, 2013) and that gesture can arise organically, it was critical to adopt a framework that would be sensitive to this phenomenon. Thus, I employed embodied cognition as my theoretical perspective, which allowed me to interpret my participants' reasoning via gesture and actions taken within a DGE. In the next section I summarize my interpretation of embodied cognition.

Theoretical Perspective

Embodied cognition is mainly concerned with the relationship between reasoning and actions within the physical environment (Anderson, 2003), though the nature of this relationship differs between researchers. While some suggest embodied cognition is a tool for mental cognition, (Alibali & Nathan, 2012; Lakoff & Nuñez, 2000; Wilson, 2002), others dispense with mental models entirely by equating reasoning with body-based activity, such as is found in Nemirovsky's (2012) fluid "realm of possibilities." Under the second view, bodily experience is itself an inextricable part of the learning process. So, one view is concerned with mental models influenced by embodied action, while the other focuses on personal experience. These views do not seem entirely incompatible; an impersonal description of pain as "the firing of C-fibers" (Nemirovsky et al., 2012, p. 2) neither invalidates nor takes precedence over someone's personal experience with pain. Similarly, postulations about the cognitive way the mind responds to bodily actions may not be contradictory to inferences made about a learner's experience. I align more closely with this second viewpoint. Similar to Soto-Johnson and Troup (2014c), I interpret embodied cognition to include bodily actions taken within the physical environment. I believe perceptuo-motor activity (including DGE activities) can influence reasoning and that reasoning can influence bodily actions. Rather than postulate any cognitive mechanisms, I simply suggest a relationship between how my participants utilized DGEs, gestures, and inscriptions. Particularly, participants reasoned with *GSP* via construction and manipulation of geometric inscriptions and via the production of virtual gesture through mouse movement. Thus, I take this reasoning and participants' usage of *GSP*, gestures, and inscriptions to be inseparable.

Methods

This report is a summary of my Ph.D. thesis. Thus, in this section, I describe some of the aspects of research performed, including participant selection, task design, and data analysis.

Setting and Participants

To help with participant selection and triangulation, I attended complex analysis class sessions related to the derivative. I video-recorded these classes and took notes paying particular attention to gestures employed. Four students agreed to participate in my study, who I refer to as Christine, Zane, Edward, and Melody. I conducted two sets of interviews, one with Christine and Zane, and another with Melody and Edward. Each group worked on tasks over four non-consecutive days. Each interview lasted two hours.

Concept Analysis of *Amplitwist*

Within the context of real-valued functions, the derivative function has a well-recognized geometric interpretation as the slope of a tangent line. However, as the graph of a complex-valued function is four-dimensional, the generalization of this concept is not straightforward. To help overcome this problem, one can represent the graph of a complex-valued function as two sets of axes: one for domain and one for range. Thus, graphing a complex-valued function can be represented as a transformation $f: C \rightarrow C$. In describing the derivative of a complex-valued function geometrically, Needham (1997) considers how a complex-valued function maps an extremely small circle centered about the point z in the domain. "The length of $f'(z)$ must be the magnification factor, and the argument of $f'(z)$ must be the angle of rotation," (p. 196) a concept that Needham refers to as an *amplitwist*. Needham further elaborates that the derivative of a complex-valued function provides a linearization that locally approximates the function, as "'expand and rotate' is precisely what multiplication by a complex number means" (p. 196).

The Tasks

The overall goal of the tasks I developed for my interview sequences was to encourage reasoning about the derivative of a complex-valued function as described by Needham's (1997) concept of an amplitwist. I utilized tasks developed from a previously conducted pilot study.

In Tasks 1 and 2, students followed instructions on a lab worksheet to construct the function $f(z) = z^2$ and $f(z) = e^z$ with the aid of *GSP* and predict how the function maps points, lines, circles, and the complex plane (see Appendix B). The goals of this task were for participants to establish proficiency with *GSP* and determine the mapping of circles under a complex-valued function. For Task 3 I prepared the linear complex-valued function $f(z) = (3 + 2i)z$ with a complex-valued derivative in order to reduce the likelihood that students reasoned that the real part of the derivative is a dilation factor and the imaginary part of the derivative is a rotation factor. I asked participants to describe their geometric reasoning about the derivative of a complex-valued function both with and without *GSP*, and to use $f(z) = (3 + 2i)z$ to demonstrate. I re-introduced *GSP* later to allow them to test their conjectures and continue to explore their reasoning. The purpose of this task was to help participants relate the magnitude and argument of the derivative to the way the linear function dilates and rotates a circle. In Task 4, I asked participants to generalize their reasoning from Task 3 to the functions from Tasks 1 and 2 as well as the functions $f(z) = z^2$, $f(z) = e^z$, and $f(z) = \frac{1}{z}$. The goal of this exercise was to support students' efforts to generalize the geometric reasoning they developed in Task 3 to the general case. Finally, in Task 5, I asked students to determine the value of a derivative at a particular point for the rational transformation $f(z) = \frac{(2z+1)}{(z+i)(1-z)}$. I gave them only geometric information about a rational transformation, and asked them to use this information to reconstruct the algebraic formula. The goal of this task was to encourage students to develop reasoning about the derivative as a local property and to develop reasoning about points of non-differentiability as they relate to the amplitwist concept.

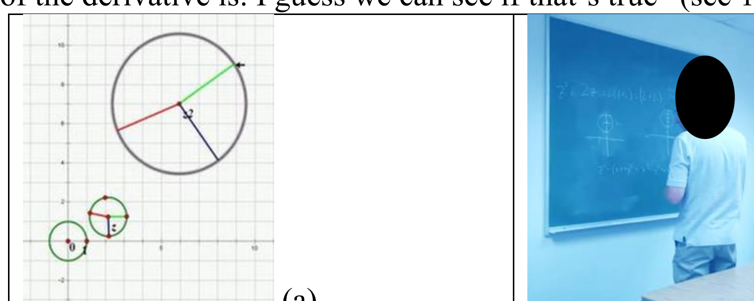
Data Collection and Analysis

To obtain data, I video-recorded class sessions the instructor deemed relevant. I recorded all interviews with both a camera to capture gesture and screen-capture software to record actions taken with *GSP*. My analysis began by watching the videos in conjunction with the screen-captured *GSP* recordings to determine where the participants appeared to be making progress

toward a conception of the derivative of a complex-valued function as a local linearization. I transcribed all recorded gesture, speech, and usage of inscriptions, after which I coded lines as algebraic or geometric based on this data. Then, I wrote summaries of each day for each set of participants wherein I detailed the progression of selected events.
Finally, I performed both a cross-case and within-case (Merriam, 2009; Patton, 2001) analysis on the written summaries, referencing both the Excel spreadsheet and the actual raw data as needed.

Results and Discussion

My findings suggest that *GSP* helped my participants generalize how the derivative describes the rotation and dilation of an image with respect to its pre-image for non-linear complex-valued functions. Furthermore, asking participants to construct an algebraic formula from geometric data served as a reminder that the derivative is a local property.
For the first two tasks, I did not ask the participants anything about the derivative. Rather, I asked them to construct the function $f(z) = z^2$ for Task 1, and $f(z) = e^z$. In the process, I answered their questions about how to use *GSP*, and asked them questions about how the function mapped various circles. During this questioning, both groups noted that circles mapped to other roughly circular shapes, and recalled that t points "rotate" and "dilate" or "stretch" when multiplied by a complex-valued function. They did not appear to say anything about rotation and dilation in conjunction with the derivative of a complex-valued function, however. Rather, Christine states simply, "I don't know like what slope means in complex world,"
When participants reasoned about the geometry of a linear complex-valued function $f(z) = (3 + 2i)z$ in Task 3, they verbalized that the function maps a circle to another circle which is rotated by the argument of $3 + 2i$) and dilated by $|3 + 2i|$ with respect to the original circle. While Melody and Edward made this observation in Task 3, Christine and Zane did not verbalize this same point until Task 4, although they did mention that the "stretch" and "rotation" factors do not change (see **Error! Reference source not found.**(a)). Melody and Edward observed, "the derivative is rotating this consistently wherever it is and then it's expanding it out whatever the length of the derivative is. I guess we can see if that's true" (see 1(b)).



(a) (b)

Figure 1: $\boldsymbol{f(z) = (3 + 2i)z}$ transforms green input circle and spokes to blue output circle and spokes of corresponding color (a) and Edward transforms a circle under $\boldsymbol{z \to 2z}$ (b).

Later, during Task 4, Melody adds gesture to their description:

Melody: Like the center (points at $(2,0)$) would be at 2? So the center of the circle doesn't necessarily depend on the derivative. Like where the output one is located doesn't depend on the derivative (curls fingers slightly into claw (see Figure 2(a)), beats toward screen while moving arm counterclockwise in an upper circular arc) The output one is just the size (hand makes claw shape, extends fingers outward and back in) of it and (twists hand first clockwise like a doorknob (see Figure 2(b)) then back counterclockwise) the rotation not the, like the location would depend on the z squared.

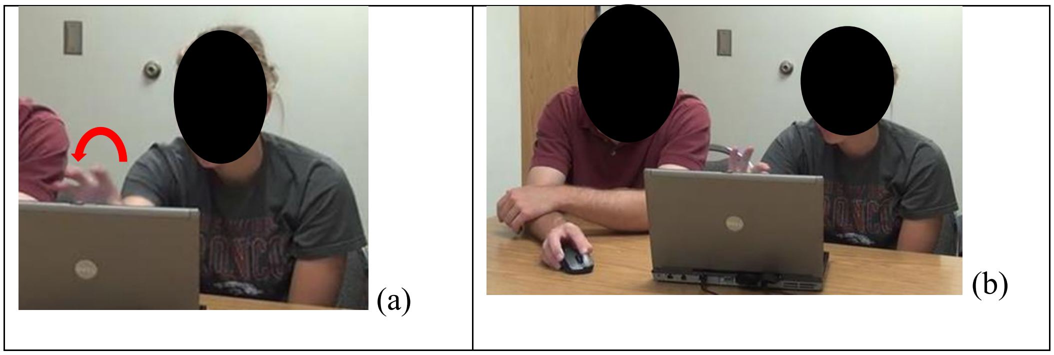


Figure 2: Melody produces a “claw-like” gesture for dilation (a) and produces a “doorknob” gesture for rotation (b).

One of the most interesting findings resulted from Task 5, wherein participants utilized geometric data to construct an algebraic formula for a rational function. In this task, Edward and Melody explicitly connected strange output behavior to non-differentiable points, stating, “that can’t be differentiable there…It’s weird” (see Figure 3). At this point, Edward was able to verbally reason geometrically about what made a point differentiable, by stating, “okay, so to know if this is differentiable, we want to kind of know when, where, goes to, small circle goes to small circle.” This utterance is an atypically precise geometric description of the fact that the derivative is a *local* property. It was during this task that participants most precisely characterized the derivative as a local property. Note that only Edward and Melody accomplished this task, as Zane and Christine progressed more slowly through the tasks.

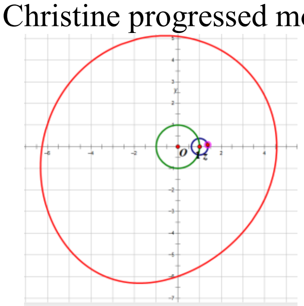

Figure 3: Edward and Melody zero in on a non-differentiable point.

Overall, I answer the two research questions listed above in the following ways. To answer the first, I argue that my participants reasoned about the derivative of a complex-valued function via embodied cognition in three distinct ways. In particular, they grounded their algebraic and geometric inscriptions via gesture and speech as in Goldin-Meadow (2003) (see leftmost cycle in Figure 4), integrated their algebraic and geometric reasoning methods via these inscriptions as in Soto-Johnson and Troup (2014) (see center cycle in Figure 4), and grounded these reasoning methods in both the real and virtual environments as in Hollebrands (2007), Olive (2000), and Tabaghi and Sinclair (2013) (see rightmost cycle in 4. To answer the second question, I detail three developments in reasoning which arose during their work with *GSP*, and seemed critical to my participants’ reasoning about the derivative.

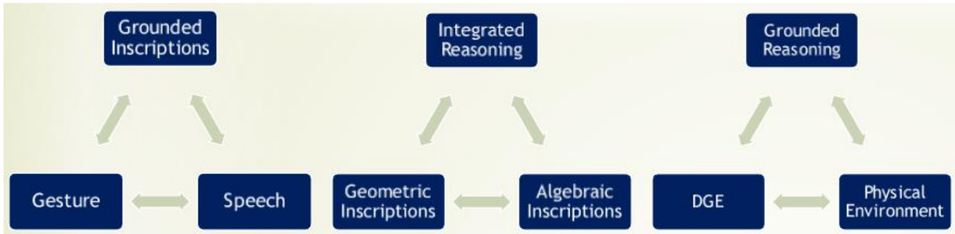

Figure 4: Integration through Embodied Cognition.

These three developments are as follows. First, my participants recognized a need for a geometric characterization of linear complex-valued functions, which was supported by grounding algebraic and geometric inscriptions via gesture and speech. Many of these inscriptions were displayed by *GSP*. This development allowed participants to begin extending their reasoning about real-valued functions to the complex-valued case. Second, my participants reasoned geometrically that linear complex-valued functions rotate and dilate every circle by the same amounts $Arg\left(f'(z)\right)$ and $|f'(z)|$, respectively. Finally, the participants observed small circles map to small circle-like objects under any complex-valued function.

Concluding Remarks

Thus, it appears that in my case study, gesture, DGEs and speech really did work together to aid students in developing reasoning about the derivative of complex-valued functions. I conclude by describing some possible teaching implications and directions for future research.

Teaching Implications

The findings described above suggest a few implications for teaching the derivative of a complex-valued function. First, it demonstrates potential learning trajectory for students seeking to develop their geometric reasoning about the derivative of a complex-valued function. In particular, my students first developed reasoning about the geometry of lines in $\mathbb{C}$, then reasoned geometrically about a constant derivative in terms of rotation and dilation, and finally reasoned about the need to reason specifically about small circles. Second, it suggests that my students worked beneficially with DGEs when placed in pairs and allowed some opportunity for free exploration of related algebraic and geometric reasoning, as in Olive (2000). Finally, my research suggests that it may be helpful to direct students' focus to key points over the course of their mathematical investigations, even when aided by a dynamic geometric environment (DGE).

Future Research

One possible direction for future research is to increase the breadth of these results by implementing dynamic geometric environments (DGEs) on a large scale in real classrooms and collecting quantitative data on student performance on tasks related to reasoning about the derivative of a complex-valued function as an amplitwist. Such research would theoretically allow these or related results to achieve some level of generality. Another possible direction is to increase depth of the results in this case study by iterating on the last task specifically. My participants reported beneficial effect from constructing algebraic information from exclusively geometric information from *GSP*, so further research on the effects of similar tasks for other students could prove highly interesting.

Calculus Students' Reasoning about Slope as a Ratio-of-Totals and its Impact on Their Reasoning about Derivative

Jen Tyne
University of Maine

Although studies have shown that students have difficulty with slope and derivative concepts, little is known about connections between these difficulties. In this study, written surveys and clinical interviews were used to examine students' understanding of both slope and derivative in real-life contexts. The dominant incorrect reasoning was thinking of slope as the ratio-of-totals $\left(\frac{y}{x}\right)$ *instead of the ratio-of-differences* $\left(\frac{\Delta y}{\Delta x}\right)$. *This incorrect thinking about slope influenced students' understanding of derivative. Thinking of slope as a ratio-of-totals implies that all linear relationships are directly proportional. Students interpreted slope as something that can be used to calculate values of dependent variables (by multiplying them by the value of the independent variable). As a result, they often interpreted the derivative as something that could be used to find the value of dependent variables (by multiplying the derivative by the value of the independent variable), implicitly using the incorrect relationship* $f(x) = f'(x) * x$.

Key words: Calculus, Application of Derivative, Rate of Change, Slope, Student Understanding

Introduction and Research Questions

A robust understanding of derivatives and instantaneous rates of change in calculus requires understanding slope and average rate of change (Hackworth, 1994). Calculus students may not have the robust understanding of slope and rate of change that instructors assume, which has consequences for their learning. It is thus important for instructors to be alert to students' understanding of slope coming into calculus so derivative instruction can be designed that expands on that knowledge. Furthermore, students must understand not only instantaneous rates of change but also continuously changing rates. This covariational reasoning is essential for interpreting dynamic function situations (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002).

My work builds on research about student understanding of slope and rate of change (Barr, 1980, 1981; Orton 1984; Stump, 2001); rates of change involving and not involving time (Stump, 2001); derivatives (Bezuidenhout, 1998; Ferrini-Mundy & Graham, 1994; Zandieh, 2000); rates of change of linear and non-linear functions (Orton, 1983), and how students' knowledge of rate of change was affected by derivative instruction (Hackworth, 1994). Findings from these studies indicate that students have difficulty understanding slope as a constant rate of change and derivative as an instantaneous rate of change.

This study investigates students' interpretation and use of slope and derivative in real life contexts. Such applications problems require students to translate from the context to the abstract level of calculus and then back to the context, a process that requires conceptual knowledge (White & Mitchelmore, 1996). Educators have emphasized the utility of these sorts of problems, noting that "not only do real-world situations provide meaningful opportunities for students to develop their understanding of mathematics, they also provide opportunities for students to communicate their understanding of mathematics" (Stump, 2001, p. 88).

There has not been much research on students' interpretation of the derivative as a rate of change, students' interpretation of slope as a constant rate of change, or students' understanding of the differences in making predictions involving constant and instantaneous rates of change.

Knowing more about students' understanding of slope and derivative as rates of change can help improve our instruction by helping educators build better derivative instruction based on students' knowledge of slope. Improving instruction is one way to retain more STEM majors, an overall goal of the mathematics education community (Holdren & Lander, 2012)

Building on prior research on students' difficulties with slope and derivative, this study focuses on the connections between students' verbal interpretation of slope and their verbal interpretation of the derivative. It also probes students' abilities to critique the reasoning of others, a Standard of Mathematical Practice in the Common Core (National Governors Association Center for Best Practices, 2010). These were assessed with questions focusing on the appropriate use of rate of change to make a prediction. Both are new research areas at the college level, and led to the following research questions:

- Is there a relationship between calculus students' understanding of slope and their understanding of derivative? Specifically, do students' abilities to correctly interpret the slope as a constant rate of change make them more likely to be able to interpret the derivative as an instantaneous rate of change?
- Given predictions based on slope and derivative, can students appropriately critique the reasoning used to make the predictions?

Methodology

I collected written solutions from 69 students enrolled in differential (i.e., first semester) calculus classes at a public university in the northeast. Students were approximately 80% through the course. I then performed follow-up clinical interviews (Hunting, 1997) with thirteen students during the first half of second-semester calculus; eight had completed the written survey the previous semester. My research approach, an analysis of student understanding gained from direct students responses, is consistent with a cognitive theoretical perspective and is well established in the mathematics education community (Byrnes, 2000; Siegler, 2003).

The survey and interview questions were based on linear and non-linear one-variable relationships, concepts likely familiar to first-year calculus students. Sample questions are shown in Figure 1. The questions about linear relationships were posed to gain insight into students' knowledge of predictions based on linear change. These questions were adapted from a general education textbook written to emphasize conceptual understanding (Franzosa & Tyne, 2010). To answer these questions, students must understand linear change as a constant rate of change. The questions about nonlinear relationships were more complex, and were adaptations from *Calculus, 6th edition* (Hughes-Hallet et al., 2013). To answer these questions, students must understand the derivative as an instantaneous rate of change that can be used to predict marginal change, and that the derivative *cannot* be used to make predictions at other input values.

Answers were coded as correct or incorrect. To investigate possible relationships between performance on linear and non-linear questions, 2x2 contingency tables were used to examine combinations of right and wrong answers. A sample table is shown in Table 1, which presents the survey data comparing the critiquing linear questions and the critiquing non-linear questions.

The focus in the contingency tables is on the shaded diagonal cells, namely those students who got exactly one of the questions correct. I performed McNemar's test on each table, testing whether there was an asymmetry in the success levels of students (Agresti, 2007). The outcome of this test reveals relationships between correctness on the two questions. In the case of the example in Table 1, the significant McNemar test results signify that students performed significantly better on the linear slope critiquing questions as compared to the non-linear derivative critiquing questions. After performing McNemar's test, I then used a modified Grounded Theory approach (Strauss & Corbin, 1990) to categorize common incorrect responses from the unit, interpretation, and critiquing questions (Figure 1). The categories that emerged from this analysis formed the basis of my interview questions.

For certain drugs, the amount of dose given to a patient, D (in milligrams), depends on the weight of the patient, w (in pounds).

A. Assume that D(w) is a linear function with a slope equal to 2 (m = 2).
 0. On the graph below, give a rough sketch of what the function D(w) looks like. Label the axes, but no need to scale them.
 1. What are the units on the slope, m = 2?
 2. Explain what this slope (m = 2) means in the context of the problem.
 3. Using the slope (m = 2), Nurse Jodi predicts that a patient's dose will increase by 2 mg when the patient's weight changes from 140 pounds to 141 pounds. How much confidence do you have in her reasoning? (circle one and provide explanation)
  Very Confident   Somewhat Confident   Not Confident
 4. Nurse Jodi accurately doses a 140-pound patient using the model. Her next patient is twenty pounds heavier and she reasons that she must increase the dose by 40 mg (2 mg for each pound of weight). How much confidence do you have in her reasoning? (circle one and provide explanation)
  Very Confident   Somewhat Confident   Not Confident

B. Now, assume D(w) is a non-linear function.
 0. On the graph below, give a rough sketch of what the function D(w) might look like.
 1. What are the units on $\frac{dD}{dw}$? (also known as $D'(w)$)
 2. Explain the meaning of the statement $D'(140) = 2$ in the context of the problem.
 3. Using the fact that $D'(140) = 2$, Nurse Jodi predicts that a patient's dose will increase by 2 mg when the patient's weight changes from 140 pounds to 141 pounds. How much confidence do you have in her reasoning? (circle one and provide explanation)
  Very Confident   Somewhat Confident   Not Confident
 4. Nurse Jodi accurately doses a 140-pound patient using the model. Her next patient is 160-pounds and she reasons that since $D'(140) = 2$, she must increase the dose by 40 mg (2 mg for each pound of weight). How much confidence do you have in her reasoning? (circle one and provide explanation).
  Very Confident   Somewhat Confident   Not Confident

Figure 1. The interview instrument.

	Non-Linear Context			
		Correct	Incorrect	Total
Linear Context	Correct	30%	39%	69%
	Incorrect	3%	28%	31%
	Total	33%	67%	N=69

Table 1. 2x2 contingency table for the critiquing questions, McNemar's test significant ($p<0.001$)

Based on findings from the analysis of survey data and on pilot interviews, I created questions to explore students' understanding of the appropriateness of using the slope and derivative to make predictions. In differential calculus, students are taught what the derivative represents, but rarely are asked when it is appropriate to use the rates of change to make predictions. During the interviews, which were recorded with LiveScribe™ technology, students were asked to "think out loud" while they worked through problems. Interviews allowed me to probe student thinking more deeply, especially focusing on the themes that emerged during the survey data analysis. Analysis of interview data was done using both the categories developed from the survey data analysis and techniques from Grounded Theory when additional category identification was needed. A major goal of the analysis was to further illuminate students' reasoning about slope, derivative and how they are used and interpreted.

Results

With regard to research question #1, in both the surveys and interviews, students who interpreted the slope correctly were no more likely to interpret the derivative correctly than those who did not interpret slope correctly (questions A2 and B2; Figure 1). Success rates were low for interpreting both the slope and derivative (Table 2).

	Slope Interpretation	Derivative Interpretation
Surveys (N=69)	17%	13%
Interviews (N=13)	31%	38%

Table 2. Comparison of success rates for the survey and interview interpretation questions

For the slope interpretation, the dominant incorrect method was a ratio-of-totals approach $\left(\frac{y}{x}\right)$, implying a directly proportional relationship of the form $y = mx$ with a y-intercept of zero (Table 3). For example, Missy and Jackie were asked the meaning of a slope of 2 mg per pound and both gave a ratio-of-totals response. Missy said, "You multiply [the weight] by 2 to get the dosage." Jackie said "it means that for every pound, 2 milligrams of the dose." The correct response is "for each additional pound of weight, the patient would need 2 additional mg of drug." Characteristic of this type of response, neither Missy nor Jackie included "additional" in their response.

	Ratio-of-Totals Approach
Surveys (N=69)	39%
Interviews (N=13)	54%

Table 3. Rates of incorrect ratio-of-totals reasoning for the slope interpretation questions

It is important to note that the difference between the correct answer and a "ratio-of-totals" answer is very subtle but it appeared that students were not just inadvertently leaving out the word "additional." Most students who interpreted the slope incorrectly as a ratio-of-totals interpreted the derivative similarly as $f(x) = f'(x) * x$. That is, they treated the derivative as something that could be used to find the value of the dependent variable. For example, when asked what $D'(140) = 2$ meant, Dawn answered using ratio-of-totals, stating, "it would tell you how much drug to get. So, if it is 2 mg/pound, with a 140-pound patient, your dosage would be 2 times 140, or 280 mg.” In the interviews, six of the seven students who interpreted the slope as the ratio-of-totals went on to interpret the derivative similarly (as a rate of change that can be used to calculate the total). Students’ ways of thinking about this appear to be quite stable and four of the five students who did interpret slope correctly went on to interpret the derivative correctly. Rates of the ratio-of-total approach for derivative interpretation questions are shown in Table 4.

	$f(x) = f'(x) * x$ Approach
Surveys (N=69)	16%
Interviews (N=13)	54%

Table 4. Rates of incorrect $\boldsymbol{f(x) = f'(x) * x}$ reasoning for the derivative interpretation questions

With regard to research question #2, most students had difficulty critiquing others’ reasoning about slope and derivative predictions. Considering that students were not particularly successful interpreting slope and derivative, it is not surprising that students struggled with critiquing the reasoning of others, many showing little understanding of the covarying nature of the derivative. In particular, they had difficulties with the idea that the derivative is an instantaneous rate of change whose value changes depending on its input. Students applied the dominant incorrect way to interpret the slope and derivative (ratio-of-totals) to the critiquing questions, where many concluded that they could calculate the total by using the derivative ($\text{e.g.}, f(x) = f'(x) * x$). Seven of the thirteen interviewed students said that they did not agree with Nurse Jodi because they needed another derivative (the derivative at 141 or 160 pounds) to calculate the total dosage (multiplying the derivative times the weight to yield total dosage). Six of these seven students had interpreted slope as a ratio-of-totals, thus extending their incorrect ratio-of-totals interpretation to derivatives and concluding that $f(x) = f'(x) * x$. Table 5 shows a comparison of success in critiquing for the surveys and interviews.

	Correct	Need another derivative
Surveys (N=69)	16%	14%
Interviews (N=13)	31%	62%

Table 5. Response rates for critiquing questions in the non-linear context for surveys and interviews

Discussion

The findings related to research question #1 support prior research that showed that rates of change are hard for students (Carlson, 1998; Hackworth, 1994). The findings also extend findings about high school students’ difficulties with slope (Stump, 2001) to college students. Research question #2’s findings support prior research that highlighted students’ difficulties using calculus to analyze dynamic situations (Carlson, 1998) and students’ struggles with use of the derivative to approximate the function near a point (Asiala et al., 1997). These finding extend prior research by identifying students’ common incorrect use of the derivative as a ratio-of-totals to be used to calculate the function value.

In summary, findings suggest one common incorrect way of thinking, anchored in students’ misunderstandings of slope as a ratio-of-totals. This influenced students’ thinking about calculus in that they incorrectly generalized it to the derivative.

Implications for Teaching

Expanding on previous findings that have shown that students lack a solid understanding of rates of change in general (Hackworth, 1994; Orton, 1984), present findings suggest that students do not have a robust understanding of what slope and derivative mean as a rate of change in the context of modeling situations, nor do they understand appropriate uses of slope and derivative to make predictions. Findings also suggest that students' incorrect interpretation of slope (as a ratio-of-totals which translates to a directly proportional relationship of the form $f(x) = m * x$) seems to influence their incorrect interpretation and use of a derivative (as $f(x) = f'(x) * x$). These findings have instructional implications for calculus instructors and pre-service teachers.

Calculus instructors could benefit from knowing what beginning calculus students' understanding is of slope and their interpretation of slope in modeling contexts. By asking questions similar to those in this study, instructors can assess students' initial understandings. Findings suggest that when students answer slope interpretation questions using a ratio-of-totals approach, they are not merely leaving out the word "additional." These answers are symptomatic of their under-developed understanding of slope. To address these shortcomings, instructors can help students revisit the middle school concepts of slope, linear relationships, and directly proportional relationships (a subset of all linear relationships). Based on the results of this study, which showed a large percentage of the students having a ratio-of-totals approach, it may be valuable to take time at the start of our calculus course to help ensure that all students understand the differences between directly proportional relationships and other linear relationships, and how the interpretation of slope is different in each. This could be addressed when ideas of average rates of change are introduced. When interpretations of the derivative are addressed later on in the course, questions about linear equations and slope could be revisited, and distinctions made between the two to help combat students' incorrect generalizations.

Second, it could be productive to focus on not just what derivatives can be used for (linear approximation, marginal cost, etc.), but also stress their limitations in making predictions. Students could be given opportunities to compare the estimated values (from the derivative) with the actual value (from the original function), both by calculating the values and showing the error graphically. Discussions around how much error might be appropriate in different contexts could be beneficial.

Findings from this study suggest that many calculus students do not know how to appropriately use a derivative to make an estimate. Opportunities to discuss the appropriateness of predictions are not extensive; instead students are asked to make estimates without being asked to consider how far away the input value is, or how rapidly the function is changing around the point of interest. It could be valuable to provide students with more opportunities to reflect on the appropriateness of their predictions.

Concepts related to slope are addressed at the middle school level, and findings from the present study have several implications for the pre-service education of teachers. First, given the similarity in populations, pre-service teachers may have the same understandings about slope and rates of change as were displayed by participants in the present study. In addition, pre-service teachers could benefit from becoming aware of how ideas about directly proportional relationships can influence student understanding about slope and be given opportunities to consider ways of addressing this with their future students. For example, future teachers could provide more extensive opportunities for students to understand that directly proportional relationships are a subset of all linear relationships, and that not all linear relationships are of the form $f(x) = mx$. For example, students could calculate both $\frac{y}{x}$ and $\frac{\Delta y}{\Delta x}$ for linear relationships of the form $f(x) = mx$ and $f(x) = mx + b$ and make conclusions about the slope based on the results. Extending to slope interpretation, students could be given the opportunity to interpret slope as a rate of change via questions similar to those from this study, but specifically focusing on interpreting slope of directly proportional relationships versus those that are not. By highlighting differences between directly proportional relationships and other linear relationships, students can have opportunities to understand how interpretation of slope differs.

We also know that current curricula "provide little opportunity for developing the ability to: interpret and represent covariant aspects of functions, understand and interpret the language of functions, interpret information from functional events, etc." (Carlson, 1998, p. 142). As a mathematics education community, we need to continue to improve our instruction and focus our attention on the topics (such as covariational reasoning and interpretation) that research points to as critical to student success.

Implications for Future Research

More research is needed on students' interpretations of both slope and derivative as rates of change. Findings from the present study suggest that students' most common incorrect interpretation of slope as a ratio-of-total (as $\frac{y}{x}$ instead of $\frac{\Delta y}{\Delta x}$) is influencing their ability to understand the derivative. How early do these ways of thinking form? Student thinking about slope as a rate of change can be researched at the middle school level to see whether the ratio-of-totals interpretation is prevalent in those early years. We know that "full concept development appears to evolve over a period of years" (Carlson, 1998. p.143). The concept of slope is first introduced in middle school, utilized throughout high school, and then expanded on in calculus with the introduction of the derivative. Research could examine how students' understanding of slope evolves over these key years to further illuminate the role of this way of thinking.

At the college level, one could also focus on the effectiveness of instruction that is specifically designed to address these issues via design or teaching experiments. Differential calculus students' knowledge of slope as a rate of change could be assessed at the start of the course, and then instruction on slope and interpretation of slope (for linear functions of the form $f(x) = mx + b$ and $f(x) = mx$) could occur prior to starting derivatives. After instruction on derivatives, a post-test could measure student gains on interpreting both slope and derivative, to see whether the targeted instruction on slope aids in students' understanding of derivative.

Knowing more about students' understanding of slope and derivative as rates of change can help improve instruction. The concept of slope is fundamental to the mathematics curriculum from the middle grades and on; we must do better to ensure that our students have solid conceptions of this rate of change. If we can help pre-service teachers support develop these understandings when the concept is first introduced in middle school, and address difficulties they bring forward to high school and beyond, we can ensure that students in our calculus course have the solid foundation necessary to understanding the complexities of the derivative.

Students' Understanding of Vectors and Cross Products: Results from a Series of Visualization Tasks

Monica VanDieren
Robert Morris University

Deborah Moore-Russo
University at Buffalo, SUNY

Jillian Wilsey
Niagara County Community College

Paul Seeburger
Monroe Community College

Previous studies have explored student understanding of vectors in physics, engineering, or linear algebra settings, but there has been scant research on student understanding of vectors in a multivariable calculus context. In this study, we begin to explore how students think about vectors and cross products by analyzing student responses to open-ended questions from an online, conceptually-oriented multivariable calculus cross product activity. We identify several themes consistent with previous research on physics students including confusion between the cross product and its magnitude as well as difficulty identifying or communicating the direction of the cross product vector. This preliminary research begins to develop categories that could outline a conceptual model of student understanding of vectors and cross product. The analysis also informs several recommendations for improving the cross product activity.

Key words: [vectors, cross products, student understanding, visualization]

In mathematics, engineering, and physics, vectors play a foundational role. Vectors are used extensively throughout physics and engineering within mechanics topics such as force, velocity, and acceleration, and in mathematics coursework vectors appear in multivariable calculus, geometry, linear algebra, and differential equations. While basic vector concepts, representations, and operations with vectors are presented in both high school and preliminary college mathematics, students often will not be introduced to vector dot and cross product operations until they undertake college-level calculus coursework. Despite the regular occurrence throughout the curriculum, students continue to have significant conceptual difficulties with vector concepts and manipulations.

One approach conjectured to improve student understanding of three-dimensional topics is to improve students' visualization skills using computer exercises (Sorby & Baartmans, 2000). CalcPlot3D is an online, freely available 3D-graphing applet that allows students to visualize and manipulate concepts including vectors, vector fields, parametric curves, surfaces, and gradients. In addition to the graphing calculator feature, CalcPlot3D offers discovery-learning activities for students to explore multivariable calculus concepts (Seeburger, 2016). This study analyzes student responses to Seeburger's cross product activity.

The purpose of this study is to investigate students' transitional conceptual understanding of vectors, and more specifically the cross product of vectors, as they work through an exploration activity with embedded questions while using the CalcPlot3D visualization tool. This research is partially supported by the National Science Foundation under Grant Numbers 1524968, 1523786, 155216.

Background Literature

There is extensive literature that explores students' misconceptions when confronted with problems involving force and motion (i.e., mechanics), both of which are represented by vectors (Aguirre & Rankin, 1989; Barniol, Zavala, & Hinojosa, 2013; Flores, Kanim, & Kautz, 2003; Hestenes & Wells 1992; Hestenes, Wells, & Swackhamer, 1992; Miller-Young, 2013). Both force and motion utilize vector concepts; however, the students' misconceptions regarding vector concepts, properties, and fluency in vector operations are not explored directly. Rather, these concepts are embedded within the application. For instance, Hestenes, Wells, and Swackhamer (1992) utilize a Force Concept Inventory to assess student understanding of Newtonian physics, but the inventory does not directly assess students' understanding of vectors.

Others (Barniol & Zavala, 2014; Knight, 1995; Nguyen & Metzler, 2003; Van Deventer & Wittmann, 2007; Wang & Sayre, 2010; Zavala & Barniol, 2010) provide more explicit consideration of students' understanding of vector concepts, representations, and operations outside of a kinematic or mechanics context. Knight (1995) found that approximately 40% of students in an introductory calculus-based physics course had no idea what a vector was. About 50% of the students could add vectors correctly; however, none of the students were able to evaluate a vector cross product. Barniol and Zavala (2014), using their Test of Understanding of Vectors (TUV), examined the knowledge of university students who had completed an introductory calculus-based physics course. The TUV contains non-contextual multiple-choice problems covering vector properties and basic vector operations. Three of these problems address the cross product. Two are computations and the third asks the students to select an appropriate geometric interpretation of the cross product from a list of options. The percentage of students who could correctly answer this problem was 57% (Barniol & Zavala, 2014).

Research on student understanding of vectors in college-level mathematics courses tends to focus on the transitional proof courses such as linear algebra and geometry. For instance, Stewart and Thomas (2009) developed a framework for vectors in linear algebra that combines an action-process-object schema (Dubinsky, 1991) for vectors with Tall's (2004) categorization of three mathematical ways of thinking: embodied world, symbolic world, and formal world. Kwon (2013) presents a new framework for conceptualizing vectors in college geometry that identifies three representations of a vector: vector as a translation; vector as a point and point as a vector; and geometrical vector sum.

Theoretical Framework

While many studies highlight student misconceptions, this study focuses on students' transitional conceptions, since understanding is not necessarily static. *Transitional conceptions* relate to students' current notions of a concept that are cued by the task at hand and that may include what some would call misconceptions. Transitional conceptions are not fully integrated in a coherent manner, and hence tend to be in flux. Yet, they do result from a sense-making activity even though they may only address some (but not all) aspects of the concept and may be productive in some (but not all) contexts. Studying transitional conceptions can potentially lead to a better or more accurate view, perhaps even to a conceptual model, of student understanding of the concept (Moschkovich, 1999). To understand students' meaning-making processes, it is imperative that instructors consider the transitional conceptions that occur when students are engaged in learning new concepts (Wolbert, Moore-Russo, & Son, 2016). Many have begun to consider college students' transitional concepts (Chiu, Kessel, Moschkovich, & Muñoz-Nuñez, 2001; Cho & Moore-Russo, 2014; Nagle, Casey, & Moore-Russo, 2015; Wolbert, Moore-Russo, & Son, 2016) in various areas of post-secondary mathematics. However, there is little research on transitional conceptions specific to vectors in multivariable calculus classes. This study aims to add to the existing body of knowledge, focusing, in particular, on students' transitional conceptual understanding of the vector cross product.

Conceptual understanding encompasses both "what is known (knowledge of concepts)...[and] the way that concepts can be known (e.g. deeply and with rich connections)" (Star, 2005, p. 408). It can be considered as "a connected web of knowledge, a network in which the linking relationships are as prominent as the discrete pieces of information" (Hiebert & LeFevre, 1986, p. 4). When concepts are first learned, students' understanding can be fragmented and lack either organization or connections to related concepts (Schneider & Stern, 2009).

Both intra- and inter-connections are possible for a concept. Tall and Vinner (1981) described an individual's concept image as the entire cognitive structure related to a particular concept. Past research has considered the many "conceptualizations," "notions," or "connected components" associated with a particular concept in mathematics (e.g., work on slope by Moore-Russo, Conner, & Rugg, 2011; Nagle & Moore-Russo, 2013); these are the intra-connections for a single concept. There are also inter-connections between different topics (e.g., Zandieh and Knapp's (2006) work that inter-relates rate, limit, and function to look at how students come to understand derivatives); however, this paper focuses only on intra-connections.

Understanding is dynamic, and students' conceptions regarding a topic are transitional. As students advance in mathematics, there are instructional expectations that they will develop internal networks that are rich in relationships where they are able to move flexibly among representations and notions of the concept as they advance in the learning of a topic. Assessment to confirm that students are making such intra-connections to form robust, flexible concept images is important since conceptual understanding, in combination with procedural fluency, is necessary for success in mathematics (Hiebert & Carpenter, 1992).

Methods

This study is situated within a larger research program to determine if student understanding of cross products can be enhanced through visual explorations. Before being able to assess the impact of visual explorations on student understanding, it is necessary to build a model of student understanding of the cross product. As a first step to this goal, we sought to begin to characterize students' transitional conceptual understanding of cross products by examining their responses to four open-ended questions on a conceptually-oriented cross product assignment.

Subjects and Setting

The data analyzed were from electronic responses of 434 college-level multivariable calculus students to four open-ended questions from an online assignment. The data was collected over four years from students from community colleges, four-year private colleges, and four-year public colleges. Each student completed a pre-test, exploration assignment, and post-test.

The exploration assignment consisted of 10 open-ended and 2 multiple choice questions about vectors and cross products. The students were directed to a visual applet that contained two vectors (one red and one blue) along with their cross product. The red and blue vectors were graphed with initial points situated at the origin in the *xy*-plane. Students could manipulate the length and direction of the two vectors on the *xy*-plane, and based on the students' input, the applet automatically redrew the cross product, computed the magnitude of the cross product, and indicated the angle between the two given vectors.

Previous research on the pre- and post-test multiple choice questions indicate some knowledge gain on the relationships between the angle between two vectors or between the length of two vectors and their cross product through the use of the exploration (Seeburger, 2009). Here we examine student responses to the first four open-ended questions embedded in the pre-existing exploration to gain a better view of how students understand cross product. The remaining questions will be examined in a follow-up study. The questions examined here are:

Q1. What is the geometric relationship between the cross product vector and the two vectors that form it? (Hint: This is NOT a formula.)

Q2. How is the cross product vector geometrically related to the two vectors that form it? (Hint: This is NOT a formula.)

Q3. For vectors of fixed length, but varying the direction of one of the vectors, when is the magnitude of the cross product at a maximum?

Q4. For vectors of fixed length, but varying the direction of one of the vectors, when is the magnitude of the cross product at a minimum?

Analytical Method

The items were examined for emerging themes through a general inductive analysis. According to this method, the researcher does not begin with a preconceived structure but allows categories to emerge from the data. The researchers utilize categories to make sense of what is observed (Thomas, 2006). To identify emerging categories, one member (the first author) of the research team began the task of reading all responses to the four items to note what was observed. These emerging categories were shared with another member of the research team (the fourth author) for general consensus. A third member of the research team (the second author) then read all the responses and tried to see if the initial categories could be collapsed into unifying topics. She shared her findings with the third author until consensus was reached; both agreed on all the identified categories, but refinements were made to the topic descriptions. The list of categories was then shared and discussed with the first author, who also agreed with the identified categories and then helped further refine the topic descriptions. All, but the miscellaneous incorrect category and the blank category, were coded on three levels: as not being present (0), being present but with a developing or transitional understanding (-), or being present with a correct or accurate (+), but perhaps not complete, understanding. Finally the first and second authors coded all the items using the category descriptions in Table 1.

After coding was completed, interrater reliability statistics for each code were computed with ReCal (Freelon, 2013). With the exception of the miscellaneous category, all codes resulted in Krippendorff's alpha above 0.80. The first and second authors then came to a consensus on the few instances in which they were in disagreement.

Table 1
Categories and Codes with their Descriptions

Category and Codes		Description
Angle between two vectors	V+	angle must be between 0 and 180 degrees
	V-	angle between two vectors can be negative or greater than 180 degrees
Orthogonality	O+	cross product vector is orthogonal/perpendicular/90 degrees from the two vectors that form it
	O-	developing, but not correct/precise, statement about orthogonality
Right-hand Rule	R+	Mention of the right hand rule; Statement that correctly addresses the need to attend to orientation of one vector relative to another
	R-	developing, but not correct/precise, statement about the right hand rule
Parallelogram	P+	magnitude of cross product is area of parallelogram formed by two vectors
	P-	developing, but not precise, statement about parallelograms or area (e.g. “cross product forms a parallelogram.”)
Formula for magnitude of the cross product	F+	magnitude of cross product = $\|\|axb\|\|=\|a\|\|b\| \sin\theta$; correct statement involving sine and vectors
	F-	incomplete or incorrect statement involving multiplication, sine, cosine, or other formulas.
Angle impact on magnitude of the cross product	A+	correct statement describing how the angle between vectors influences the magnitude of the cross product
	A-	incorrect or vague statement about how changing the angle between two vectors will affect the length of the cross product (e.g. “cross product depends on the angle between the two vectors”)
Length impact on magnitude of the cross product	L+	correct statement describing how the length of the two vectors influences the magnitude of the cross product
	L-	incorrect or vague statement about how changing the length of one of the vectors will affect the length of the cross product
Other incorrect	I	incorrect statement involving x and y coordinates; vector addition; statement involving quadrants or planes; other nonsensical statements
Blank	B	no response; “I don’t know”

Table 2
Number of Responses in Each Category Code for Questions 1-4 (Q1-Q4) of 434 Participants

	Codes															
	V+	V-	O+	O-	R+	R-	P+	P-	F+	F-	A+	A-	L+	L-	I	B

Results

In Table 2 we summarize the results of the coding by question for the 434 students. While some of the codes were rarely assigned (e.g. L+, L-), the complete data set contains responses to other questions in which these themes are more prevalent. The authors plan on applying the methods tested in this initial analysis to the remaining questions in the exploration in the next phase of research.

Overall students evidenced some understanding of the cross product. The percentage of students providing a correct (+) response which may, or may not, be complete, for either Q1 or Q2 was 75% and for Q3 or Q4 was 88%. Note that some of these students may have also indicated additional incorrect or transitional understanding (-) of another aspect of the cross product in their responses as well.

Although the first two questions are nearly identical, some students answered them differently. Another theme we noted in Q1 and Q2 answers was that only 4% of all students referred to the right-hand rule or the orientation of the cross product to the two vectors that formed it (in either a correct (+) or transitional (-) way). The students who did describe the orientation of the cross product to the two vectors that form it appear to be recalling previous knowledge since the right-hand rule is not explicitly referred to in the exploration until later on. Nearly all of these students only quote it by name: "These vectors also form what is called the Right Hand Rule." Only a few students made an attempt at describing the right-hand rule in their own words. For example:

> *The direction of the cross product is found by using the right hand rule which involves placing your thumb on the first vector of the cross product and your forefinger on the second vector and seeing where your middle finger is pointing. The direction it is pointing is the same as the direction of the cross product.*

Furthermore, when considering the relationship between the two given vectors and their cross product, students more often only describe how the angle between the two given vectors impacts the length of the cross product, but do not consider how the length of the two given vectors would affect the magnitude of the cross product.

Discussion

Although concentrated to the analysis of four open-ended questions concerning the cross product, this study reveals difficulty in student understanding of cross products consistent with the literature. In particular, students have difficulty with the right-hand rule, tend to rely on formulas, and confuse the cross product with its magnitude. Further analysis of the remaining cross product exploration questions along with this preliminary study will inform recommendations for future versions of the CalcPlot3D concept exploration and provide insight into the intra-connections of vector cross products that students are and are not understanding.

While 65% of students correctly stated that the cross product was orthogonal to the two vectors that form it in responses to the first two questions, only 4% of students made any reference to the right-hand rule, orientation, or noncommutativity of the cross product vector. Similar results are found in a physics context by Zavala and Barniol (2010) and by Scaife and

Heckler (2010). Note, however, that in their research the students were required to compute the cross product while in our study the cross product was provided to the students graphically. Barniol and Zavala found that 44% of the students were able to interpret the cross product (AxB) as a vector perpendicular to both A and B, although only 22% of the students identified the correct direction. In the context of magnetic force, Scaife and Heckler (2010) saw that in a series of four similar questions, 40% of students made a sign error for the cross product at least once. They conjecture this is due to confusion about the application of the right-hand rule and failure to recognize that the cross product is a noncommutative operation.

Another theme found in our data was that 5% of the responses to Q1 and Q2 in our study included some (either correct or incorrect) reference to a formula, even though both questions explicitly state "Hint: This is NOT a formula." This supports research of Zavala and Barniol (2010) who found 9% of third semester physics students studied referred to a formula for the cross product in their open-ended responses to interpret the cross product. This additionally advances the notion, witnessed by Miller-Young (2103) in the context of an engineering class, that students often rely on memorized equations and procedures, even when instructed not to do so.

Zavala and Barniol's (2010) analysis showed 32% of students did not distinguish the cross product magnitude from the cross product itself. In our data set, this same trend is present in many of the (P-) responses similar to "The area of the two vectors equals the cross product." On the other hand 50% of students in our study focused on the direction of the cross product and did not describe its magnitude. This might suggest that students did not have a robust concept image, or they might not have seen the need to report on all connected components of the concept.

Future Recommendations

One of the limitations of the CalcPlot3D exploration is that the applet does not allow students to move the vectors off of the origin or off of the *xy*-plane. This may have led to incorrectly over-generalized responses; for example, "[The cross product] point[s] in the z axis direction." Marton and Booth's Variation Theory suggests that activities be structured to ensure students experience a diversity of examples (Lo, 2012). In this case students should experience vectors in a variety of orientations, not just those on the *xy*-plane.

The exploration provides students the opportunity to communicate and describe the geometric features of vectors and their cross product. Some students had difficulties accurately and precisely describing these features which may contribute to only a limited understanding of the relationships. For instance, in Q4, 86% of the students who described the angle between vectors as negative or larger than 180 degrees also demonstrated only a transitional understanding of the relationship between the angle of the vectors and the length of the cross product. Adding more examples of verbal descriptions of the geometric features of vectors may provide students with scaffolding to better communicate mathematics in open-ended responses.

The next step for the research team is to complete the analysis of all of the responses to the remaining exploration questions to gain more insight into what intra-connections of cross product are being made by the students and how the CalcPlot3D explorations can be improved to better address student difficulties.

Variations in Precalculus Through Calculus 2 Courses

Matthew Voigt, Chris Rasmussen, Naneh Apkarian, and the Progress through Calculus Team[1]
San Diego State University

In this paper we analyze variations in the structure of courses designed for the Precalculus through Calculus 2 (P2C2) sequence. We examine the nature of such variations, frequency nationally, and how DFW rates and instructional approach compare to the standard courses. While most identified variations in course structures have on average lower DFW rates when compared to the national average, a comparison within institutions indicates that these alternative course structures have higher DFW rates when compared to the standard P2C2 sequence offered at the respective institution. In addition, we observed that course variations which allow for increased instructional time have greater amounts of active learning techniques as part of the instructional format. Results from these findings along with their implications for the next phase of the Progress through Calculus project are discussed.

Keywords: Calculus, Precalculus, Curriculum, Course Variations

There is abundant literature highlighting the importance of student success in introductory undergraduate mathematics courses, often pointing to how such courses are a hurdle for students intending to continue into STEM majors and future related careers. Even for those students who do not choose to major in a STEM field, success in entry-level undergraduate mathematics courses such as calculus can impact a student's overall persistence in postsecondary education. Research examining students' success in introductory mathematics courses consistently indicates that students are not learning the intended curriculum (Tallman, Carlson, Bressoud, & Pearson, 2016; Thompson, 1994), resulting in lower preparation for subsequent courses (Carlson, 1998; Selden & Selden, 1994) and a marked decrease in their desire to pursue a STEM degree (Bressoud, Mesa, & Rasmussen, 2015; Ellis, Fosdick, & Rasmussen, 2016; Seymour & Hewitt, 1997). These students often cite the poor instructional experiences in introductory level courses as the primary reason for their departure from the STEM fields.

Institutions of higher education and departments of mathematics are becoming increasingly attuned to the particular challenges faced by these students and are seeking new ways of supporting student success in introductory mathematics courses. Rasmussen et. al (2016) found that most departments are aware and value characteristics of more successful calculus programs, yet they are not always successful at implementing these features at their institutions. As such, departments have responded in a number of ways to support student success in the P2C2 sequence. Departments are utilizing local data to inform placement procedures, using active learning pedagogy techniques, creating course coordination systems, and developing or improving graduate teaching assistant training. Another departmental response, which is the focus of this report, is to offer alternative P2C2 course structures. An alternative course structure reimagines the "standard" P2C2 sequence, which we take to be three, one semester courses consisting of Precalculus, Calculus I, and Calculus 2. An example of an alternative course structure is to offer, in addition to the standard sequence, a "stretched out" Calculus 1 course that takes two semesters and infuses additional algebra and trigonometry in the context of the calculus. In this report we address the following research questions:

1. What variations to the standard P2C2 course sequence are currently in place and how common are they nationally?
2. What are the relationships between variations to the standard P2C2 course sequence, instructional approach, and student success?

Data for this analysis comes from a national census survey focused on the P2C2 course sequence. This census survey is Phase 1 of a five-year project which began in 2015, and was distributed to all mathematics departments that offer a graduate degree in mathematics. These institutions were selected because they produce the bulk of STEM graduates while often struggling to find a balance between the demands of research and teaching. Phase 2 will consist of longitudinal case studies of selected institutions.

Theoretical Background

We address our research questions and frame alternative P2C2 course offerings in terms of the intended, enacted, and assessed curriculum (Kurz, 2011; Porter, 2006; Webb, 1997). The intended curriculum refers to the knowledge and skill targets for students (Porter, 2006), in this case the course objectives for precalculus and mainstream calculus. In addition, this includes variations of the intended curriculum deigned as specialization for service disciplines (engineering, biosciences, etc.). The enacted curriculum refers to the knowledge and skills delivered during instruction which varies based on instructional time (allocated time for instruction), content coverage (amount and variety of academic standards), and instructional approach (Kurz, 2011). For example, a stretched out Calculus 1 course might be configured to allow for more active learning, but this is an empirical question and one that we address in this report. We also investigate how institutional response to the alignment between the intended and enacted curriculum affects the assessed curriculum. We use DFW rates (grades of F, drops and withdrawals) as a proxy for the assessed curriculum.

Figure 1 captures how we make use of the intended, enacted, and assessed curriculum in this study. In particular, the survey data allows us to detail intended curriculum aspects such as course objectives and intended audience, and the enacted curriculum aspects such as instructional time, content coverage, and instructional approach.

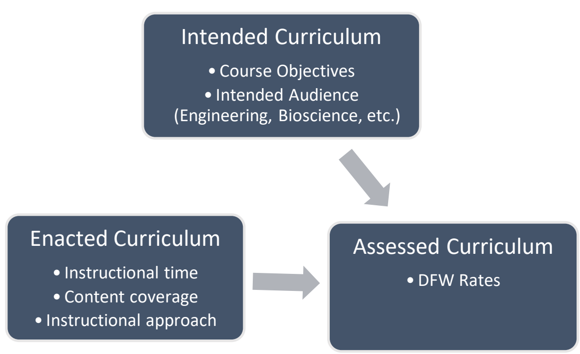

Figure 1. Observed components for the intended and enacted curriculum, and their relation on the assessed curriculum.

Methods

In the United States there are a total of 330 departments that offer either a Masters or PhD in mathematics. All 330 institutions (178 Doctoral and 152 Master's) were surveyed yielding a 68% response rate. We designed the census survey to gather information on the implementation of the features of successful programs identified by the CSPCC project and to gain an understanding of the variety of P2C2 programs being implemented across the country, the prevalence of such programs, and what institutions are doing to improve their programs. The survey consisted of three main parts. Part I asked for a list of all courses in the mainstream P2C2 sequence. Mainstream refers to any course in this sequence that would be part of student preparation for higher-level mathematics courses such as a first course in differential equations or linear algebra. Part II asked about departmental practices in support of the P2C2 sequence. Part III asked for detailed information about each course in the mainstream P2C2 sequence, including enrollment data and details about course delivery.

Survey responses were then cross-referenced and updated to the extent possible by a comprehensive search of publicly-available course catalogs and department websites. This led us to a collection of 1108 courses from 223 institutions, with details supplied for 895 of these courses by 205 institutions. We used a grounded theory approach (Corbin & Strauss, 2008) to code and categorize variations to the standard P2C2 course sequence. Based on this analysis, 11 variants of the standard P2C2 courses were identified and are outlined below. We choose to highlight these variations since they demonstrate the response from institutions to support student of varying preparedness levels and interest.

Results

We present results according to the two research questions. We first describe existing course variations in terms of three main themes: intended audience, instructional time, and content coverage. We then provide a summary table (Table 1) specifying the frequency in which these variations are present. We then address the second research question by analyzing how course variations fare in terms of DFW rates and instructional approach.

Intended Audience

Several institutions have specialized their mainstream calculus sequence to tailor the intended curriculum to service different disciplines. The most common variation is *calculus for the biosciences*, which is a mainstream calculus course designed explicitly for students in biological or life science majors. Often time the course includes applied topics in biological modeling and investigation of real-life phenomenon. *Calculus for engineering* is another course variation on the mainstream calculus course that is intended for students in engineering majors. Often this course includes emphasis on physical applications to engineering and computational techniques. Seymour and Hewitt (1997) found that a disconnect between calculus content and intended major to be a major contributing factor in students' decision to leave a STEM field. Such variations have the potential to address such concerns.

In addition, we identified institutions that offered a mainstream calculus for another subject, which was specifically designed for students in a non-STEM major (e.g. Calculus for Economics). Mathematics departments often have to provide non-mainstream introductory mathematics courses for students in other disciplines, yet these students face a subsequent challenge if they intended to switch to a STEM intending degree. Some institutions have responded to this potential audience by providing a transition to mainstream course variation. This course serves as a bridge between a non-mainstream calculus course and a mainstream calculus course or upper-division mathematics course that has a lower credit load, and does not require the student to retake the entire mainstream P2C2 sequence.

Instructional Time

The most common course variation observed alters the standard curriculum by allowing the course content to be covered over a longer duration of time, which addresses another major factor that students cite for leaving a STEM major – overpacked courses taught at too fast a pace (Seymour & Hewitt, 1997). For the preparation for calculus courses we observed institutions that offered the choice between a single course covering the requisite skills necessary for enrolling into calculus or a two (or more) course sequence, typically consisting of a course in trigonometry and a course in college algebra. We denoted these options as *modular precalculus* and *modular stretched-out precalculus.* We use the term modular since students are able to modularize or choose between the necessary sequence. In addition, we observed institutions that offered only a single course option or only a two course sequence as preparation for calculus. We denoted these options as *standard precalculus* and *standard* stretched-out *precalculus* .

For single variable calculus we observed two unique course variations that allowed for the formal curriculum to be covered over an extended length of time. The *stretched-out calculus* course takes the traditional one-term course and stretches the content over a two-course sequence, often including additional requisite material when appropriate. This option is usually intended for students who would be at-risk in the traditional calculus sequence and would benefit from a slower paced delivery of the material. The *stretched-out Calculus 1&2* is a variation on the stretched-out calculus where three courses, when taken together, are the equivalent to the standard two-course single variable calculus sequence.

Content Coverage

While some variations seek to allocate more time for course delivery by spreading the curriculum over extra courses or terms, another set of calculus course variations are designed to provide background content and requisite skills as supplements to course offerings. The most common variation in this category is *calculus infused with precalculus,* which is a single-term calculus course (typically with more credit hours) designed to include requisite pre-calculus topics covered throughout the course duration. A similar course variation, referred to as *co-calculus*, is a one-term course taken concurrently with a single variable calculus course that covers selected precalculus topics, coordinated with the content of the calculus course. This course variation is intended for at-risk students who can be identified early in the term through low-course performance and subsequently enrolled in the co-calculus course to provide supports for study skills and the coverage of precalculus content.

While the previous two course variations are typically intended to support students in the first course in single variable calculus (Calculus I), we also observed one course variations intended to specially support students in the second term of single variable calculus (Calculus 2). *Accelerated calculus* is a calculus course explicitly designed for students who have taken calculus in high school (usually with AP credit). These courses cover mainly material that would be considered Calculus 2, but also include Calculus 1 material that may not have been covered in sufficient depth in an AP course. All variations in the "content coverage" category involve strategies to supplement the mathematics content of regular course *while keeping students on-track* in terms of time to graduate.

Other

In addition to previously mentioned variations we also observed several unique course offerings that failed to warrant their own code, but were identified as *other* unique course structures. This category included: courses (or course sections) explicitly designed for students who have not seen calculus before; a course designed to divert less-prepared students mid-term; precalculus courses which include a preview of calculus topics; courses designed for transfer students; applied courses in technology; courses offered only in summer as preparation; etc.

Course Variation Summary

Overall, 125 (56.3%) of the institutions have at least one course variation and excluding the most common variation, for modular precalculus and modular stretched-out precalculus, 75 (33.8%) of the institutions have at least one calculus course variation. The frequency for which we observed each of the course variations at surveyed institutions is presented in Table 1. The remaining results present a descriptive account of the survey responses describing the enacted curriculum (instructional approach) followed by measures of the assessed curriculum (DFW rates) stratified by the observed course variations. The descriptive statistics are only provided for variations which had data from three or more observations.

Table 1. Overview of course variations offered nationally

Category	**Variation**	**Institution (n=223)**	**Percent (%)**
Intended Audience	Calculus for biosciences	15	6.8
	Calculus for engineering	14	6.3
	Calculus for other subject	3	1.4
	Transition to mainstream	3	1.4
Instructional Time	Modular Stretched-Out Precalculus/ Modular Precalculus	62	27.9
	Stretched-out calculus	20	9.0
	Stretched-out calculus 1&2	7	3.2
Content Coverage	Calculus infused with Precalculus	11	5.0
	Co-calculus	3	1.4
	Accelerated calculus	14	6.4
Other	Other	10	4.5

Course Variation DFW Rates and Instructional Approach

For each of the P2C2 courses provided, respondents were asked to indicate the primary instructional format during the regular class meetings. The response options along with the percentage for which they occurred for each of the course variations is presented in Figure 2. We observed the highest amounts of active learning techniques implemented in course variations that increase the amount of instructional time, with the greatest observed amounts in the stretched-out Calculus 1&2 variation, followed by the stretched-out calculus variation. In addition, we observed greater amounts of computer based instruction in calculus for engineering and the stretched-out Calculus 1&2 course variation.

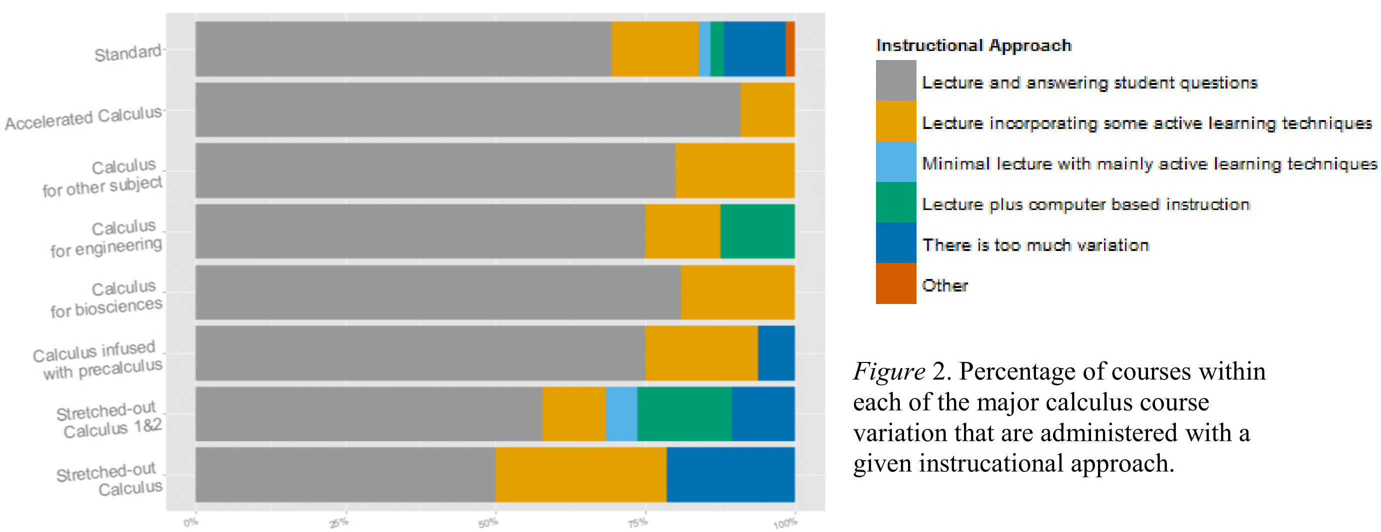

Figure 2. Percentage of courses within each of the major calculus course variation that are administered with a given instrucational approach.

Respondents also indicated the typical drop, fail, or withdraw rate for each of the courses they listed as part of the mainstream P2C2 sequence. We observed that the DFW rates between the variations of the preparation for calculus courses (Figure 3) are markedly similar, with no significant differences.

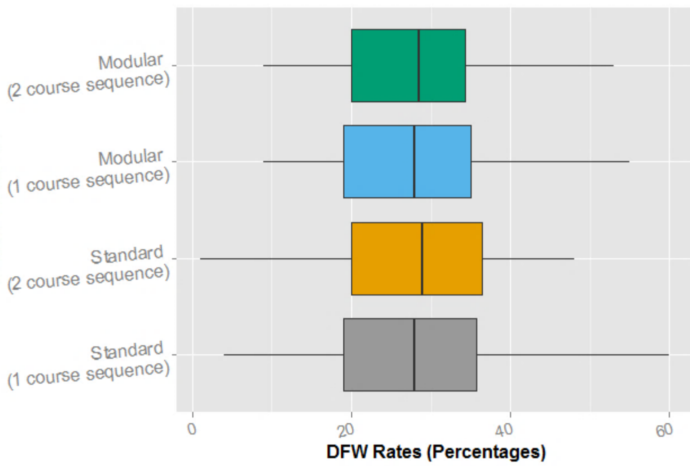

Figure 3. Box-and-whisker plot depicting DFW rates for the four major course variations of preparation for calculus along with the reported averages: modular two course (n 60, 27.6%), modular one course (n = 47, 27.2%), standard two course (n = 34, 27.1%), and the standard one course (n = 90, 27.5%).

The DFW rates for course variations in mainstream calculus (Figure 4) however do show major differences when compared to the national average. We computed the average DFW rate for any standard calculus course (24.1%), but isolated those courses intended for honors students, as these courses are typically intended for high-achieving students. We observed that each of the course variations had on average lower DFW rates compared to the standard course structure, except stretched-out calculus which had a similar yet higher DFW rate (25.3%). Indicative of our qualitative descriptions the lowest DFW rates occurred in course variations intended for high achieving students with strong prior backgrounds (Stretched-out Calculus 1&2, and Accelerated Calculus).

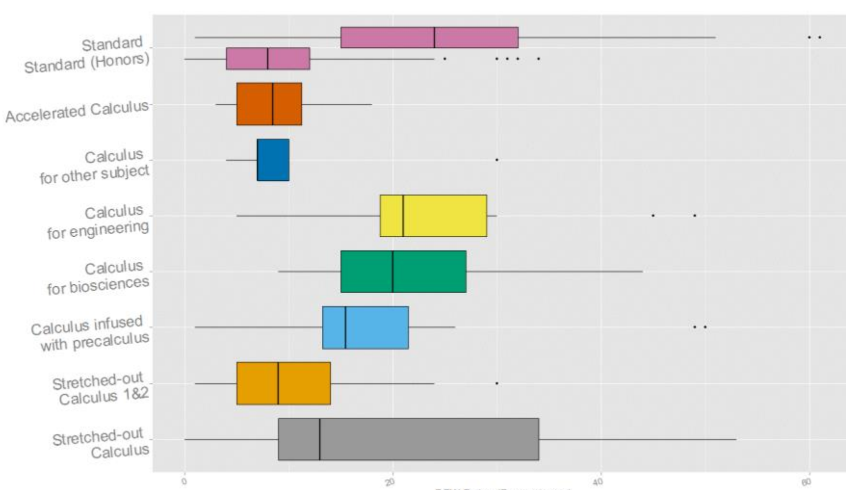

Figure 4. Box-and-whisker plot depicting DFW for the major course variations of calculus along with the reported averages:
Standard (n = 383, 24.1%), Standard (honors) (n = 68, 9.6%), Accelerated Calculus (n = 8, 9.12%), Calculus for engineering (n = 16, 23.6%), Calculus for biosciences (n = 19, 22.0%), Calculus for other subjects(n = 3, 14.6%,), Calculus infused with Precalculus (n = 14 18.9%), Stretched-out Calculus 1&2 (n = 17, 11.0%), Stretched-out Calculus (n = 38, 25.3%).

In addition to comparing DFW rates against the national average, we also analyzed the DFW rates for a given course variation against the DFW rates for the standard course sequence offered at that given institution (Table 2). While accelerated calculus has the same trend in comparison to the national average, the other course variations present an entirely different picture with regards to the DFW rates. We observed a larger amount of comparisons in which the alternative course variation had higher DFW rates compared to the equivalent standard course sequence at that particular institution.

Table 2. Institutional comparison of DFW rates for alternative and standard course sequences in single variable calculus.

Course Variation	**Avg. DFW rate for variation**	**Avg. DFW rate for standard**	**Institutional comparisons where DFW rates were higher for:**		
			Variation	*Standard*	*Identical*
Accelerated Calculus	8.2	20	0	3	1
Calculus for other subjects	10.2	8	2	2	2
Calculus for Engineering	25.3	26.1	11	3	2
Calculus for Biosciences	22.1	23.6	11	6	2
Calculus infused with Precalculus	19.0	13.1	7	3	1
Stretched-out Calculus 1&2	12.8	11.6	5	0	0
Stretched-out Calculus	22.4	19.6	7	3	2

Conclusion

Our project presents the first description of the variety (and frequency of) nonstandard curricular structures for P2C2 courses across the nation. In particular, we are able to paint a picture of how institutions across the country are attempting to address concerns about student success in introductory mathematics courses by addressing the intended and enacted P2C2 curriculum. We note that relatively few departments across the country are experimenting with these innovations, but our results indicate that these innovative structures have some potential at impacting the assessed curriculum. Given that this information comes from Phase 1 of a multi-year project, we find ourselves with the unique opportunity to further investigate the implementation of alternative course structures during Phase 2 of our case study analysis. The in-depth institutional analysis will provide a richer understanding of the surrounding programs and context in which such structures support student success, and to explore more nuanced measures of success and student understanding.

While Phase 2 of our research will reveal much more about the nature of alternative course structure, we can begin to comment on some of the potential advantages of these non-standard offerings. First, we note that many variations involve increasing the time dedicated to courses – be it stretched over extra terms or supplemented with co-requisite units. This increase in contact hours may free up class time in order to leverage active learning while alleviating concerns about content coverage. Secondly, many alternative course structures are aimed at supporting students who are underprepared for calculus. While the DFW rates in these courses tend to be higher than their non-standard counterparts, we expect this is related to the proportion of underprepared students in each – though further exploration is needed to conclude this with certainty. As failure in calculus is akin to an exit from STEM, supporting these students and bringing them up to speed with their peers may be an important piece of stopping the leaking pipeline.

Using Expectancy Value Theory To Account For Students' Mathematical Justifications

Keith Weber Rutgers University
Kristen Lew Arizona State University
Juan Pablo Mejía-Ramos Rutgers University

There is a robust body of research demonstrating that when students are asked to justify a mathematical assertion, they will frequently generate empirical arguments to do so. They also sometimes claim a deductive argument does not supply them with certainty that the assertion is correct. Mathematics educators frequently attribute this to students having deficient standards of conviction. In this paper, we illustrate another theoretical account. Students might believe that they lack the cognitive capacity to produce a superior argument to an empirical argument or to verify that a deductive argument is correct.

Key words: Expectancy value; Justification; Proof

In this paper, we consider two robust findings from the research literature on proof. First, when students are asked to justify a mathematical assertion, they frequently do so by generating an empirical argument (e.g., Coe & Ruthven, 1994; Healy & Hoyles, 2000; Recio & Godino, 2001). Second, when some students are presented with a valid deductive argument (i.e., a proof) in support of a mathematical assertion, they will claim not to be certain that the claim is correct (e.g., Chazan, 1993; Fischbein, 1982; Morris, 2002). The research questions addressed in this proposal question why is this the case.

Theoretical Perspective

The Proving as Convincing Research Paradigm

According to Stylianides, Stylianides, and Weber (in press), much of the vast mathematics education on justification and proof uses the metaphor that proving is tantamount to convincing, in which a critical goal of the Proving as Convincing paradigm is to identify the types of arguments that students find convincing. A common methodology to do so is to provide students with justification tasks, classify the students' justifications by the types of arguments that they use to support the assertion (e.g., empirical generalizations, logical deduction, appeals to authority), and then infer that students presented these arguments because those are the types of arguments that are most convincing to students. Consequently, when students justify claims by empirical arguments, these researchers infer that students gain certainty on behalf of empirical arguments, or at least that empirical arguments are students' preferred mode of justification. Researchers find this inference undesirable on the grounds that mathematicians obtain conviction from deductive arguments or proofs, not from empirical arguments (c.f., Harel & Sowder, 2007). Another common methodology in the Proving as Convincing paradigm is to present students with a proof of an assertion and then see if they see if they behave as if they still harbor some doubt about that assertion. When students do, researchers also interpret this as undesirable because mathematicians, unlike these students, gain certainty from proof (c.f., Harel & Sowder, 2007).

Recently, the methodologies described above, as well as the epistemological assumptions that underpin them, have been challenged by some researchers. We briefly review some of the challenges here. First, the notion that mathematicians always gain certainty in mathematical assertions on behalf of proofs and that mathematicians never gain certainty on behalf of empirical arguments has been shown to be an oversimplification that does not accord with modern mathematical practice (e.g., Weber, Inglis, & Mejia-Ramos, 2014). Second, studies in which students are interviewed by their purportedly non-normative judgments, such as claiming to be convinced by an empirical argument or retain doubts in a statement that has been proven, have found students to appear more sensible and mathematically normative than the common interpretations for the literature suggest (e.g., Bieda & Lepak, 2014; Stylianides & Al-Mourani, 2010; Weber, 2010). Third, the results from some empirical studies have suggested that assertions that are difficult to prove questions were more likely to elicit empirical arguments because proofs might be too difficult for students to generate (e.g., Knuth, Choppin, & Bieda, 2009; Stylianides & Stylianides, 2009).

Our Alternative Expectancy Value Account

In the educational psychology literature, expectancy value theories are broad theories of motivation that study the relationship of beliefs, values, and goals with action (Eccles & Wigfield, 2002). The central goal of this paper is to show how three central constructs in expectancy theories—values, costs, and likelihood of success—can be used to qualitatively account for students' willingness or refusal to seek proofs of conjectures that they form.

Before sketching out our theory, we highlight an important distinction made by Bandura (1997) on two different expectancy beliefs, a difference that until now generally has not been taken accounted for in the research literature on proof. Bandura distinguished between *outcome expectations*—beliefs that certain behaviors will lead to certain outcomes—and *efficacy expectations*—beliefs that whether one has the capacity to perform the behaviors to achieve these outcomes. When students produce an empirical argument, we argue that we need to distinguish between two accounts: (i) the student believes the empirical argument provides certainty and (ii) the student believes that he or she does not have the capacity to produce a better argument. (i) is an outcome expectation and (ii) is an efficacy expectation. As we noted earlier, (i) is a common inference in the literature and suggests that students are not aware of the limitations of empirical arguments. However, we will argue that (ii) is sometimes the more accurate account. Similarly, if students are not certain of a claim after reading a proof of the claim, two possible accounts are (i) the student does not think that proofs can provide certainty or (ii) the student questions whether he or she has the ability to be certain that a proof is correct. Again, researchers often infer (i), an outcome expectation, but we believe that (ii), an efficacy expectation, often provides a more accurate account.

Value. When students are asked to justify a mathematical assertion, we assume that students want to achieve a high level of conviction for why an assertion is true. Our premise is that the *value* that students put on obtaining high levels of conviction will influence how hard students will work to obtain a better justification and whether they will settle for a non-optimal explanation as good enough. These values can be externally or internally imposed. Externally, submitting a false conjecture for an assignment (or a true conjecture that is not adequately supported) can result in the student receiving a negative outcome, such as a low grade for a course, or otherwise result in some other consequence that would hurt their academic or career goals. Eccles and Wigfield (2002) referred to this as Utility Value. Internally, students may wish to resolve a genuine curiosity as to whether a conjecture is true or false; Harel (1998) referred to as Intellectual Need. Also, a student may wish to avoid presenting a false conjecture to his or her peers or teacher as this would harm his or her mathematical self-image; Eccles and Wigfield (2002) referred to as Attainment Value. The higher the perceived value of determining the truth of a conjecture, the more likely a student is to work to produce a justification that bestows a high level of conviction.

Cost. Once a student has an imperfect justification for why a mathematical statement is true, the time spent searching for a superior justification, including a proof, is time that could be spent on other enjoyable activities, such as talking to friends. Here it is important to observe that the cost of searching for a proof may depend heavily on the individual and the situation. For many students, attempting to write a proof is a painful activity that brings up feelings of intellectually inferiority (e.g., Weber, 2008). Other students and mathematicians may *enjoy* seeking a proof, so engaging in the activity of proving is an end in and of itself—having what Eccles and Wigfield (2002) referred to as a high Intrinsic Value. In the latter case, individuals will *avoid* having someone else show them a proof because it would deny them the opportunity to search for that proof themselves. The higher the cost, the less likely it is that a student will work to produce a proof.

Likelihood of success. In deciding whether to pursue an objective, students will make a subjective estimation of how likely they are to achieve that objective. If students have an imperfect justification for why a mathematical statement is true, they are unlikely to seek a proof unless they believe that there is a reasonable chance that their search will be successful. If students think it is highly unlikely that they can prove a statement, they may simply not seek one and settle for an empirical justification, even if they are aware that a proof, in principle, bestows more conviction than the empirical argument.

Earlier, we argued that when a student submitted empirical arguments, researchers have often drawn the conclusion of that student having a limited epistemology. The researcher made the inference that the student believed that empirical arguments can bestow certainty, or at least more conviction than deductive arguments. Here we offer three other possibilities: (i) students might not be interested in being certain of the conjecture in question, (ii) they might find searching for a proof to be an unpleasant endeavor that is not worth the effort, or (iii) they might settle for the empirical argument because they believe that they lack the capacity to find a proof.

Methods

Rationale

In this study, we asked prospective and inservice secondary mathematics teachers to work on challenging problems that invited students to use empirical reasoning to make conjectures. We asked participants to share with us both their answer to the problem and a justification for why they believed their answer was correct. Following Stylianides and Stylianides (2009), we also asked participants how confident they were in their answers on a scale of 0 through 100. In cases where participants gave a response of less than 100, we asked them why they retained doubt about their answer, what further evidence could give them more confidence that their solution was correct, and why they were not seeking that evidence.

The goal of this study was twofold. The first is to argue that the Proving as Convincing research paradigm often does not offer an accurate account of why students will justify their conjectures with empirical arguments. Consistent with the research literature, in our study, we found that participants frequently justified their answers with empirical arguments. If participants were doing so because they held undesirable standards of conviction, we would expect the participants to have certainty, or at least a high degree of confidence, in their answers on behalf of these empirical arguments. At a minimum, the participants should aver that the empirical arguments provided them with at least as much confidence as a proof could provide. However, this is not what we observed. Second, we want to illustrate how our expectancy value model can explain why participants offered the empirical arguments that they did. Taking into account the participants' perceived value of obtaining complete conviction, cost anticipated in searching for a proof, and likelihood of success in finding a proof allows us to provide coherent accounts of why students produced and settled for empirical arguments. Indeed, we will further argue that in many cases when participants offer empirical arguments, participants are neither behaving irrationally nor inconsistent with mathematical practice.

Research Context

This study occurred at a large state university in the northeast United States. The data was collected in the first six weeks of a content-based course for prospective and practicing teachers of secondary mathematics focusing on problem solving. The aim of the course was for these teachers to develop the mathematical knowledge and dispositions to solve mathematical problems effectively and to enable these teachers to help their future students to do so. The course met weekly and was co-taught by the first two authors of this paper.

For the first six weeks of the course, class meetings were comprised of the students solving challenging problems in groups for about one hour, presenting their solutions to the larger class, and then reflecting on how this experience related to the nature of mathematical problem solving and the teaching of mathematics. The data from the paper was collected in four of these six meetings.

Our analysis focuses on the 11 prospective or practicing mathematics teachers who completed the course, all of whom claimed to have completed some courses in advanced mathematics. The students worked in four groups, which we call Group A, B, C, and D, which were mostly stable throughout the semester.

Materials. The data was collected when the students worked on four problems, two of which have multiple parts. These problems were chosen such that the answer to the questions could be conjectured via empirical reasoning but each answer could also be justified by deductive argumentation or proof. Problems 1, 2, 3, and 4 were given in the first, second, fourth, and sixth week of the course, respectively. (The problems in week 3 and week 5 were a geometry and a modeling problem respectively. These were not included in our analysis because they did not permit empirical generalizations).

Procedure. For the first six weeks of the semester, class began by having students work collaboratively on the mathematical problems. They were given one hour to work on the problems. If a group had agreed upon an answer to the problem, they could raise their hand to discuss the answer with one of the two course instructors. When this occurred, the instructors would interview the students about their solutions. Otherwise the instructors would circulate the room observing the students' behavior and answering questions that the students may have had about the meaning or interpretation of the problem. The instructors would not, however, provide hints or assistance to the student or confirm that their answers were correct or that the students were on the right track. After 60 minutes had elapsed, if a group did not discuss their solution with the instructors (which was usually the case), the instructors would then go to each group and ask them to discuss the answer that they obtained.

The interviews between each group of students and a course instructor were semi-structured and audiotaped. The instructor photographed the students' written solution. The instructor first asked the student what their solution was and then asked the students to explain and justify their solution. At this stage, the instructor sometimes asked for clarification if he or she was not sure that she understood the students' arguments. The interviewer then asked the students to state how certain their solution was correct on a scale of 0 through 100. If any students gave a response of less than 100, they were asked why they were not certain in their solution, what further evidence could give them more confidence in their answer, and why they were not seeking this evidence. In these discussions, the interviewer carefully distinguished between students' *answers* and their *justifications*. The interviewer would explicitly say that he or she wanted the students' confidence about the correctness of the answer, not the correctness or permissibility of the justification. Interviews typically lasted between five and ten minutes.

Problem 3 had two sub-questions and Problem 4 had three sub-questions. For these class meetings, each sub-question was treated as a separate problem. (i.e., the instructor would go through the protocol for each explanation that each group provided for one of the problems). Hence, each group was given the opportunity to supply seven answers—one for Problem 1, one for Problem 2, two for Problem 3, and three for Problem 4. For some problems, the groups disagreed on the answer and offered multiple justifications. In these cases, each answer was treated separately. In total, 31 answers were offered.

Analysis. All of the audio-recorded data was transcribed. The analysis proceeded through three stages. In the first stage of the analysis, we categorized each justification as empirical or deductive. For the sake of brevity, we do not discuss how we assigned these codes here. In the second stage, we determined the confidence that individual students had in their group's answer. In the third stage, we engaged in thematic analysis (Braun & Clarke, 2006) to categorize the reasons that (1) students expressed certainty in an answer, (2) why students expressed some doubt in their answer (i.e., gave a conviction score of less than 100), and (3) why they did not seek more evidence when they gave a conviction score of less than 100.

Results

Table 1 presents a summary of the arguments that students' produced as well as how confident that the students were that the argument was correct. Table 1 reveals that the majority (18 of 31) of students' justifications for their answers were empirical in nature, replicating the result from the research literature that students frequently justify by empirical arguments. However, when students justified their answer with an empirical argument, they usually retained some doubt about the correctness of their answer, giving a confidence rating of less than 100 in 32 of their 39 (82%) of their ratings. Consequently, these data indicate that students' propensity to justify their mathematical claims with empirical evidence does not imply they believe that empirical evidence can provide certainty that a mathematical claim was true.

	Deductive Justification	Empirical Justification
Number of justifications	13	18
Students with a confidence level of 100 for the justification	27	7
Students with a confidence level of less than 100	6	32
Average confidence level	99.4	68.9

Table 1. Confidence level of students in deductive and empirical justifications.

To understand why students gave the responses that they did, consider Group B's solution and justification for Problem 1, where Billy offered the incorrect answer of ¾.

Problem 1: Suppose there are a row of squares with each square numbered 1, 2, 3, and so on. You start on square 1. You flip a coin. If you get heads, you move up one space. If you get tails, you move up 2 spaces. You repeat this process indefinitely. What is the probability that, at some point, you are on square 25?

[1] Int1: Okay. On a scale of 0 through 100, how confident are you that your solution is correct?

[2] Int2: That the answer is ¾.
[3] Billy: ¾. [Laughter]
[4] Int2: 75. Is that a fair number?
[5] Bob: Wasn't it like the same pattern when he worked it out with 3? So first he worked it out with like 3 and then he tried from like 23 to 25 and then he got like the pattern was still continuing. So that kind of convinced me too.
[6] Brenda: I'd say 98.
[7] Bob: I'm confident. So I'd say 98 too.
[8] Int2: So none of you said 100. So why didn't you say 100? What doubts do you still have?
[9] Billy: For me, I'm a little doubtful because I know like the long way of finding the answer of finding the exact, like the number of heads, the number of tails, the number of choices, blah, blah, blah, but that's way too long. So I'm trying to shorten my way and find the answer. Which means I'm like eyeballing it to say. Because of that, I'm not 100% sure but I'm pretty confident that this is the right way.
[10] Int2: So are you saying you are willing to take a slight risk that this might not be right to avoid the longer process… I'm sorry do you have anything that you would like to add to that Brenda?
[11] Brenda: No, I mean, I'm pretty confident. I would say, because I don't know, if this was a question, I would probably stop at that and be like, I'm going with this question. If it was like an exam and it was pass or fail, this would be my final answer.
[12] Int2: Would there be any evidence or further work that would make you more confident?
[13] Brenda: I guess like what Billy was saying, maybe doing the whole long way, going out but realistically, I don't know. I'm kind of lazy in that aspect.
[14] Int2: You started to answer this, but why wouldn't you seek that evidence…
[15] Billy: It's too long.
[16] Brenda: Yeah.

In this excerpt, we again see the students claiming that they did not find the empirical argument to be fully convincing [lines 6-8]. Billy and Brenda said they would be more convinced by a deductive argument [9, 13] yet both said that they would not seek the deductive argument because it would not be worth the effort [15-16]. What is striking is that Billy claimed that he knew how to produce a proof [9] and he felt that the likelihood of obtaining a proof was high [9]. Even though Billy's confidence in the answer that he offered was relatively low [3], he did not produce this proof. For Brenda and Billy, the value of raising his confidence level was not worth the cost of seeking a lengthy proof.

Group B was told that their answer was incorrect and they were asked to continue working on the problem. Later, Group B obtained the correct answer, justifying it with a deductive argument (the one surveyed by Billy in [9]).

[17] Int: Let me ask you the same question. How confident are you on a scale of 0 through 100 that that is correct?
[18] Billy: [pause] I'll go with 100 for this one.
[19] Brenda: 100.
[20] Bob: I'll go with 99.
[21] Int: 100. Why are you certain?
[22] Billy: For no reason. [laughs] Because I worked, I calculated, I've come up with a formula then I applied it to getting to 3 from 1 and getting to 5 from 1 and it worked out.
[23] Int: So you had the logic for your formula…
[24] Billy: Yeah.
[25] Int: And you checked it for small cases.
[26] Billy: Yes.
[27] Int: Bob, is there a reason that you still have a scintilla of doubt?
[28] Bob: I don't know. [pause] It's just I'm kind of shaky about the whole choose thing. But the way he kind of presented it, I kind of like, did it in an old-fashioned kind of list and I got the same maximum of

like 24 and minimum of like 12 flips. So like I'm agreeing with what he's saying. What's kind of stopping me is the whole choose thing and then we're assuming that order doesn't matter, right?

We observe two things in this transcript. First, Billy claims certainty in his answer [18], but this is not just because he verified the logic in his argument. It is also because he checked that his argument worked in the case of a simple example [22]. This was a common occurrence in this study. Second, Bob obtains a high degree of confidence but not certainty in Group B's answer [20] even though he can follow Billy's argument [28]. Our interpretation of the explanation in [28] is that Bob felt that he lacked the background in combinatorics ("I'm kind of shaky about the whole choose thing") to ensure that there was not a mistake in Billy's reasoning.

In the full paper, we will illustrate that the themes discussed here—that students settled for empirical arguments due to a lack of motivation, that they obtained certainty in deductive arguments by coordinating them with empirical evidence, and that students who expressed doubt in a proven statement did so because they were not confident in their ability to verify a proof, were common occurrences in this study.

Discussion

In our study, we found that, consistent with the research literature, students often justified their mathematical assertions with empirical arguments and sometimes expressed doubt in a statement after reading (and accepting) a proof of that statement. The Proving as Convincing perspective in the mathematics education literature (as described by Stylianides, Styliandies, & Weber, in press) can account for some of these occurrences. There were instances in which a student genuinely appeared to gain certainty from an empirical argument. However, for most instances, the participants submitted empirical arguments because they lacked the motivation to seek a proof or doubted that they could produce a proof if they sought one. Consequently, we propose that our broader Expectancy Value framework can offer a more accurate account for why students offer the justifications that they do. One implication for mathematics education researchers is that they should ask students to express the level of confidence that they have in their solution after they supply a justification (e.g., Stylianides & Stylianides, 2009; Weber & Mejia-Ramos, 2015).

As a final caveat, we note that our study occurred with mathematics teachers who had experience in proof-based mathematics courses. This population appears to differ from other populations in how they construct and evaluate justifications (e.g., Iannone & Inglis, 2010; Weber, 2010). Hence, we do not claim at this stage that our empirical findings will generalize to these populations, only that the theoretical account that we provide in this paper should be taken into account when conducting research with this population.

Expert vs. Novice Reading of a Calculus Textbook: A Case Study Comparison

Emilie Wiesner, Aaron Weinberg, John Barr, & Nikki Upham
Ithaca College

We present case studies of a student and a non-mathematics professor reading an excerpt from a calculus textbook. We use the ideas of sense-making frames and gaps and the implied reader to compare their reading experiences. In particular, we attempt to distinguish the role of calculus background knowledge from reading expertise in making sense of the text.

Key words: calculus, textbooks, sense-making, implied reader, expert vs. novice

Textbooks have long been a staple of mathematics classes, and recent trends toward blended instruction mean that students are increasingly expected to learn independently from a variety of text materials (e.g., Maxson & Szaniszlo, 2015). However, research has suggested that mathematics students struggle to read their textbooks effectively (e.g., Shepherd, Selden & Selden, 2012). Consequently, it is important to understand how students make sense of and learn from reading mathematics text materials.

There has been relatively little research investigating how students read and comprehend mathematical texts. Osterholm (2006) found that students were less successful at interpreting passages that were written in "mathematical English." Shepherd, Selden, and Selden (2012) found that undergraduate calculus and precalculus students struggled to read their textbooks effectively. Shepherd and van de Sande (2014) compared the reading practices of first-year mathematics students, mathematics graduate students, and mathematicians, and differentiated their reading strategies by background knowledge, self-monitoring, and resource use.

This paper presents a case study of two people reading an excerpt from a calculus textbook. We build on prior research by investigating the sense-making practices of the readers and the interaction of these practices with the readers' background knowledge. In order to highlight the different roles played by sense-making practices and background knowledge, we compare reading episodes for a calculus student and a non-mathematician STEM professor.

Theoretical Framework

To capture the interactive nature of the reading process as well as the constraints inherent to the text, we use two interpretive tools: sense-making frames and gaps (e.g., Dervin, 1983; Klein, Phillips, Rall, & Peluso, 2007) and the implied reader (e.g., Weinberg & Wiesner, 2011).

Sense-Making Frames and Gaps

During the reading process, a person experiences and seeks to organize a collection of phenomena. Based on prior knowledge and experience, the person selects a *sense-making frame*: "a mental structure that filters and structures an individual's perception of the world by causing aspects of a particular situation to be perceived and interpreted in a particular way" (Weinberg, Wiesner, & Fukawa-Connelly, 2014, p. 169). The reader then encounters *gaps*, which are questions that the reader (explicitly or implicitly) asks in order "to construct meaning for the mathematical situation" (Weinberg, Wiesner, & Fukawa-Connelly, 2014, p. 170). *Bridges* are the answers that the reader constructs in response to these questions.

Weinberg, Wiesner, and Fukawa-Connelly (2014) identified four types of sense-making frames: *content frames* focus on the meaning of the mathematical content of the text; *communication frames* focus on the text's organizational structure; *situating-mathematics frames* focus on the mathematical significance of the text; and *situating-pedagogy frames* focus on pedagogical choices that reveal the meaning or significance of the mathematical ideas.

The Implied Reader

To realize the learning opportunities afforded by a text, there is a limited range of productive interactions with—and interpretations of—the text. Weinberg and Wiesner (2011) defined the *implied reader* as "the embodiment of the behaviors, codes, and competencies that are required for an empirical reader to respond to the text in a way that is both meaningful and accurate" (p. 52). For example, competencies for reading a calculus text that describes an application of integrals might include understanding integrals as accumulation. Codes might include recognizing that an image next to text implies that the text describes the image. Behaviors of the implied reader could include filling in logical details of an argument or derivation.

Drawing on this framework, our research questions are:

1. What gaps does each reader experience and how do they bridge those gaps?
2. How can the reader's gaps and bridges be characterized in terms of their sense-making?
3. How can the reader's gaps and bridges be explained by the implied reader of the text?

Methods and Methodology

We invited two groups to participate in the study. For the first group, we invited all 20 students in a second-semester calculus class (at a midsized undergraduate institution in the northeast) to participate in the study; five students volunteered and all participated in the interviews. For the second group, we personally invited (from the same institution) three faculty members in the physics department and one each in the chemistry, biology, computer science, and economics departments; all agreed to participate.

For this paper, we selected one student, "Peter," and one professor, "Professor M," to use as case studies. At the time of the interview, Peter was a sophomore with a major in architectural studies and a minor in mathematics. He had earned a B in Calculus I and ultimately earned an A- in Calculus II. Prior to the interview, Peter had regularly read sections from his textbook (Hughes-Hallett et al., 2012) and completed related activities, such as writing summaries and solving problems. Professor M was a tenured professor with a PhD in chemistry, and had taken two semesters of calculus in the early 1990's. He indicated that he did not use calculus ideas in his research or teaching but regularly performed algebraic manipulations as part of teaching.

In order to have the students match the implied reader's competencies as much as possible, we selected textbook excerpts for interviews where the students had been taught the prerequisite knowledge. Both interviewees read two excerpts from *Section 8.2: Applications to Geometry in Calculus* (Hughes-Hallett et al., 2012). The first excerpt, shown in Figure 1, gave a description of the general computational strategy used in the section. The second excerpt, shown in Figure 2, included a derivation of the arc length formula.

At the beginning of the interview, we asked participants to describe their knowledge of integrals and Riemann Sums and gave them a problem about interpreting an integral for a graph of electrical current vs. time to assess their understanding of integration concepts. Next, they were asked to read an excerpt from the textbook using a message q/ing protocol (e.g., Dervin, 1983): we instructed the participants to hold a pen next to the line they were reading, and identify places where they thought the text was unclear or confusing. After completing the reading, participants were asked to describe the main ideas of the section. The interviewer then used an *abbreviated timeline* protocol (e.g., Dervin, 1983), revisiting each paragraph in the text and asking the participants whether they felt that any aspect of the paragraph was unclear.

In Section 8.1, we calculated volumes using slicing and definite integrals. In this section, we use the same method to calculate the volumes of more complicated regions as well as the length of a curve. The method is summarized in the following steps:

To Compute a Volume or Length Using an Integral

- Divide the solid (or curve) into small pieces whose volume (or length) we can easily approximate;
- Add the contributions of all the pieces, obtaining a Riemann sum that approximates the total volume (or length);
- Take the limit as the number of terms in the sum tends to infinity, giving a definite integral for the total volume (or total length).

Figure 1. Section 8.2 Overview

A definite integral can be used to compute the *arc length*, or length, of a curve. To compute the length of the curve $y = f(x)$ from $x = a$ to $x = b$, where $a < b$, we divide the curve into small pieces, each one approximately straight.

r Eight USING THE DEFINITE INTEGRAL

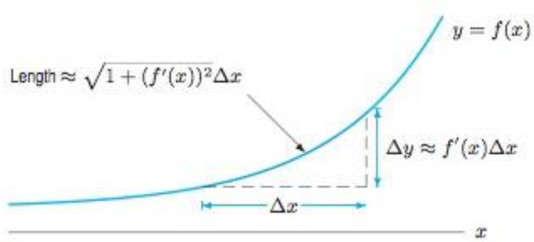

Figure 8.27: Length of a small piece of curve approximated using Pythagoras' theorem

Figure 8.27 shows that a small change Δx corresponds to a small change $\Delta y \approx f'(x)\,\Delta x$. The length of the piece of the curve is approximated by

$$\text{Length} \approx \sqrt{(\Delta x)^2 + (\Delta y)^2} \approx \sqrt{(\Delta x)^2 + (f'(x)\,\Delta x)^2} = \sqrt{1+(f'(x))^2}\,\Delta x.$$

Thus, the arc length of the entire curve is approximated by a Riemann sum:

$$\text{Arc length} \approx \sum \sqrt{1+(f'(x))^2}\,\Delta x.$$

Since x varies between a and b, as we let Δx tend to zero, the sum becomes the definite integral:

For $a < b$, the arc length of the curve $y = f(x)$ from $x = a$ to $x = b$ is given by

Figure 2. Arc length introduction, diagram, and formula derivation

All interviews were video-recorded to capture the discussion and participants' gestures. The audio portions of interviews were transcribed, and notations were added describing participants' gestures. We then collaboratively identified the following aspects of each interview:

- a description of each gap, summarizing the question that the reader experienced;
- our hypothesis about the source of the gap (e.g., mismatches with the implied reader);
- a description of each bridge and a hypothesis about how the reader formed the bridge;
- the sense-making frames the interviewee used while experiencing each gap and bridge.

Results

Case Study 1: Professor M

We identified 12 distinct gaps that Professor M experienced while reading. Here we describe four gaps, representing the variety in Professor M's gaps, bridges, and sense-making frames. The italicized questions below each represent a gap as summarized by the research team.

Background Knowledge. When asked what he knew about integrals and Riemann sums, Professor M recalled some ideas related to integrals: "taking areas under curves" and "doing areas of three-dimensional shapes." However, when working on the pre-reading problem, he appeared to confuse integrals and derivatives. He indicated no knowledge of Riemann sums beyond recognizing the phrase.

What is a Riemann sum? Professor M gave a summary of the first excerpt (Figure 1):

> We started learning how to calculate volumes of fairly simple shapes, now we're going to use what we learned to do more complicated shapes by cutting these complicated shapes into pieces that are easy to approximate. And then add them together by taking what's called this Riemann Sum, I think.

Professor M's phrasing—"what's called this Riemann sum, I think"—suggested that he experienced a gap about the meaning of a Riemann sum or how it was being used in the text. He appeared to think of this gap as related to terminology knowledge (suggesting a content frame); this was consistent with his self-reported knowledge of Riemann sums and reflected a missing calculus competency that was part of the implied reader.

Professor M appeared to initially guess about the role of the Riemann sum. However, by the end of the interview, he had bridged this gap: he thought of Riemann sums as a sum of small lengths that approximated the length of the curve:

> So I think the Riemann sum is basically taking all these, they're breaking this curve up into very tiny, little lines. Right? And then they're measuring the length of each of those little lines and adding them together.

Professor M also described the relationship between a Riemann sum and an integral:

> The arc length is taking a definite number of smaller lines and adding them together. So you get an approximation of what the length of this whole curve is. This [the integral] is sort of doing the same thing, but with an infinite number of points.

Finally, Professor M responded to a question about why Riemann sums appeared in the text:

> Because that's conceptually easier, I think, to understand…. Like take smaller steps, make smaller ones, and then—conceptually, I think that's a lot easier to, um... process, um… I think—connect that to something real.

Professor M's responses suggest that he built a bridge by coordinating multiple pieces of the text, including the section overview and the arc length introduction. Although his gap appeared to have emerged from a content-oriented frame, his final response suggested that he also employed a situating-pedagogy frame. By coordinating these frames, Professor M was able to make sense of the Riemann sum's role in the derivation process.

Does the diagram go with the first paragraph? What does the first paragraph mean? Reading the second excerpt (Figure 2), Professor M initially experienced two related gaps:

> "To compute the length of the curve y".... Is—Is this [points to diagram] the curve that they're talking about? I guess.... The graphic, this here [points to diagram], is supposed to accompany this [points to first paragraph]? Oh wait [points to 'Figure 8.27' in paragraph after diagram], no. Okay, not really.... Alright, let me then go back. It looks like they're referring to the figure here [points to "Figure 8.27" in paragraph after diagram].

Professor M first expressed a gap about whether or not the first paragraph in Figure 2 referenced the diagram below it. He appeared to initially expect that the "curve" in the first paragraph referred to the diagram. He bridged his gap by examining the text further, locating the text "Figure 8.27" in the paragraph below the diagram, and—based on this—deciding that the diagram was *not* in reference to in the first paragraph. His focus on the organization of the text indicates that he was employing a communication frame.

Resolving this gap prompted Professor M to re-examine the first paragraph in Figure 2. His verbal hesitations suggest that he experienced a gap about the meaning of the mathematical objects described in the first paragraph; he then bridged this gap as he continued to read:

> Okay, 'Compute the length of the curve *y=f(x)*... from *x=a* to *b*.' Okay, *a* to *b*. This [points to *x*-axis on diagram] is the *x*-axis, where *a* is LESS than *b*. Okay. We divide the curve into small pieces. Okay. Alright, alright. Each one approximately straight. So we're taking a bunch of little straight lines [drags pen across diagram as he makes "ch ch ch ch" sounds] and putting them together.... Alright.

In this excerpt, Professor M switched to a content frame, focusing on the mathematical content of the text. Although he identified the diagram as accompanying the paragraph following it, Professor M used the diagram to create his own instantiation of the content of the first paragraph by adding an "*a*" and "*b*" to the "*x*-axis" and drawing lines on top of the diagram.

What is happening algebraically in the "Length" approximation? As Professor M read the "Length" approximation (Figure 2), he appeared to experience and quickly bridge a series of gaps about the algebraic manipulations involved, consistent with a content frame:

> Okay... [moves pen across the equations] Okay.... So this is simple, sort of algebra here. Take the Pythagorean Theorem, plugging in this [points to $f'(x)\Delta x$] for the change in y, combining like terms and so forth, getting that [points to $\sqrt{1+(f'(x))^2}\Delta x$].

His speech suggests that he was implicitly asking and answering questions about how the algebraic expressions were connected. Since the text did not explicitly address how each expression on the line was connected, the process of questioning this line of text and filling in reasoning was a behavior of the implied reader. As illustrated by Professor M's work, effectively doing so required coordinating information from the diagram (about the Pythagorean theorem) and from the previous line of text, as well as drawing on knowledge of algebraic manipulations.

Case Study 2: Peter

We identified nine distinct gaps that Peter experienced and evidence of content, communication, and situating-pedagogy frames during Peter's reading. Below, we describe several of the gaps that Peter experienced, which reflect common themes in his reading experience as well as overlap with the gaps Professor M experienced.

Background Knowledge. Peter described an integral as the area under a curve and indicated that a Riemann sum "splits up the area." While working on the pre-reading question, Peter determined that an integral and a Riemann sum would both measure the total number of electrons passing by a point in a circuit over a certain period of time. He then expressed uncertainty about his conclusion and about whether an integral and a Riemann sum would measure the same quantity. He also indicated confusion about the purpose of a Riemann sum:

> They always just, like, take the Riemann sum and they just have a formula—the formula doesn't change—and then they just put it in an integral. So I was kinda, like, thinking on how.... Why couldn't we just kinda skip the Riemann sum step, 'cause they never really

go over that too much in a book and… Whenever like teachers try to explain it, it's kinda just, like, so you know the change in the A or whatever the change in value could be.

Peter's experience appeared to be that one puts a formula into a Riemann sum and then changes the summation symbol into an integral, but he did not know the purpose of doing this.

Where are a and b in the diagram? Like Professor M, Peter experienced a gap while trying to connect the first paragraph and the diagram in Figure 2:

> What threw me off was that in the picture—the graph—there wasn't really an *a* or a *b*. So I was kinda looking for those—I was kinda assuming that there would be an *a* here and a *b* here [traces his pen from the curve down to the *x*-axis in two different spots] but, um.... So I'm thinking those come in later, but I don't know what they had to do with it for now.

Peter used a communication frame to focus on the physical layout of the text and employed a formatting code that graphics should be associated with adjacent text. This code, misapplied to the text, created a gap for Peter about the lack of association that he did not resolve.

What is happening in the "Length" approximation? Peter articulated several distinct gaps while reading the string of equalities and approximations for "Length" in Figure 2. He first indicated confusion about the "1" under the square root sign: "But then they kinda just put one for the change of x squared." Then, he expressed confusion at the appearance of the derivative and the move of Δx: "And then they just put derivative of x squared and took out the change of x"; and finally the relationship between Δy and $f'(x)$: "Like yeah, they kinda just threw that [$\Delta y \approx f'(x)\ \Delta x$] in there without really explaining it."

Peter's attempts to identify the justification for each new term in the derivation suggests that he was using a content frame. He enacted the behavior of the implied reader to question how the algebraic expressions were connected, but he didn't implement the needed competencies to identify the mathematical reasoning for these connections and continued reading without evidence of having bridged any of these gaps.

Why is it important to use a Riemann sum? After reading the integral formula for arc length (in Figure 2), Peter stated:

> It was saying before with the Riemann sum. Like they put the formula that they got here [points to "Length" formula in Figure 2] into the Riemann sum and that's fine. Um.... And then they kinda just say they're putting it into a definite integral.

After completing the reading, the interviewer asked Peter why he thought a Riemann sum was used before an integral in the reading. Peter responded:

> For finding the length of the curve, I don't really understand entirely yet. I was under the impression that Riemann sums were there kinda just to show the understanding that um.... As the change of x gets smaller, then you're, um, you're gonna have a more accurate answer. But change of x in this case [pointing to the diagram] is the... I guess, length of this triangle they're trying to make. And as that gets smaller, it's not like you're getting a more accurate answer, but you're just gonna get a smaller answer for the curve.

Peter hadn't coordinated the sum with the individual terms in the sum, failing to possess the implied reader's fluency with Riemann sums. He largely employed a content frame in these excerpts, focusing on how the Riemann sum fit into the derivation of the integral formula for arc length. However, his attempt to link Riemann sums to larger pedagogical goals indicated he was also using a situating-pedagogy frame. Although this frame could potentially have provided a foundation to make important conceptual connections, Peter's limited mathematical competencies kept him from effectively creating a bridge by coordinating the two frames.

Discussion

The readers described here experienced related gaps about the same parts of the text. However, differences in the ways that they experienced and responded to these gaps gives insight into the role of sense-making frames and background knowledge in the reading process.

Both readers experienced a gap about the diagram in Figure 2 in relation to the text. From the researchers' perspective, the diagram had three potential roles: a "zoomed-in" segment of a generic curve (explicitly referenced in the text), an exemplar of the curve *f(x)* described in the first paragraph, and a display of the result of the "Length" calculation. Each reader's gap was a product of their attempt to employ a formatting code—proximity between text and figures indicates they are related—and the undifferentiated roles of the diagram in the excerpt. However, Professor M experienced this gap as a questioning of the initial formatting code and used another formatting code—texts reference figures where they are being used—to resolve the gap productively. In contrast, Peter expected the issue to be addressed by the text and moved on.

Both readers experienced multiple gaps while reading the "Length" derivation in Figure 2. These gaps were compatible with the implied reader rather than the result of a mismatch between implied reader and actual reader: Here, the text provided little justification for the algebraic derivation, requiring the reader to interrogate the text and to have the appropriate background competencies to fill in reasoning. Professor M was more successful in addressing these gaps, exhibiting a closer match to the behaviors and competencies of the implied reader.

Both readers also experienced a gap about the role of the Riemann sum in the derivation of the formula for arc length. Here, missing or incomplete competencies about Riemann sums, on the part of each reader, played an important role. However, the extent of the mismatch between the implied and empirical readers did not fully explain the degree to which the readers bridged this gap. Peter arguably knew more about Riemann sums (and Calculus in general) than Professor M. Peter attempted to draw on his previous experience with the textbook and instructors' input, but was not able to bridge the gap. Moreover, Peter did not use the reading itself as a source of insight for his confusion. In contrast, Professor M was able to bridge this gap by drawing on different parts of the reading—as well as coordinating pedagogical and content sense-making frame—to deduce what Riemann Sums were mathematically and why they might be pedagogically useful.

The two readers also differed in how effectively they employed non-content sense-making frames. In particular, Professor M used a communication-oriented frame as a launching point for understanding the introduction to arc length, and he ultimately drew on this description as part of his understanding of Riemann sums. Professor M also exhibited a situating-pedagogy frame while describing Riemann sums. Although Peter used communication and situating-pedagogy frames, his use of these frames was not as sustained or reflective and limited their effectiveness.

A mismatch between the implied and actual readers explained some but not all of the gaps that the readers experienced. This suggests that a focus on teaching "content" is insufficient to help students read textbooks more effectively. Moreover, these case studies highlight that some gaps are inherent to the reading process (such as the algebra gaps associated with the "Length" calculation). Normalizing this experience for students and helping them to distinguish between gaps that are inherent to the text and gaps that are related to background competencies may be important for increasing the effectiveness of textbook reading. Lastly, these case studies highlight that an implied/actual reader mismatch does not necessarily prevent the reader from creating valid meaning from the reading; effectively implementing non-content sense-making frames may be one way that readers can effectively overcome this mismatch.

Mentor Professional Development for Mathematics Graduate Student Instructors

Sean P. Yee
University of South Carolina

Kimberly Cervello Rogers
Bowling Green State University

Abstract

To develop graduate student instructors' (GSIs) skills and abilities as collegiate mathematics instructors, researchers at two universities implemented a peer-mentorship model where experienced GSIs completed a 15-week professional development (PD) to learn how to mentor novice GSIs in teaching undergraduate mathematics. Using pre-survey, post-survey, and semi-structured reflective interviews, we studied changes in 11 mentor GSIs' perspectives on teaching and learning practices and what aspects of the mentor PD were deemed valuable by the mentors. Results suggest that this mentor PD, as a peer-mentorship model, helped GSIs deconstruct the dichotic mathematical paradigm of statements being true or false when discussing teaching. Moreover, mentor GSIs valued how the mentor PD helped guide them to facilitate novice GSI post-observation discussions.

Key words: Graduate Student Instructors, Professional Development, Peer-Mentoring

A key ingredient in a successful collegiate mathematics department is the "effective training of graduate teaching assistants" (Bressound, Mesa, & Rasmussen, 2015, p. 117). This training is crucial because graduate student instructors (GSIs)[1] serve as instructors of record for hundreds of thousands of undergraduate mathematics students each semester (Belnap & Allred, 2009; Lutzer, Rodi, Kirkman, & Maxwell, 2007) and significantly impact the quality of collegiate mathematics instruction across the US. Despite their prevalent role as instructors of undergraduate mathematics, GSIs typically lack guidance and support to teach undergraduate students effectively (Latulippe, 2009; Rogers & Steele, 2016; Speer, Gutmann, & Murphy, 2005; Speer & Murphy, 2009).

When an instructor lacks teaching support, they draw on their teaching beliefs, attitudes, and dispositions to define their pedagogy (Welder, Hodges, & Jong, 2011). Research has shown that an instructors' initial experiences with teaching develops their beliefs and practices of teaching that may last their entire career (Lacey, 1997; Lortie, 1975; Zeichner & Tabachnick, 1985). Thus early teaching experiences of GSIs may shape how GSIs teach in the short term and in the long term as potential future faculty members. Without guidance, for instance, GSIs may struggle to distinguish between how their graduate-level mathematics courses are taught and how they should teach their undergraduate mathematics courses (Speer, King, & Howell, 2014). In order to address this critical need for early support in GSIs' development as effective teachers, this study generated and implemented a mentor professional development (PD) at two American universities to develop experienced GSIs into mentors for novice GSIs (protégés). This paper focuses on the effect of the mentor PD[2] on mentor GSIs' views of teaching and learning.

[1] GSI was used instead of TA (Teaching Assistant) because GSI targets the specific set of graduate students who are full instructors of record.

[2] The implementation of this mentor PD was supported by a National Science Foundation grant at two universities (NSF GRANT 1544342 &1544346).

GSI Guidance and Support

In K-12 teacher education, the critical role of student teaching with a mentor teacher has been recognized as a vital precursor to fully instructing a course (Council for the Accreditation of Educator Preparation, CAEP Standard 2). At the collegiate level, no such standard precursor exists across doctoral granting institutions (Speer et al., 2014). This is due, in part, to the wide variety of roles graduate students may be assigned (e.g. tutors, graders, recitation instructors, or instructors of record) and the limited resources within mathematics departments.

Consequentially, researchers have determined that GSIs are unable to articulate their pedagogical decisions clearly. Rogers & Steele (2016) studied teaching mathematics content courses for preservice elementary teachers and found that GSIs:

> did not demonstrate strong abilities to articulate the reasons for their instructional decisions or identify alternative pedagogical moves that may have led to different outcomes; instead, their interview comments often focused on sufficiently covering the mathematical content and the importance of preparing PSTs with strong content knowledge to be able to teach their future elementary students. (page number)

This lack of explicitly articulating pedagogical decisions could be due, in part, to the fact that mathematics graduate students often start their doctoral program with limited pedagogical course experience (Speer et al., 2014).

Although there can be many individuals who offer general advice about teaching to graduate students, including mathematics faculty members and course coordinators, rarely is this advice individualized enough for the GSI to justify and reflect on their pedagogical decisions (Speer et al., 2014). Shulman (1986) reminds us that for GSIs to justify pedagogical decisions within mathematics requires an understanding of pedagogical content knowledge, "which goes beyond knowledge of subject matter per se to the dimension of subject matter knowledge *for teaching*" (p. 9). The links between content and pedagogy do not develop automatically in teaching (Ball, Thames, & Phelps, 2008) and teachers need to be aware of the goals orienting their decisions from the teacher's and student's perspective (Schoenfeld, 2010). This is where a mentor teacher can be helpful by offering specific advice and justifying that advice with the necessary pedagogical decisions. Many universities have used faculty as mentors for GSIs, however Johnson and Nelson (1999) found that such relationships are ethically complicated and multifaceted because of other hegemonic roles faculty must play, such as doctoral advisors and qualifying exam evaluators. We posit that to be genuinely aware of the individualized pedagogical decisions requires a mentor closely in tune with a protégé's current experiences. To that end, we focused on a mentor PD for experienced GSIs to guide and support protégés.

Mentoring GSIs

Research has indicated that mentoring has social and cultural benefits if mentor GSIs were inclined to help protégés learn how to teach. Johnson and Nelson (1999) indicate that mentoring is central to "quality graduate education" (p. 205), a key component of a successful mathematics department (Bressound et al., 2015). Crisp and Cruz's (2009) meta-analysis of mentoring literature from 1990 through 2007 found that certain subgroups (minorities and females) benefited greatly from peer mentoring, as mentors offer support to socialize professionally, work, navigate, reflect on academic discourse, and help alleviate stress within doctoral programs. Zaniewski and Reinholz (2016) looked at mentoring from a cultural perspective of identity in a peer mentoring program. Admittedly, Zaniewski and Reinholz's study focused on a different population, experienced undergraduates mentoring freshman undergraduates in the physical sciences, but their results demonstrated positive psychosocial and academic interactions resulting in friendships that generated a *community of practice* (Kensington-Miller, Sneddon, & Stewart, 2014) amongst certain majors. Such results are desired within doctoral programs. Thus the literature supports the design and implementation of peer-mentoring for GSIs, yet raises the question: How do we mentor the mentors?

Mentoring curricula

Although teaching experience is necessary, it is not sufficient for mentoring because mentors need to understand *their* role and purpose in facilitating meaningful pedagogical decision-making conversations with protégés (Rogers & Steele, 2016). Consequentially, the design of a mentor PD curriculum should focus training mentors to guide and support protégés' understanding of their pedagogical decisions. Despite the small body of literature structuring mentor PD curricula (Crisp & Cruz, 2009), we note Boyle and Boice's (1998) seminal work on mentor PD that studied mentoring both novice faculty and novice GSIs with tenured faculty where they considered mentoring as the "cousin of faculty development" (p. 158). These researchers compared spontaneous mentoring (talk to the mentor if there are problems) and systematic mentoring (meeting regularly every week) and found that the systematic mentoring was more effective in supporting GSIs and faculty because the mentor could not prepare appropriately when it was spontaneous. Boyle and Boice also observed the topics that dominated mentor meetings in decreasing order of frequency were (1) discussions of undergraduates, (2) teaching styles, (3) teaching-related goals, (4) grading issues, and (5) course preparation.

Boyle and Boice's (1998) results informed the framework of our mentor PD because all five frequented topics could be discussed within the mentor PD through two main responsibilities: observing protégés teach and running small group protégé meetings systematically (not spontaneously). Thus our mentor PD curriculum revolved around observing protégés (including post-observation discussions) and facilitating small group discussions. A natural next question becomes, what impact did the mentor PD have on experienced GSIs? This study examines the results of a 15-week mentor PD around two research questions:

(RQ1) How did the mentor PD change mentors' perceptions of student behavior, student learning, and effective teaching?

(RQ2) What specific aspects of the mentor PD curriculum did the mentors view as most valuable in their preparation as mentors?

Method

Participants

Experienced graduate students at two universities applied and were selected to be mentors by the researchers based on their teaching experiences (aptitude for implementing student-centered techniques), their pedagogical accolades (teaching awards and student evaluations), and most importantly their desire to help novice GSIs to improve teaching at their university (essay responses were required). The number of participants was determined by the average size of each university's mathematics GSI program. Eleven mathematics and statistics doctoral candidates were selected to participate in the mentor PD seminars (four from one university and seven from another).

Mentor PD Curriculum

The goal of the 15-week mentor PD was to equip the 11 experienced GSIs to be effective peer-mentors. The participants and a mathematics education researcher met for 50 minutes once a week to discuss the responsibilities of the mentor as well as to generate frameworks and perspectives necessary for mentoring. Building on the GSI mentoring literature, the Mentor PD curriculum was structured around two main mentor responsibilities: (1) observing protégé GSIs including feedback, and (2) facilitating bi-weekly small group meetings (one mentor with four protégés) which provided a space to discuss teaching.

The first two weeks of the mentor PD incorporated a review of aligning lessons plans, goals, and assessments that mentor GSIs had previously learned in their mathematics teaching pedagogy courses. The next month (weeks 3-6) focused on the GSI Observation Protocol (GSIOP), which was generated by building off of the MCOP2 (Zelkowski, Gleason, & Livers, 2016) and forms used for GSI teaching evaluations. This work prepared the mentors to observe each of their four designated protégés classes three times during the protégé's first course.

The middle of the Mentor PD (weeks 7 & 8) introduced the notion of different colored flags to help mentors prioritize observational feedback for the protégés to digest easily. Although the GSIOP offers a thorough observation, feedback was focused to not overwhelm protégés. No more than two specific issues of each color were flagged (green flag: good, yellow flag: area for growth, red flag: immediate area of concern). Flagging was revisited in the mentor PD (weeks 13 & 14) with hypothetical scenarios in which the mentors role-played post-observation discussions to understand how to approach different teaching styles and perspectives without sounding overly critical or evaluative.

Another major topic addressed was how to effectively design, organize, implement, and facilitate biweekly small group meetings (weeks 9-12). By analyzing written scenarios, mentors learned how to structure and guide their small group meetings by determining who is driving the discussion and how it is being driven. Finally, week 15 brought many ideas together around the theme of *critical reflection* (Brookfield, 1995) by focusing on curricular hegemony and pedagogical efficacy over efficiency. Although researchers collected rich observational data from the mentor PD, space limitations mandated this paper remain focused on the results that would answer our research questions.

Mentor PD Data Collection

At the beginning and end of the mentor PD, the 11 mentor GSIs answered a survey (adapted from Jong, Hodges, Royal, & Welder, 2015) to examine their attitudes, experiences, and conceptions about teaching collegiate mathematics. Since the original survey drew upon the Mathematics Experiences and Conceptions Survey focusing on preservice teachers, we modified Jong and colleagues' instrument to focus on the tertiary instructors. The pre- and post-surveys shared a group of questions that asked the mentors to rate how strongly they agreed with statements in three categories: (a) beliefs about students (15 statements), (b) teacher characteristics (11 statements), and (c) lesson design (3 statements). That is, on a scale of one to five, with one being strongly disagree and five being strongly agree, participants rated their agreement with statements such as: (a) students should use multiple ways to represent concepts and solve problems (beliefs about students), (b) as a teacher I provide wait time and think time regularly (teacher characteristics), and (c) the structure of my lesson must be well organized to effectively achieve its goals (lesson design). We analyzed the mentors' pre- and post-survey responses to help address RQ1. Additionally, we included a question unique to the post survey: "List up to three things you learned from the mentor PD that you believe will help you as a mentor. Please list them in order of significance and briefly explain why." All 11 mentors listed what they learned most and second most while only nine listed a third lesson learned. Our analysis of these responses informs RQ2.

After the conclusion of the mentor PD, an external evaluator conducted 1-hour, semi-structured reflective interviews with each mentor. The mentors were given a copy of their pre- and post-survey responses and asked to elaborate on what they saw in their own responses to triangulate the data. Mentors' responses about how and why their attitudes changed throughout the mentor PD also informs RQ1.

Mentor PD Data Analysis

We first examined the quantitative data by analyzing the pre- and post-survey questions. This quantitative analysis informed the design of the semi-structured reflective mentor interviews, which we qualitatively coded relative to the mentor's responses to the attitudes, experiences, and conceptions on teaching questions. For all 29 pre and post questions, t-tests were used to determine variance before and after the mentor PD. Aggregate quantitative analyses of the pre- and post-survey data were shared during the semi-structured interviews to help answer RQ1. The additional post-survey question (top three things learned) was qualitatively analyzed relative to the topics and course design to determine what aspects of the mentor PD were deemed valuable by the mentors (RQ2).

Results

Change in Attitude (RQ1)

Paired sample t-tests were implemented on all 29 pre and post survey questions to look for variance (N=11 with *alpha*=5%). Although, no variance was significant (which may be due to the limited number of participants, N=11), a few descriptive statistics on change in mean offer insight into how the mentor PD affected specific mentors' attitudes. Due to limited space, we discuss the survey question with the greatest change in attitude. Mentors attitudes that "students' success in mathematics depends primarily on how hard they work" had the largest average negative value change after the mentor PD (ΔM=-0.64, ΔSD=1.43). This indicates that, on average, mentors agreed less with this statement after the mentor PD (not statistically significant however with *alpha*=5%).

In the reflective interviews, 9 of the 11 mentors did explicitly discuss their negative change in attitude on the survey relating student success and hard work. One mentor said,

> When I first took this [pre-survey], I strongly agreed because it sounded right, the way it should be, but what caused me to change was the word 'primarily' because success in mathematics is *in part* how hard they work…but a good teacher *certainly* makes a difference, the resources available *certainly* makes a difference. If not, we are assuming students…are lazy and just don't work hard, which is not true in my opinion.

A second mentor corroborated this perspective in their interview by directly connecting his negative change in attitude to the mentor PD.

> I probably changed my answer after the seminar because I had seen poorer examples of instruction in the mentor PD, which leads me to believe that, despite what I would like, the quality of instruction plays a role in how well they learn the subject material.

Another mentor focused on deconstructing the word success.

> The hard part for me to really piece together about this question is 'student success' in mathematics. If I have a student who comes in with really strong [mathematical] background

comes in and aces all the homework, aces all the exams, versus the student who improves greatly but does not get as good of a grade, what is that in terms of success?

Fundamentally, we see the mentors critically reflecting (a topic from week 15 during the Mentor PD) during these interviews because the mentors are deconstructing the meaning of certain words such as "primarily" and "success" that were taken for granted prior to the mentor PD.

Most Valuable Topics from Mentor PD (RQ2)

In the post-survey, mentors listed the three most important things they learned from the mentor PD in free-response form. We qualitatively coded their responses relative to the curricular topics. For example, a mentor stated that they most valued learning "methods for offering constructive criticism", which was coded under facilitating post-observation discussion. Curricular topics are listed in order of ranking by mentors in Table 1.

Table 1

Top Three Things Mentors Learned from the Mentor Professional Development (PD)

Mentor PD Curricular Topics (Weeks of the Mentor PD Seminar Curriculum)	Number of Mentors who Rated This Topic		
	Highest	Second Highest	Third Highest
Facilitating post-observation discussion (Weeks 7, 8, 13, & 14)	6	2	2
Designing, organizing, & implementing small group meetings (Weeks 9 & 10)	2	2	3
Designing, organizing, & implementing GSIOP (Weeks 3-6)	2	1	3
Facilitating small group meeting discussions (Weeks 11 & 12)	0	4	0
Critical reflection during small group meetings (Week 15)	1	1	0
Lesson goals, assessments, & mathematical task alignment (Weeks 1 & 2)	0	0	0
OTHER-It is okay for people to have different teaching beliefs	0	1	0
OTHER-Teaching is difficult and messy	0	0	1

Two mentors stated comments that spanned multiple curricular topics and were thus listed as "other" in Table 1. As no mentor was coded as indicating the same curricular topic more than once, Table 1 shows that 10 of 11 mentors valued learning how to facilitate post-observation discussion, but critical reflection during small group meetings was mentioned by only two mentors.

Discussion

Summary

In sum, our study provides valuable information about how a peer-mentorship model influenced mentor GSIs' perspectives on teaching and learning (RQ1) and identifies aspects of the model that mentor GSIs found valuable in learning (RQ2). Although the t-tests indicated no significant variance in mentors' perspectives on teaching and learning, the reflective interviews indicated qualitatively that the mentor PD resulted in mentors thinking about certain terms, such as "success" as relative to courses and students they were currently teaching. Thus mentors were able to deconstruct the dichotic paradigm (true/false) prevalent in mathematical statements but not mathematics education. These results align with the results for RQ2 because the mentors suggested that they greatly valued focusing on post-observation discourse. When mentors provide constructive feedback to protégés after observing their classroom teaching, it is crucial that they address teaching concerns with subjective understanding of words such as “success” so as not to indicate to protégé GSIs that there is an absolute correct way of teaching or defining student “success”.

Implications for Research

This study informs the field’s knowledge of GSI guidance and support by illustrating how this mentor PD in the context of a peer-mentorship model can influence experienced GSIs’ understanding of mentorship, teaching, and learning. Through the peer-mentorship model, our research illuminated that the mentor PD did influence GSIs ability to justify their pedagogical understanding of certain terms. Although this does not directly indicate that mentor GSIs were able to justify pedagogical decisions they made in their own classes, their choice to value discursive facilitation and their ability to deconstruct terms such as “primarily” and “success” indicate their ability to consider multiple factors needed to reason and justify pedagogical decisions, a crucial concern of the current literature (Rogers & Steele, 2016).

Additionally, the results of RQ2 corroborate Boyle and Boice’s (1998) recommendation that mentor meetings focus on productive discourse. That is, Boyle and Boice identified that discussion of undergraduates and teaching styles were the most frequented discussions in mentor meeting and Table 1 indicates that facilitating post-observation discourse and facilitating group meeting discussions were the most popular of the highest and second-highest learned topics, respectively. This emphasis on discourse was the foundation of Smith and Stein’s (2011) canonical work on discourse best-practices, which was used in the topics from the review weeks (1 & 2) and creation of the peer-mentorship model.

Implications for GSI Programs

The emphasis on discourse illustrated by the results of this study is an ideal way to begin in developing peer-mentoring programs for GSIs because from this discourse stems the need and value of a community of practice amongst GSIs within mathematics departments. In their research on how mathematics teaching practices shifts undergraduate instructors’ academic identities, Kensington-Miller et al. (2014) emphasize the need for a community of practices for an improvement in teaching practices to take place. These researchers define a community of practice as “a place of collaborative inquiry where various approaches to teaching can be tested through a reflective sharing process . . . . [A community of practice] can contribute to deeper levels of awareness and achieve new learning that can, in turn, lead to significant change” (Kensington-Miller et al., 2014, p. 829) . To work through reflective sharing for achieving awareness, a community requires a safe environment with a knowledgeable facilitator for productive discourse, which was an aspect of our mentor PD that the mentor GSIs greatly valued. Thus our data corroborates and aligns with prior research (Boyle & Boice, 1998; Kensington-Miller et al., 2014; Smith & Stein, 2011), by underscoring the need for mentors to be skilled at facilitating productive discourse in a collaborative environment and systematically organizing mentor meetings in hopes of generating a sustainable community of practice.

Order of Operations: A Case of Mathematical Knowledge-in-Use

Rina Zazkis
Simon Fraser University

I describe reactions of secondary school mathematics teachers to the following assertion: "According to the established order of operations, division should be performed before multiplication". I use the notions of local and nonlocal mathematical landscape (Wasserman, 2016) to analyze teachers' responses to the convention of order of operations in general and the presented assertion in particular.

Key words: order of operations, local and nonlocal mathematical landscape, knowledge at the mathematical horizon, associativity

In Canadian schools the acronym BEDMAS is used as a mnemonic, which is supposed to assist students in remembering the order of operations: Brackets, Exponents, Division, Multiplication, Addition, and Subtraction. In American and British schools the prevailing mnemonic is PEMDAS, where "P" denotes parentheses, and it further assists memory with the phrase "Please Excuse My Dear Aunt Sally". Note that while "parentheses" and "brackets" are synonyms, the order of division and multiplication (D and M) is reversed in PEMDAS vs. BEDMAS.

While researchers and educators argue against the use of mnemonics, as it does not support conceptual understanding and may lead to mistakes (e.g., Ameis, 2011, Hewitt, 2012), it is still a shared practice among many teachers. Ongoing discussions related to the order of operations attend to how this order is interpreted by various computational devises, noting considerable inconsistency. My study is concerned with interpretation and explanation of the *order* in the conventional order of operations by secondary school teachers.

Mathematical Landscape and Knowledge-in-Use: Theoretical Underpinning

Wasserman (2015) described how knowledge of "advanced mathematics may positively impact instruction" (p. 29). ("Advanced mathematics" here refers to topics beyond school curriculum, noting significant similarities in curricula across the world). He focused on topics and ideas of abstract algebra and demonstrated not only how these are connected to school mathematics, but also how they can shape or alter the teaching of school mathematics. Arithmetic operations and their properties were among the identified topics, for which abstract algebra can impact teaching. Wasserman included particular examples of planned teaching activities where abstract algebra experience transformed teachers' perceptions, and ultimately their teaching.

In his more recent work, Wasserman (2016) introduced the topological metaphor of *mathematical landscape*. He considered the *local mathematical landscape* to be the mathematics being taught and the *nonlocal mathematical landscape*, as consisting of "ideas that are farther away" (p. 380). He suggested that this division "tackles the notion of mathematical knowledge beyond what one teaches" (p. 380). These metaphors are linked to the notion of "knowledge at the mathematical horizon", focusing on teachers' (rather than students' or curricular) horizons, which Zazkis and Mamolo (2011) re-conceptualized as advanced mathematical knowledge used in teaching.

Wasserman distinguished three perceptions on the significance of exposure to nonlocal (advanced) mathematics: advanced mathematics for its own sake, advanced mathematics as connected to school mathematics, and advanced mathematics as connected to the *teaching* of school mathematics. He asserted that "teachers' development of and understandings about nonlocal mathematics must not only relate to the content of school mathematics, but to the teaching of school mathematics content" (p. 386). This is because exposure to advanced mathematics helps teachers in developing Key Developmental Understandings (KDUs) (Simon, 2006), which change perceptions about content and influence mathematical connections, so in turn, have an impact on teaching.

In what follows I present a story where nonlocal mathematical knowledge can influence teaching in a 'situation of contingency'. I borrow the notion of contingency from the "Knowledge Quartet" framework (Rowland, Huckstep & Thwaites, 2005), in referring to an event that is unforeseen or deviates from the agenda when planning for instruction.

A Story in Two Accounts

I follow the narrative inquiry methodology, where "narrative inquiry is aimed at understanding and making meaning of experience" (Clandinin & Connely, 2000, p. 80). In presenting the story I rely on Mason (2002) in distinguishing between *account-of* and *accounting-for*. The term 'account-of' provides a brief description of the key elements of the story, suspending as much as possible emotion, evaluation, judgment or explanations. This serves as data for 'accounting-for', which provides explanation, interpretation, value judgement or theory-based analysis.

The story is situated in a course "Foundations of Mathematics" for secondary mathematics teachers (n=16), which is a part of the Master's program in mathematics education. Building and strengthening connections between advanced mathematics and school mathematics was an explicit goal of the course.

Account of – Part 1. Background: Conventions Task

One of the assignments for secondary mathematics teachers (here also referred to as 'students') was to consider mathematical conventions. This assignment followed discussion on the choice of a particular mathematical convention, the use of superscript (-1) in different contexts. In prior research, prospective secondary teachers' explanations of the "curious appearance" of superscript (-1) in the two contexts – inverse of a function and reciprocal of a fraction – were studied by Zazkis and Kontorovich (2016). It was found that the majority of participants do not attend to the notion of 'inverse' with respect to different operations, that is, do not view "reciprocal" as multiplicative inverse. Rather, the differences between the contexts were emphasized and analogies were made to other words and symbols, whose meaning is context dependent.

In the conversation with students about the superscript (-1) similar ideas were initially voiced, but later an agreement converged towards a group-theoretic perception of inverse, as exemplified in two different contexts. This provoked interest in the choice of other mathematical conventions, conventions that are often introduced and perceived as arbitrary, rather than necessary (Hewitt, 1999), without any particular explanation. The "Mathematical conventions task" was designed to address this interest.

The idea behind this task was to extend a conversation on the choice of conventions, and acknowledge either the arbitrary nature or the reasoning underlying some of these choices. The students were asked to write a script for a dialogue between a teacher and students, or between students, where interlocutors explore a particular mathematical convention and a reason behind it. The particular conventions were left for the students' choice. The detail of the task is found in Figure 1.

> Choose a mathematical convention and consider possible explanations for the particular choice.
>
> IN YOUR SUBMISSION:
>
> 1. Reflect on the process of choosing the particular mathematical convention for this task. Share alternative conventions that you considered for this task and explain why they were not chosen. (1-2 paragraphs)
>
> 2. Write a script for a dialogue in which interlocutors consider possible explanations for the convention you explored. The dialogue should reflect possible doubts, uncertainties and arguments regarding the suggested explanations. The dialogue should end either with an explanation that interlocutors accept or a summary of the disagreement between the characters. (3-5 pages). The dialogue can begin in the following way:
>
> Sam: Hey Dina, have you ever noticed that (the chosen convention)?
> Dina: Well, everybody knows that.
> Sam: Yes, but did you ever think about why it is so?
> Dina: Why should I think about it? It's a convention.
> Sam: But, still… Can you propose an explanation?
> Dina: Maybe, this is because…
>
> Feel free to modify the proposed beginning of the dialogue.
>
> 3. What have you learned, if anything, from completing this task? (1-2 paragraphs)

Figure 1: Mathematical conventions task

Account of – Part 2. Order of Operations Convention

One of the repeated examples for a convention (chosen by 3 out of 16 students) was order of operations when performing arithmetic calculations. Below is an excerpt from the script written by Andy, who describes a conversation occurring in Grade 8 class.

Sam:	Hey Mr. X, a couple of us can't decide on answer to the following question: $25 + 5 \times 7 - 2 \times 10 \div 5$
Mr. X:	What do you mean?
Mary:	I bet them a dollar that they couldn't get the correct answer to a question I made: $25 + 5 \times 7 - 2 \times 10 \div 5$
Sam:	Well I got 40. Jane says it's 56. Tom believes it's 436, and no one can agree on a solution.
Tom:	Mine is correct! I know it.
Mr. X:	Tom why do you say that?
Tom:	I had a process of how I did mine.
Mr. X:	How so?
Tom:	I just did one operation after another: 26 plus 5 times 7 and so on. See: $25 + 5 \times 7 - 2 \times 10 \div 5$

	$30 \times 7 - 2 \times 10 \div 5$ $210 - 2 \times 10 \div 5$ $218 \times 10 \div 5$ $2180 \div 5$ 436
Sam:	I did something similar, but I started on the right side of the problem: $25 + 5 \times 7 - 2 \times 10 \div 5$ $25 + 5 \times 7 - 2 \times 2$ $25 + 5 \times 7 - 4$ $25 + 5 \times 3$ $25 + 15$ 40
Mary:	You guys did the operations in the wrong order.
Jane:	I agree with you Mary.
Mr. X:	What order would you suggest?
Jane:	Well I did the division first followed by multiplication, addition and subtraction. $25 + 5 \times 7 - 2 \times 10 \div 5$ $25 + 5 \times 7 - 2 \times 2$ $25 + 35 - 4$ $60 - 4$ 56
Tom:	I don't understand why you started with division. Why would you start there?
Jane:	Everybody knows that's the proper order to do operations.
Sam:	Mr. X is that correct?
Mr. X:	Jane is correct. That is the correct order to do those operations.
Sam:	But why?
Mr. X:	A long time ago a group of people had a very similar situation that we have now. They were confused and couldn't figure out who had the correct solution to a problem that involved the very operations you are having problems with. It happened around the early 15th century in a small European kingdom, it was called the Kingdom of Math. The King of Math, as it were, was a very intelligent leader and believed that his people should always come together to solve their problems.
Jane:	Really, Mr. X, a kingdom of math?
Mr. X:	Oh yeah, they were a very progressive country. Several of the King's subjects had come to him to settle a problem that they were having. They couldn't decide on an order of the operations that needed to be used. Sound familiar?
Mary:	Very funny, Mr. X.
Tom:	So what did the King do?
Mr. X:	The king commanded his most trusted advisors, members of the Order of Knowledge, to look into the problem. It took several months before the Order had a response for the King. They proposed that the only way to solve this problem was for the King to proclaim an order to the operations so that everyone would know the correct way to solve the mathematical problem.
Sam:	That makes sense. Then everyone would follow the same order and no one would be confused about what steps to do first.

Andy offered the following comment at the end of the assignment:

"I felt that there was only one reason that I could students: "We need to have an order that everyone follows so we can be consistent". "This is the way we all do it". "We" being us in the math community. Whether you're in France, New Zealand, or Canada it's the same. This is because we've all agreed to use the same order so as to have the same understanding of the operations. I tried to find an actual history of the order of operations, but couldn't find anything concrete. So I decided to make up a story that would hopefully give them some connection to the problem and some entertainment along the way."

Accounting for – Mathematics of "Division First"

It is clear from Andy's commentary that accompanied the script that he perceives the convention of order of operations as an arbitrary decision. The reasoning behind this choice, other than the need for consistency, was unclear to Andy and was not found when sought. Other secondary school teachers agreed with this view.

The teacher-character's agreement with the student statement, "division first followed by multiplication, addition and subtraction" could have been overlooked, as the result was correct. It is further unclear from the script whether the listed order refers to the general convention, or to the particular case. Nevertheless, both the claim of "division first", and the order in which the operations were performed in Jane's example, attracted my attention. For simplicity, let us consider only the last short computation that involves multiplication and division only,

$2 \times 10 \div 5$

Performing "division first" means interpreting this calculation "as if" there are parenthesis around the operation of division

$2 \times (10 \div 5)$

But actually, "division first" and "in order of appearance" yields the same result:

$2 \times 10 \div 5 = 20 \div 5 = 4$ and $2 \times (10 \div 5) = 2 \times 2 = 4$

Is this a coincidence? In other words, is it a "general case" that

$\mathrm{a} \times \mathrm{b} \div \mathrm{c} = \mathrm{a} \times (\mathrm{b} \div \mathrm{c})$?

The situation is easily resolved attending to (a) division is an inverse operation of multiplication and (b) multiplication is associative. Therefore, division can be performed "out of order", as

$$\mathrm{a} \times \mathrm{b} \div \mathrm{c} = \mathrm{a} \times \mathrm{b} \times \frac{1}{c} = \mathrm{a} \times \left(\mathrm{b} \times \frac{1}{c}\right) = \mathrm{a} \times (\mathrm{b} \div \mathrm{c})$$

Account of – Part 3. Addressing "Division First" Assertion

As a consequence of "division first" suggestion in Andy's script, the following assertion was presented to a class discussion:

> Assertion: "*According to the established order of operations, division should be performed before multiplication*."

It was presented a student's claim, for which a teacher's response was sought.

Four students (out a class of 15) agreed with the claim, while others insisted on the "left to right" order, when only division and multiplication appear in a computation. BEDMAS was the presented argument that supported the assertion*. However, majority of students claimed that "division first" was wrong and attempted to find a counterexample, where giving priority of

---

* Of interest is that in a class of prospective elementary school teachers, about 70% agreed with the assertion based on BEDMAS

division over multiplication vs. performing these operations in order they appear will lead to different results. (An analogous idea of "multiplication first" or "order does not matter" was suggested, but immediately rejected by a counterexample.)

When "simple" computations did not lead to a counterexample, students turned to more complicated examples. These examples included a longer chain of computations, fractions, and negative numbers. An additional conjecture was voiced that "division first" works only in case there is divisibility between the chosen numbers for division. This resulted in more complicated examples, but the conjecture was refuted after several tests.

In a class session, a search for a counterexample lasted for about 25 minutes. There were occasional exclamations of "Eureka!", which eventually resulted in double checking that uncovered computational errors. A failure to come up with a counterexample, resulted in a conjecture that prioritizing division over multiplication will always work.

Considerable scaffolding was needed to prove this conjecture. When someone suggested that "it works" because "division is just an inverse of multiplication", I countered the claim with "multiplication is just an inverse of division" and "it doesn't work". The suggestion of associativity was voiced only after students were asked explicitly to consider in what ways division and multiplication are different. As a result of focusing on this difference, the assertion was rephrased: *Division can be (rather than should be) performed before multiplication*.

Accounting for – Analysis of Responses

The assertion presented for discussion for secondary school teaches caused a cognitive conflict to both supporter and objectors. Those who supported the conjecture based on BEDMAS were surprised to find out that performing addition before subtraction (A before S) does not lead to an expected result. Those who believed that conjecture was false, and claimed that division and multiplication have the same priority and should be performed in left-to-right order, were surprised to find out that giving priority to division indeed "works".

Each group exhibited a robust "strength of belief" (Ginsburg, 1997), based on knowledge that was entrenched and never questioned, as evident in a lengthy search for a counterexample. Extending the example space in search for counterexamples indicates, in accord with Zazkis and Chernoff (2008) that different examples have different convincing power.

The justification and reformulation of the assertion, based on associativity of multiplication, was readily accepted, and even came with an "AHA!" experience for some teachers. As such, it is curious why such an argument was hard for teachers to find on their own. The theoretical constructs presented above provide a possible explanation.

I suggest that the notion of associativity, even if not so "advanced", does not belong to secondary school teachers' local mathematical landscape. That is to say, they do not teach associativity, and even when this property is acknowledged together with other properties of arithmetic operations, it is mentioned together with commutativity. To elaborate, operations discussed in school mathematics are either commutative and associative, or neither commutative nor associative, which results in frequent confusions between the two (Hadar & Hadass, 1981, Zaslavsky & Peled, 1996). Associativity appears as a property "on its own" when considering groups and their structure. As such, while the notion itself does not require advanced background, knowledge of advanced mathematics reshapes how associativity is perceived. For teachers, associativity appeared to be found in the nonlocal environment, and the connection between local and nonlocal mathematics was not immediately articulated. Furthermore, I suggest that the discussion of the assertion helped in connecting nonlocal mathematics (associativity) to local mathematics (order of operations) in a potential situation of contingency in their teaching.

Discussion

With respect to the conventional order of operations in arithmetic, should division have priority over multiplication? If yes, why so? If not, does giving priority to division lead to an incorrect result? These questions, and unexpected answers, were explored with a group of secondary mathematics teachers. It was concluded that while teachers indeed possessed nonlocal knowledge needed to address these questions, it was not exploited in connection to a contingency situation that may appear in their teaching.

In relation to teachers' mathematical knowledge Wasserman (2016) uses the terms 'nonlocal' and 'advanced' as almost synonymous, referring to knowledge beyond what is taught in school. The example of order of operations demonstrates that 'nonlocal' is not necessarily 'advanced', but situated beyond teachers' "active repertoire" of knowledge used in teaching.

I concur with Wasserman (2016) that "knowledge of nonlocal mathematics becomes potentially productive for teaching at the moment that such knowledge alters teachers' perceptions of or understandings about the local content they teach" (p. 382). While Wasserman (2015) and Wasserman and Stockton (2013) exemplified how planning of instructional sequence and instructional examples can be influenced by teachers' exposure to advanced mathematics, I demonstrated how such exposure can be useful in the situation of contingency.

Can/Should Students Learn Mathematics Theory-Building?

Hyman Bass
University of Michigan

Mathematicians commonly distinguish two modes of work in the discipline: Problem solving, and theory building (Gowers, 2000). Mathematics education offers many opportunities to learn problem solving. This paper explores the possibility, and value, of designing instructional activities that provide opportunities to learn mathematics theory-building practices. It begins by providing a definition of these theory-building practices on the basis of which to formulate principles for instructional designs. The paper argues that theory-building practices serve not only the synthesizing role that they play in disciplinary mathematics, but they also have the potential to enrich learners' reasoning powers and to enhance their problem solving skills. These instructional designs offer a new approach to supporting student work on generalization and abstraction. They have been piloted with preservice and practicing secondary teachers.

Key words: theory building, problem solving, abstraction, instructional design.

The Common Core has promoted the teaching of mathematical practices. I take *the practices of an occupation to be the things one does when so occupied.* So what do (research) mathematicians do? Well they commonly distinguish two modes of doing their work: problem solving and theory building (Gowers. 2000). Does (or should) this duality find any expression in mathematics education? Certainly problem solving has a robust presence (Polya, 1957; Schoenfeld, 1994); what about theory building? I argue here that it does make sense, and have value, to give students opportunities to learn what I call (and shall define) to be *mathematics theory-building practices*, and I will present some instructional designs to support this.

Mathematics Theory-Building Practices

Mathematical knowledge is cumulative. Rarely are ideas discarded. What saves it then, after several millennia of relentless growth, explosively in the last two centuries, from sinking under its own weight into some dense mass of ideas? This is achieved through ongoing processes of abstraction, whereby diverse phenomena are made to all appear as particular manifestations of a single unifying theoretical construct. The latter is essentially a piece of conceptual invention with no *a priori* existence. It is born as a distillation, and naming, of what is common to the variety of its existing incarnations. The large-scale cumulative products of these processes are mathematics theories.

Definition

Based on this, I define (***mathematics*[1]*) theory-building practices*** *to be creative acts of recognizing, articulating, and naming something mathematically substantial that is demonstrably common to a variety of apparently different mathematical situations,*

[1] In science, in contrast, Bereiter (2012) writes, "Theory building starts when an explanatory idea is modified or further developed to produce a better explanation."

something that, at least for those engaged in the work, might have had no prior conceptual existence. I refer to an instance of engagement in such a theory-building practice as a ***theory-building act***.

It is important to distinguish mathematical theories from the theory-building processes that produce them, just as proofs are different from the practices of proving. The most familiar example of such abstraction is that of number itself. For example, what is the number seven? We cannot point to it, or say directly what or where "seven" is in the natural world. Rather we can point to many collections of seven things; and we can say concretely what it means for two such collections to have the same cardinal. "Seven" then is a quality that all of these diverse collections have in common, but we can specify concretely only what it means for this quality to be common.

The main products of theory-building practices are of course theories. Some large-scale examples are the theories of groups, topological vector spaces, manifolds, and categories. A college level example might be linear algebra, in which the solving of systems of linear equations is eventually generalized and abstracted in terms of vector spaces, over a field of scalars, and linear transformations. Theories are general, and so achieve a kind of cognitive rescaling or compression of the knowledge edifice. Complex mathematical structures are thus identified and named so that they become, for the expertly initiated, as mentally manipulable as counting numbers are for a child. At the same time theories are sufficiently specific to be susceptible to productively detailed and incisive theoretical exploration. Note that the examples above are the names of theories, but nothing is said here about the rich history of how each of them evolved and came to be formalized, through a long trajectory of theory-building actions.

I will use the above definition of theory-building practices to formulate general principles for the design of some instructional activities that provide learners with opportunities to engage in theory-building practices. I present examples of such instructional designs based on these design principles. These designs involve seeking *relations among a given set of mathematics problems*. Learners are asked to not only solve the problems, but, importantly, to find and articulate *structural* connections among the problems. The designs have been piloted with groups of students and teachers.

The premise of this work is that theory-building, not unlike problem-solving, is a high leverage mathematical practice that, suitably adapted for instruction, is of value for all students, not only those who pursue mathematics as a career.

In a pilot of these problem designs, most students, in their reflections: 1. Professed to enjoy the activity; 2. Found that it would be useful in their teaching; and 3. Noted that, in none of their previous math courses, had they ever been asked questions like this.

A Sample of Related Literature

Mathematical theory-building practices involve a high level of abstraction. Abstraction has been much studied since the work of Piaget (1994) and Vygotzky (1997), and more recently in the study of student assimilation of already formalized abstract concepts, for example (Hershkowitz et al., 2001; Scheiner, 2016).

Some curricular interventions, e.g. the "New Math," introduced students axiomatically to some existing theories. This of course is distinct from theory building.

Early work on structural relations between different problems comes from cognitive psychology studies of transfer, to see whether knowledge of how to solve problem A transfers to the ability to solve an "isomorphic" problem B (Simon et al., 1976; Siegler, 1977). Here A and B are said to be *isomorphic* if there is a correspondence between the objects, relations, and operations of A to those of B so that any solution strategy of A transforms into one of B. Informally, A and B have the same structure, and differ only in superficial features of context. It was found that transfer generally does not occur.

Silver (1979), inspired by Polya's heuristic, "think of a related problem," and building on earlier work of Kruteskii (1976), conducted a study of students' perceptions of relatedness of families of word problems, designed to vary on dimensions of relatedness, notably mathematical structure and context. Among his findings, students with high proficiency levels, by a variety of measures, tended to sort problems by structure, while those with lower levels focused more on context. This reinforced similar findings of Kruteskii.

In Mason (1989) and Mason, et al. (2009) one finds strong arguments for the value of developing a sensitivity to mathematical structure, as well as problem-solving contexts in which there are rich opportunities for structural thinking and exploration.

Maher et al. (2010) report on one of the few longitudinal studies of children's development of high level mathematical practices, including development of schemas for connecting structurally related problems.

In 1968 Zal Usiskin published, in *The Mathematics Teacher*, a brief paper, "Six nontrivial equivalent problems." Although addressed to teachers, the paper did not discuss instructional uses. What unifies these problems is the fact that they can all be modeled by simple algebraic variants on a single Diophantine equation: Find all whole number solutions (n,m) of, $1/n + 1/m = 1/2$. In 2015 I expanded Usiskin's list to a set of thirteen problems, spanning several mathematics domains, all sharing the same mathematical model. This is accompanied by a lesson plan for its use in teacher professional development.

Instructional Design Principles

I turn now to a set of principles for the instructional design of opportunities to engage in theory-building practices. The designs comprise three components: a *problem set*; the *task* presented to the learners; and a sketch of the *instructional enactment*, or "lesson plan." The design principles guide the construction of these components.

Problem Set Design Principles

The definition of theory-building practices calls for, "recognizing, articulating, and naming something mathematically substantial that is demonstrably common to a variety of apparently different mathematical situations." Here I take a "mathematical situation" to refer to mathematics problem. I take "something mathematically substantial that is demonstrably common" to mean a mathematical structure that is centrally involved in each problem, in the sense that the "problem space," or "solution space" of the problem can be described using that structure.

With these specifications I can now state the *problem set design principles*:

1. An assigned problem set should consist of about 3 - 8 problems.

2. Individual problems should be substantial, yet accessible without formidable challenge for the given community of learners.
3. The set of problems should be significantly diverse, for example with variable contexts, or even belonging to different mathematical domains.
4. It must be possible to demonstrate that substantial subsets of the problems involve a common mathematical structure.

Rationale: #1is a practical consideration; #2 is to keep the primary focus on structural relations between different problems, not individual problem solutions; #3 captures the "apparently different" aspect of the definition; #4 is central to the concept of theory-building practice.

The Learners' Task Design Principles

Two formats are proposed.

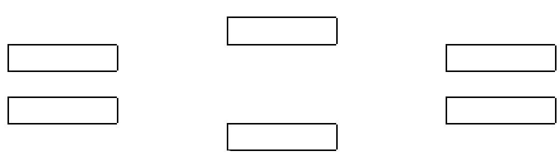
- The **discernment format**: Learners are asked to simply discern and explain relations among a set of problems that do not all involve a common structure.
- The **common structure format:** Learners are asked to identify and articulate a mathematical structure and demonstrate its presence in each of the problems.

The discernment format presents the task as in Table 1.

Table 1
Discernment Assignment Format

Below are problems, labeled A,B,C,D,E, . . . The object is to place the letter of each problem in one of the boxes below.

- *Put letters in the same box if they are mathematically the "same" problem, apart from superficial differences of context.*
- *If problems in different boxes are closely related mathematically, connect their boxes by a line, or by a double line if the connection is very strong. (Note, you need not use all of the boxes, and you may reasonably answer this question even if you have not completely solved the individual problems.)*
- *Work on this individually for a few minutes. Then compare answers in your group.*
- *Try to come to some consensus on how to* ***explain*** *(to the whole group) your choices, in particular the nature of the connections.*



The products in this format will be "connection networks," and these can be quite variable. The processes of explaining them, and then efforts to reconcile differences within and across different groups can help to develop a probing discourse about mathematical relations among problems.

The common structure format assigns the following (interactive) phases:

Phase 1. Solve the individual problems.
Phase 2. Identify and articulate a common mathematical structure, and demonstrate how it is involved in each of the problems.
Phase 3. Notice ways in which the problems are significantly different, and analyze some of the consequences of these differences.

Phase 2, expressly capturing the theory-building component of the task, appears to be the most novel and challenging aspect for the learners. It is not likely that learners will gain high levels of proficiency with theory-building practices from a limited exposure to this kind of work. But it is still possible, even with limited exposure, to awaken a sensibility to the kinds of questions posed, a foundation that can be built upon.

Phase 3 is not directly entailed in the definition of theory-building practices, but pilots of these designs show that a given mathematical structure can be situated in problems in ways that significantly vary the mathematical sense and cognitive demand of the problem. Awareness of this kind of variation is an important aspect of discrimination in theory-building practices.

Instructional Enactment Design Principles

The demands of these designs can be substantial, complex, and novel: solving a substantial collection of non-trivial and diverse problems; finding and articulating a substantial mathematical structure common to the different problems; and noticing significant differences in the structurally related problems.

I have found that the instruction works best when the students work in collaborative groups (of 3-6 students), and that the work extends over a reasonable amount of time, at least two sessions. The individual groups can pool diverse ideas, distribute the work, and reconcile different outcomes. I then have each group prepare a formal presentation of its work to the whole group, allowing then for whole group discussion.

Example Designs

Figure 2.

The 3-permutation set (Discernment)

A. What are all three-digit numbers that you can make using each of the digits 1, 2, 3, and using each digit only once?
B. In a group of five students, how many ways are there to pick a team of three students?
C. You are watching Angel, Barbara, and Clara on a merry-go-round. At each moment you see them in some order – left, middle, right. As the merry-go-round turns, what are all the different orders in which you see them?
D. If Angel, Barbara, and Clara have a race, and there are no ties, what are all possible outcomes: first, second, third?
E. From a bag full of many pennies, nickels, and dimes, I randomly choose three coins. What are all possible coin combinations that I might have?
F. In a 3 x 3 grid square, color some of the nine (unit) squares blue, in such a way that there is exactly one blue square in each row and in each column. What are all ways of doing this?
G. What are all the symmetries of an equilateral triangle?

Here B and E are outliers, not deeply related to the other problems, or even to each other, though they both have ten solutions. A structure involved in each of A, C, D, F, G, is the set of permutations of three objects and the solution to each of these problems is in fact the full set of six permutations. In A, D, and F this outcome is demonstrably inherent in the problem, though this fact is most subtle for F. However it can be argued that in C and G there is no *a priori* guaranty that all permutations will be achieved. In fact, when students were asked to reformulate the problems with 4 in place of 3, they found that the new C and G did not achieve all 4! permutations.

Figure 3.
The 8-choose-3 set (Discernment)

A. A taxi wants to drive from one corner to another that is 5 blocks north, and 3 blocks east. How many possible efficient routes are there to do this?
B. On the number line, starting at 0, you are to take 8 steps, each of which is either distance 1 to the right, or distance 1 to the left, and in such a way that you end up at -2. How many different such walks are there?
C. The home team won a soccer game 5 to 3. How many possible sequences of scoring were there as the game progressed?
D. You have coins worth 3¢ and 5¢. With 8 such coins, how many different values can you obtain?
E. From a group of 8 students, you need to select a (5-person) basketball team. How many different ways are there to do this?
F. You are to cut a 9-inch ribbon into six pieces, each of length a whole number of inches. How many ways are there to do this?
G. In the expansion of $(1 + x)^8$, what is the coefficient of x^3?

Here D is an outlier. The solution space of all of the other problems is represented by the set of all "binary sequences of length 8, with 3 terms of one type."

Table 4
The Measure Exchange set (Common Structure)

1. (Tea & Wine) I have a barrel of wine, and you have a cup of green tea. I put a teaspoon of my wine into your cup of tea. Then you take a teaspoon of the mixture in your teacup, and put it back into my wine barrel. Question: Is there now more wine in the teacup than there is tea in the wine barrel, or is it the other way around?
2. (Heads Up) I place on the table a collection of pennies. I invite you to randomly select a set of these coins, as many as there were heads showing in the whole group. Next I ask you to turn over each coin in the set that you have chosen. Then I tell you: The number of heads now showing in your group is the same as the number of heads in the complementary group. Question: How do I know this?
3. (Faces Up) I blindfold you and then place in front of you a standard deck of 52 playing cards in a single stack. I have placed exactly 13 of the cards face up, wherever I like in the deck. Your challenge, while still blindfolded, is to arrange the cards into two stacks so that each stack has the same number of face-up cards.
4. (Triangle Medians) In a triangle, the medians from two vertices form two triangles that meet only at the intersection of the medians. How are the areas of these two triangles related? More precisely, let ABC be a triangle. Let A' be the mid-point of AC, B' the mid-point of BC, and D the intersection of AB' and BA'. How are the areas of AA'D and BB'D related?
5. (Trapezoid Diagonals) The diagonals a trapezoid divide the trapezoid into four triangles. What is the relation of the areas of the two triangles containing the legs (non parallel sides) of the trapezoid? 
A structure involved in each of these problems is a simple principle of measurement: *If two quantities have equal measure, and you remove from each what they have in common, then what remains of each of them will still have equal measure.*

How Limit can be Embodied and Arithmetized: A Critique of Lakoff and Núñez

Tim Boester
University of Illinois at Chicago

In Where Mathematics Comes From, Lakoff and Núñez (2001) describe how the notions of infinity, continuity, and limit can be constructed through metaphorical extensions of embodied experiences. This paper will critique their historical and psychological analysis, revealing an unresolved tension between a simplified, geometric "approaching" conception and the arithmetization of calculus by Weierstrass. A proposal of how to rectify this conflict through acknowledging how novices can metaphorically tie these concepts together is discussed.

Key words: Embodied Cognition, Limit, Infinity

The mathematical definition of limit has gone through various refinements throughout history (Kleiner, 2001), but its current form, for two-dimensional limit, requires the coordination of two small intervals. One interval's radius, signified by the Greek letter delta (δ), surrounds the input or x-value, while the second interval's radius, represented by the Greek letter epsilon (ε), surrounds the output or the result of the function applied to the x-value. The coordination of the two intervals is accomplished through the logical quantification portion of the definition: for any epsilon, there exists a delta, such that if the input value is within the delta interval, then the output value must be within the epsilon interval. These intervals are symbolized through the distance interpretation of the absolute value, while the logical quantification uses common logical symbols for "for any," "there exists," and the "if …, then …" structure.

Limit can be mathematically conceptualized in two different ways, regardless of how a student could come to understand the concept: either in a dynamic way or in a static way (Cornu, 1992). The dynamic conception is a motion-based idea of limit, frequently expressed using the word "approaching" (or similar words describing movement), or graphically demonstrated by showing a point moving along a graph towards another point. This was also the first way in which limit was historically conceived by Newton and Leibniz (Kleiner, 2001). Students thinking in terms of a dynamic conception would describe, through words and gestures, a limit as a point traveling along a curve.

The static conception of limit is an arithmetic-based idea of limit which coordinates static intervals. This conception matches the formal definition devised by Cauchy and Weierstrass (Kleiner, 2001), and can also be thought of as a way to precisely describe closeness. Students' thinking in terms of a static conception would describe, again through words and gestures, limit as coordinated intervals. In summary, the dynamic conception emphasizes motion in describing limit, while the static conception is devoid of motion and instead emphasizes closeness.

The trajectory of mathematics education research of limit began with an initial focus on establishing misconceptions in undergraduates' understanding of limit (Bezuidenhout, 2001; Davis & Vinner, 1986; Tall & Vinner, 1981), which then evolved into proposals on how students might build appropriate conceptions of limit (Cottrill et al., 1996; Lakoff & Núñez, 2001; Williams, 1991, 2001). These proposals brought about several more studies yielding successful interventions into students' limit conceptions (Boester, 2010; Oehrtman, 2009; Roh, 2008, 2010; Swinyard & Larsen, 2012). However, while these most recent studies expanded the underlying framework for the learning of the limit concept, issues with how general theories of advanced mathematical thinking were initially applied to explain limit thinking in novices (students) remain. In particular, an unresolved tension exists between how Lakoff and Núñez explain the transition between a geometric "approaching" conception of limit and how Weierstrass arithmetized Calculus to produce our modern, static conception of limit.

The Problem of Conceptualizing "Approaching" Through the BMI

Lakoff and Núñez introduce limit in *Where Mathematics Comes From* (2001) by first discussing one-dimensional limit: an infinite sequence along a number line that approaches a particular number (the limit). To demonstrate the process of "approaching" a limit, and how this utilizes the BMI, or Basic Metaphor of Infinity (p. 155), they give an example sequence $\{x_n\} = n/(n+1)$. As n increases, the value x_n gets closer and closer to 1 (p. 187).

The authors choose to express this notion of "approaching" by utilizing the notation of the formal definition of limit in terms of sequences: the sequence $\{x_n\}$ has L as a limit if, for each positive number ε, there is a positive integer n_0 with the property that $|x_n - L| < \varepsilon$ for all $n \geq n_0$ (pp. 189-90). Unfortunately, this definition cannot use the BMI directly, because there is nothing being iterated. In order to bridge the gap, they decide to express "approaching" in terms of nested sets, whose iterative quality can be directly used by the BMI: $0 < r < |x_n - L|$, where R_n is the set of all values r bounded between zero and $|x_n - L|$. As $|x_n - L|$ gets smaller, the range of values in R_n gets smaller. Since the largest value of R_n is decreasing, these sets can be nested: $R_{n+1} \subset R_n$. This chain of nested sets is then used in the BMI to obtain the limit (where the "last" nested set, R_∞, would be the empty set). Lakoff and Núñez take the expression $0 < r < |x_n - L|$ to be synonymous with $|x_n - L| < \varepsilon$ so that we can then extend the BMI to cover the standard formal definition.

Lakoff and Núñez are required to use the BMI to explain the concept of limit, because limit utilizes the concept of infinity. Because infinity does not exist in reality, this presents a critical challenge to a theory of mathematics that is entirely based on real-world, embodied experiences, hence the necessity of the BMI. Since the standard formal definition of sequences doesn't use an indefinite iterate process contained within the BMI, they need to formulate a new definition which does, hence nested sets. Since nested sets can be plugged into the BMI as an indefinite iterative process, they can thus be used to explain our conception of limit.

While this explanation follows the standard embodied cognition model of linking metaphors (including the BMI) built up from grounded metaphors based on embodied experience, there are several problematic issues with this explanation of how we comprehend limit. First, $0 < r < |x_n - L|$ is technically not synonymous with $|x_n - L| < \varepsilon$. $0 < r < |x_n - L|$ can be used when x_n is already known to be approaching L, while $|x_n - L| < \varepsilon$ is essentially checking to make sure. For example, if the actual limit of the sequence is L_t, where L_t falls within the neighborhood defined by $|x_n - L|$ for all n, then the values of $0 < r < |x_n - L|$ can still create a chain of nested sets that follow $R_{n+1} \subset R_n$ due to the density of the real numbers, however R_∞ would no longer be the empty set (instead, it would measure the distance between L and L_t). This distinction is not possible with $|x_n - L| < \varepsilon$, as for some ε, $|x_n - L| \geq \varepsilon$. $0 < r < |x_n - L|$ assumes that L is the actual limit, while $|x_n - L| < \varepsilon$ proves it is so.

More importantly, however, in their attempt to mathematize the concept of "approaching", they are completely ignoring the natural, physical-ness of approaching. What Lakoff and Núñez are trying to do is characterize the distance between you and the limit: the distance becomes smaller as you approach the limit. However, they use a complicated mathematical concept (nested sets) encoded in a complicated mathematical notation, when a description of "approaching" as simply going towards something would suffice. This notion of "approaching" more closely resembles one of the four grounding metaphors (p. 50), arithmetic as motion along a path. However, "approaching" might even be considered a grounding metaphor for limits, because it ties the concept of limit back to the image schema of motion along a path.

In fact, thinking of "approaching" in this simple, physical way may even help students understand one very important piece of the formal limit concept. The same linguistic distinction between "jumping" and "swimming" can be made here: "approaching" is an imperfective aspect (p. 156), because it does not inherently mean that you arrive at what you are approaching. This is actually helpful because it matches the definition of limit (in that a function may not exist at the limit). You may never reach the limit, because it may not exist, even though you are approaching it. Reaching a limit is a consequence of the BMI – in order to have a limit, you must "reach" it at the infinite step (at least potentially, if not actually). While it may be important sometimes to know what happens at the limit (for example, when considering continuity), this is not required when finding the limit itself.

Oversimplifying "Approaching" by Ignoring Complicated Approaching

While Lakoff and Núñez overcomplicate matters by using nested sets, they completely oversimplify the ways in which limits can be approached that are covered through the absolute value-based definition. Recall the example sequence $\{x_n\} = n/(n+1)$. Notice that this example is strictly monotonic, in that it creeps up on the limit in one direction, always getting closer and closer to 1, never farther away. This matches the smooth, motion based "approaching" conception of limit. Taking smaller and smaller steps towards a wall would be a physical example of this.

However, sequences (and functions) can approach limits in far more complicated ways than simply monotonically. The authors make an attempt to fix this by introducing sequences which converge indirectly but still have a limit. For example, they give a "teaser sequence" 3/6, 4/6, 5/6, 9/12, 10/12, 11/12, 15/18, 16/18, 17/18, 21/24 … which bobs up and down while generally trending towards 1 (pp. 192-3). This improves their coverage of possible types of limit convergence, but does stretch the metaphorical interpretation of limits as "approaching". This would correspond to a physical example where, for each step taken towards a wall, a step a fraction of that size is taken going away from the wall (remembering that the steps towards the wall are getting smaller and smaller).

The physical interpretations of both monotonic and indirect convergence also illuminate another way that students may think of limit, as a barrier that cannot be crossed (Davis and Vinner, 1986). Mathematically, this is called a bound. Both examples presented are bounded at the limit because they only approach from one direction. You do not have to consider incredibly complicated sequences to find ones that approach a limit from both sides (even though Lakoff and Núñez (1997, 2001) restrict this property to a selection of "monster" functions that inspired the transition to the arithmetization of Calculus). There are many examples of sequences that do this, such as $\{x_n\} = (-1)^n / n$, which approaches zero from both sides.

"Approaching" from either side of a limit is covered in the absolute value portion of the formal definition: by making a range around L, it doesn't matter if you are above L or below it, as long as you are no more than ε away. Lakoff and Núñez also cover this possibility in their definition when they utilize absolute value notation for nested sets, although they do not comment about the implications of such notation. Remember that the nested sets R_n are defined as the sets of the values r can take when $0 < r < |x_n - L|$. Why should the absolute value be used here, since in the examples presented, all instances of x_n are less than L (thus simply writing $0 < r < L - x_n$ would suffice)?

While the examples only require $0 < r < L - x_n$, they use $0 < r < |x_n - L|$ because using the absolute value is necessary in the formal definition. If their definition did not cover limits which approach from both sides, they would be defining "approaching" in a lopsided way which was fundamentally different from the formal definition. In order to motivate using $0 < r < |x_n - L|$, they should have used an additional, more complicated example, but this would have stretched the physical interpretation of "approaching" past its breaking point. While it is still possible to stretch this motion-based concept to include approaching from both sides, there are some important implications of this.

First, you will be approaching the limit from both sides, which is difficult to conceptualize using the types of physically-based examples used to ground the "approaching" concept. Using the same strand of physical examples from above, it would be like trying to approach a wall from both sides simultaneously. Second, you would need to abandon the idea that the limit is a barrier or bound, because you would be (repeatedly) passing it. You could not conceptualize the wall in our example as a barrier. Third, the sequence or function may equal the limit while it is "approaching" the limit. In taking the limit of the function $y = x\sin(1/x)$ as x approaches zero, there are many times where the function has x-values near zero which yield y-values that are zero. In fact, we don't even need to turn to something this complicated to see this. A constant sequence or function will equal its limit everywhere. This really challenges the concept of "approaching" the limit, since, for a constant function, you don't actually move.

These three implications pull the "approaching" metaphor away from the natural, motion-based conception of limit stated at the very beginning of this section. They also create problems for the nested-set conception of "approaching". A set of points on one side of a limit could not be nested inside of a set made from points on the other side of the limit (without resorting to some argument either about the size of the set rather than its actual contents or using sets which straddle the limit and are not bounded at either end).

Conflating "Approaching" With the Formal Definition

If Lakoff and Núñez want to stay with the embodied, motion-based "approaching" conception of limit, they need to stick with simple examples which are not stretched too far from normal experiences (thus avoiding the implications above). However, in mathematizing these simple examples, they should not use the absolute value, because it is not necessary. This means that whatever mathematical definition they try to establish, based on the examples, it cannot use the absolute value, which means that it cannot duplicate the formal definition (figure 1, argument one).

If they want to motivate the formal definition, then they must use the absolute value as it appears in the formal definition when using the BMI. In order to motivate the usage of the absolute value, they need more complex examples which approach the limit from both sides or converge indirectly. In doing this, they then must use much more complicated explanations of "approaching" than those which naturally arise because of the implications discussed above (figure 1, argument two).

The authors try to do both. Their top-down argument originates with the desire to motivate the formal definition using the BMI. They cannot do this without using the absolute value. However, they examine the "approaching" conception of limit and use examples which naturally tie into this conception. Unfortunately, there is no reconciliation between the simple examples and their usage of the absolute value (figure 1, Lakoff and Núñez).

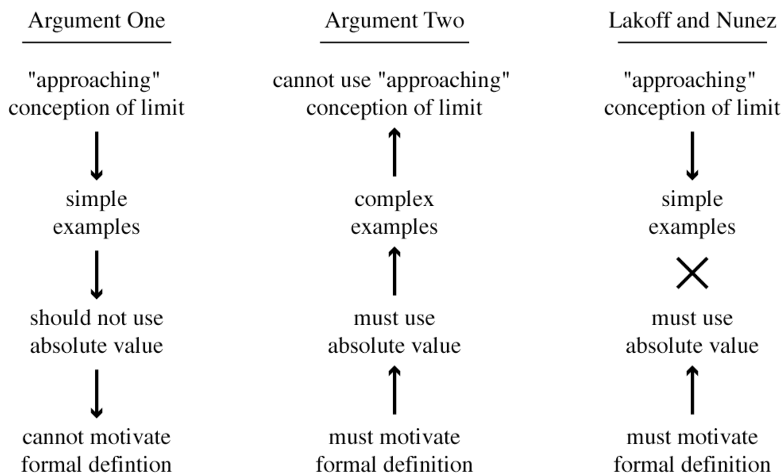

Figure 1. Linking the informal, motion-based conception of limit with the formal definition.

The authors make what, at first glance, appears to be a minor oversight. Their examples of "approaching" a limit do not require using the absolute value to characterize their behavior. When they formalize the "approaching" conception of limit through their usage of conceptual metaphor, they use the absolute value. Unfortunately, by missing the true importance of the absolute value and its cognitive implications in connection with the formal definition and the "approaching" conception of limit, their argument that this is the way in which we understand limits falls apart.

The underlying reason why this merging of the "approaching" conception of limit and the formal definition doesn't work is because the informal definition is based on motion, while the formal definition is devoid of any sense of motion because of its basis on the concept of range or proximity. The BMI uses definite iterative processes to explain indefinite continuous processes, but the formal definition is not a process as such: it is a static entity, not a dynamic one. Lakoff and Núñez had to build a stop-gap formal definition which used an indefinite iterative process (nested sets) in order to apply the BMI to the formal definition. While the BMI can explain the "approaching" conception of limit because of its basis in a dynamic process, this usage simply cannot be connected to the formal definition. In attempting to leap the gap between an "approaching" conception of limit and the formal definition through their unmotivated usage of the absolute value, it is clear that they are missing this vital distinction. Their mixing of the formal definition with the approaching conception is thus fundamentally flawed, and taints both interpretations of the limit concept.

Lakoff and Núñez (1997) attempt to get around this by stating that the formal definition actually has noting to do with a static or a dynamic conception of limit, but rather that the quantification (the logical structure) in the formal definition is the important part. They claim:

> Many students of mathematics are falsely led to believe that it is the epsilon-delta portion of these definitions that constitutes the rigor of this arithmetization of calculus. The epsilon-delta portion actually plays a far more limited role. What the epsilon-delta portion accomplishes is a precise characterization of the notion of "correspondingly" that occurs in the dynamic definition of limit where the values of $f(x)$ get "correspondingly" closer to L as x gets closer to a. That is the only vagueness that is made precise by the epsilon-delta definition. (Lakoff & Núñez, 1997, p. 71).

While it is true that mathematicians must formalize the concept of "correspondingly", that, in and of itself, does not formalize "closeness". Another way to express the "approaching" metaphor is to ask, as $f(x)$ gets closer to L as x gets closer to a, just how close do we need to be? The correct answer is: as close as we want. It is this statement, "as close as we want", that also needs to be formalized, and this is not covered by simply formalizing "correspondingly".

To demonstrate how formalizing "correspondingly" fails to include a formalization of "closeness", we can examine Lakoff and Núñez's "dynamic epsilon-delta limit" definition: "$\lim_{x\to a} f(x) = L$ means that for every $\varepsilon > 0$, there exists a $\delta > 0$, such that as x moves toward a and gets and stays within the distance δ of a, $f(x)$ moves toward L and gets and stays within the distance ε of L" (Lakoff & Núñez, 1997, p. 71). Here they retain the quantification of the formal definition, but express the rest in terms of "approaching". This mixture of the dynamic ("moves towards") and the static ("gets and stays within a distance") conceptions of limit results in a definitional overkill. Once one has the static pieces of the definition, the dynamic pieces are technically unnecessary. If you simply have the dynamic pieces, then you do not necessarily have all of the pieces of the formal definition (because of the nature of "approaching"). In their attempt to show how a formalization of "correspondingly" is the key component of the formal definition, they are unable to avoid including pieces of the static definition. Thus, while quantification is important, it is not the only difference between the formal definition and the "approaching" metaphor.

A Proposed Resolution: Connecting "Approaching" With the Formal Definition

The "approaching" conception of limit and the formal definition cannot be reconciled the way Lakoff and Núñez propose. Instead of the argument presented, the authors could have simply kept the motion-based conception and the formal definition initially separate, instead of conflating the two. First, they could have presented the motion-based, "approaching" conception of limit, the examples which match this, and a conceptual metaphor which does not use the absolute value. Then later, they could have shown how the motion-based, "approaching" conception of limit breaks down when faced with more complicated types of limit convergence, how this ultimately lead Cauchy (Grabiner, 1992a, 1992b) to move to a new conceptual metaphor of proximity or range, which was later refined by Weierstrass (Lakoff and Núñez, 2001, p. 308) and how this leads to the absolute value being used in the formal definition.

By mixing a motion-based definition with an static-based definition, Lakoff and Núñez cloud the real issue: how do people move from the intuitive, grounded, dynamic conception of limit to the formal, static definition? This is the central pedagogical question that we need to be asking, but through their casual use of absolute value, they gloss over it. The authors attempt to begin with the "approaching" conception of limit, which students use, and try to directly connect it to an understanding of the formal definition. However, while the formal definition is an important concept for students to understand, it is based on a completely different metaphorical foundation than the motion-based conception of limit. This implies that, when it is time for the transition from the "approaching" conception to the formal definition to take place, a new metaphor needs to be introduced.

The formal definition was created to solve and explain cases of limit convergence that the "approaching" conception cannot explain, thus no amount of twisting the informal conception of limit will suffice. This has happened with other prominent scientific concepts as well. For example, Einstein's general theory of relativity was created to explain not only the normal cases explained by Newtonian mechanics, but also cases where those ideas break down (particularly situations concerning the very large and the very small). Thus, a new metaphor was created which encompasses the old one, but does not build off of it. Newtonian mechanics cannot be sufficiently extended in order to link to the general theory of relativity; however, the general theory of relativity can be used in situations where Newtonian mechanics works. The same principle should be attempted here: because the "approaching" conception simply cannot be extended to cover all cases of limit convergence, a new metaphor which explains the formal definition needs to be introduced to students, at the same time making clear that, while the formal definition works in all cases, the "approaching" metaphor still works in simple cases. At the same time, the informal dynamic conception should not be abandoned, as there is value in supporting such dynamism, even if the expert view needs to contain the formal definition (Marghetis & Núñez, 2013).

Based on classroom evidence, Boester (2010) suggests that students at first connect these distinct metaphors by assuming the "approaching" conception is the correct one, and that the static conception of the formal definition is a special case, as shown by putting the synchronized ranges created in the definition into motion. This would imply that students are using the pieces of the "approaching" conception as the source domain and the static conception as the target domain, thus mapping the dynamic aspect of motion along a line to the static (now dynamic) aspect of the range. However, some students evolved past this connection, recognizing that the formal definition conception is the correct one, and that the "approaching" conception is the special case (analogous to an expert view). This would imply that the students are using the static conception as the source domain and the dynamic conception as the target domain, thus mapping the static ranges to the dynamic (now static) aspect of approaching.

Those Who Teach the Teachers: Knowledge Growth in Teaching for Mathematics Teacher Educators

Shandy Hauk
WestEd & University of Northern Colorado
Billy Jackson
University of Tennessee Chattanooga
Jenq-Jong Tsay
University of Texas Rio Grande Valley

This theory-based report gives evidence and builds a conceptual framework for a construct called "mathematical knowledge for teaching future teachers" (MKT-FT). Mathematics teacher educators construct MKT-FT as they teach courses for pre-service teachers. Connections to mathematical knowledge for teaching (MKT) are discussed, with an emphasis on the complex relationships between aspects of pedagogical content knowledge in MKT-FT and MKT.

Key words: Mathematical knowledge for teaching, Discourse, Teacher educators

In the 30 years since Shulman's (1986) seminal speech on the importance of pedagogical content knowledge, a variety of theories about such knowledge have emerged (Depaepe, Verschaffel, & Kelchtermans, 2013). Among the most well known in the U.S. is at the heart of a primary-grades-focused model of *mathematical knowledge for teaching* (MKT) introduced by Hill, Ball, and Schilling (2008). The subject matter knowledge (SMK) and pedagogical content knowledge (PCK) components of Ball and colleagues' model of MKT are illustrated in Figure 1.

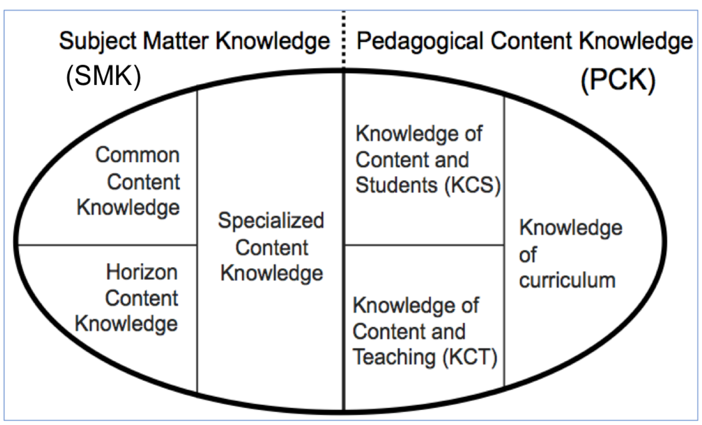

Figure 1. Model of mathematical model for teaching (Hill et al., 2008)

In the context of more advanced mathematics, others have explored how the idea of MKT may be productively refined for use in research and development in secondary and post-secondary settings (Hauk, Toney, Jackson, Nair, & Tsay, 2014; Speer, King, & Howell, 2015). Speer and colleagues considered college instructional questions such as: What are the types of specialized, horizon, and common mathematical knowledge for teaching calculus? While Hauk and colleagues have tackled: How does one productively unpack the aspects of PCK – knowledge of content and curriculum, content and teaching, content and students – when the teaching is in a college, the students are adults, the collections of mathematics experiences brought to the classroom are larger, and the sociocultural relationships between student and teacher are quite different from those assumed in the K-8 foundations of the initial framing of

MKT? Hauk and colleagues (2014) developed an expanded model for college teacher PCK. They used the PCK components in Figure 1 as the vertices of the base of the tetrahedron and added a fourth vertex which they call *knowledge of discourse* (knowledge about the nature of discourse, including inquiry, socio-mathematical norms, and forms of communication in mathematics within and outside of post-secondary educational settings) – see Figure 2.

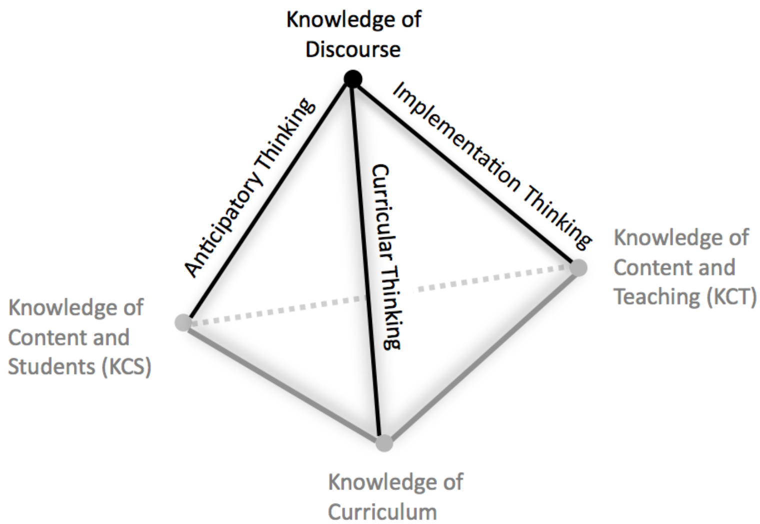

Figure 2. Tetrahedron model of PCK (Hauk et al., 2014).

Here we consider a related question: *What is the nature of "mathematical knowledge for teaching" for college instructors who teach mathematics for pre-service elementary teachers?* Such college teachers are teaching adults in post-secondary settings where the mathematical content is in the context of elementary mathematics (rather than advanced) *and yet* the content is itself linked to K-8 MKT of common, specialized, and horizon subject matter knowledge.

Indeed, Gallagher, Floden and Gwekwerere (2012) note that we know little about what skills are required to be an effective mathematics teacher educator nor do we know much about how those skills develop. Here, by *mathematics teacher educator* we mean anyone who provides guidance, mentoring, or professional learning opportunities to prospective or in-service teachers. The current paper focuses on the subpopulation of mathematics teacher educators who teach mathematics-content-rich courses where the students are pre-service K-8 teachers.

A natural question arises: Why should the Research in Undergraduate Mathematics Education (RUME) community have an interest in examining the knowledge required of mathematics teacher educators to perform their jobs effectively? First and foremost, much of the mathematical preparation for teaching among future K-8 teachers happens in colleges, most at the undergraduate level (Masingila, Olanoff, and Kwaka, 2012). In fact, Masingila and colleagues found that 88% of the teaching of "mathematics for elementary teachers" college courses happens in mathematics departments, with between 27% and 43% of faculty in these departments holding a Ph.D. in either mathematics or mathematics education. Across institution types (2-year, 4-year, and advanced-degree granting) there were more faculty with mathematics Ph.D.s teaching these courses (as opposed to those with Ph.D.'s in mathematics education).

We know that early learning experiences are formative and that children who learn to see themselves as mathematical agents do better in secondary school and beyond (Aud, et al., 2013, Shim, Ryan, & Anderson, 2008; Woodward et al., 2008). We know teaching that supports children in building skills with mathematical process, practices, and content is socio-culturally rich and responsive to societal as well as community needs (Aud & KewalRamani, 2010; Gay, 2010; Khisty & Chval, 2002; Téllez, Moschkovich, & Civil, 2011). We know that future teachers have greater resources to draw on and are more likely to offer children what they themselves have experienced as learners (including the undergraduate learning experiences that are most proximal to their launch as teachers; e.g. Ball and Bass, 2000; Conference Board of the Mathematical Sciences, 2001; Hodgson 2001). There is a need for mathematics faculty who are prepared to teach mathematics content courses for pre-service elementary teachers (PSETs) in ways that resonate with the kinds of classrooms those future teachers are expected to sustain.

In the U.S., the current population of instructors for such courses includes adjuncts, graduate students, and full time tenure- and non-tenure-track track mathematics faculty (Masingila, et al., 2012). Large segments of this instructor population have difficulty teaching courses for PSETs (Flahive & Kasman, 2013; Greenberg & Walsh, 2008). Though instructors in mathematics departments usually have a deep mathematical background, they often face challenges teaching content that is relevant and has utility for PSETs, unaware of the "cognitive and epistemological subtleties of elementary mathematics instruction" (Bass, 2005, p.419).

Given this state of affairs, Masingila, Olanoff, and Kwaka (2012) advocate for the design and implementation of professional development for mathematics teacher educators. Indeed, Masingila and colleagues note that many faculty who participated in their study asked the researchers where they could find professional learning resources! The RUME community includes experts on such matters: any design and implementation of effective professional development for mathematics teacher educators must involve attention to identifying the types of knowledge that faculty use and need in their regular practice of teaching future teachers.

For these reasons, we propose that college instructors possess a specialized constellation of knowledge to be studied: *mathematical knowledge for teaching future teachers* (MKT-FT). We posit that like MKT, MKT-FT is largely individually constructed for mathematics teacher educators, though often socially mediated. Seaman and Szydlik (2007) discussed the necessity but insufficiency of the early model of MKT for college mathematics instruction, particularly in the context of teaching future teachers. Several authors have noted the existence of what we see as components of MKT-FT. Zopf (2010) and Olanoff (2011) argued that effective teaching of future teachers requires mathematical knowledge of the work of teaching K-8 mathematics and awareness of the complexities of K-8 MKT itself.

According to Rider and Lynch-Davis (2006) and Smith (2003), the mathematical knowledge needed for teaching future teachers attends to the fact that one is teaching adult learners who have some familiarity with the mathematics (as opposed to teaching children who may be learning content for the first time). And, we note, there is a perceived autonomy of the learner in the post-secondary setting that is largely absent in K-8 and high school contexts. Smith (2005) has claimed that faculty who work effectively with future teachers have some (perhaps implicit) knowledge of educational theory and K-12 practice, as well as knowledge resources for connecting ideas and concepts in ways that prepare pre-service teachers to review, select, and engage with the wide array of curricular decisions that must be made by a teacher (e.g., decisions regarding which resources, worksheets, texts, and activities to use or avoid). Olanoff (2011) points out that Deborah Ball herself considers MKT to be the analogue of "common content knowledge" for faculty when considering what it might mean for an instructor to have MKT for teaching teachers.

Research and development on the preparation of teacher educators has long assumed a nesting of types of knowledge. One representation of that can be seen in Carroll and Mumme's work (2007). Figure 3a represents the nesting of mathematical content as subject matter knowledge (orange disk), linked to (future) teacher and elementary student within the larger context of the classroom (yellow disk). Similarly, in Figure 3a, mathematical knowledge for teaching (the stuff in the yellow disk) is linked to (future) teacher and mathematics teacher educator ("leader") within the larger context of teacher professional learning (green disk).

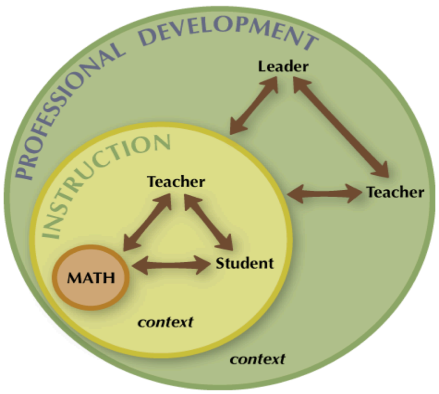

Figure 3a. Nesting of teaching and learning connections (Carroll & Mumme, 2007).

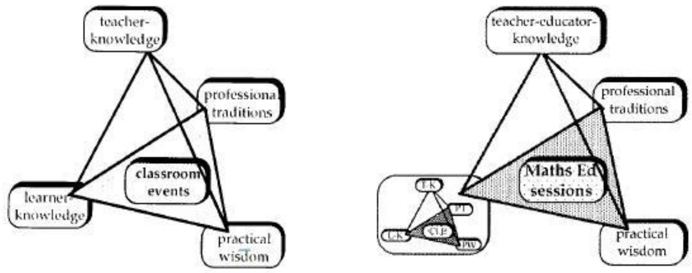

Figure 3b. Tetrahedron models for teacher-educator knowledge (Perks & Prestage, 2008).

Now we have a highly multi-dimensional situation. For each disk in Figure 3a there is an associated set of specifications for what counts as the context and for what constitutes the "content" about which one has "pedagogical content knowledge." Perks and Prestage (2008) made the case that knowledge for teaching teachers operates on several levels with a partially-nested self-similar design for their model of *teacher-educator knowledge* (Figure 3b).

The model for MKT-FT proposed in Figure 5 blends features of the three models discussed above. At each vertex are both K-8 mathematical content in the college class *and* "content" that is Knowledge of Content and Students in K-8 (illustrated for just the KCT vertex as magnified and highlighted, lower right, in Figure 5). We claim a similar cascade of knowledge structures, related to Content & Students, Curriculum, and Discourses in K-8 are related to the PCK aspect of college mathematics instructor MKT-FT (illustrated by similar "mini" tetrahedral at each of the other vertices in Figure 5).

While the nesting of knowledge structures within others is represented as geometrically self-similar, a fractal structure, the knowledge and thinking represented at each vertex is not identical. Each vertex of the "large" tetrahedron for PCK in the mathematical knowledge for teaching future teachers has a four-to-one mapping. For instance, the MKT-FT vertex for *knowledge of content and students* (KCS) is defined a la Ball as "content knowledge intertwined with knowledge of how students [who are future teachers] think about, know, or learn this particular content" (Hill et al., p. 375). In Figure 5, KCS includes knowledge of how college students engage with learning the MKT they will need in the future as teachers as well as (from the "smaller" tetrahedron) MKT related to K-8 teaching and learning. Knowledge of content and teaching in the MKT model is about teaching moves for working with K-8 mathematics students. In the MKT-FT model, knowledge of content and teaching includes a knowledge of teaching moves for mathematics as a part of teaching the college course for future teachers as well as of teaching moves for including attention to K-8 MKT in teaching that college course.

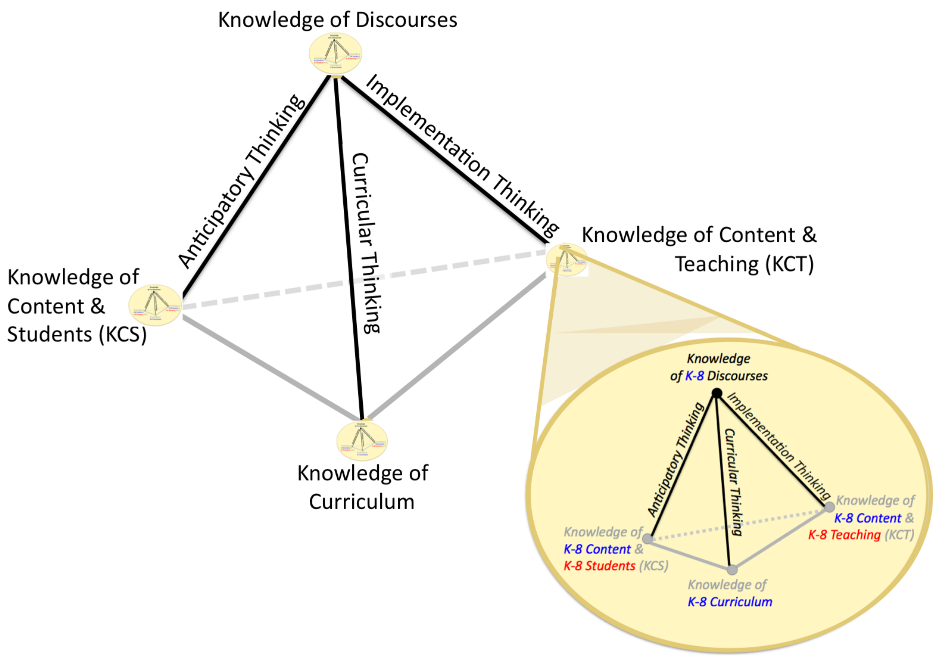

Figure 5. Model of MKT-FT pedagogical content knowledge – each vertex itself contains knowledge structures related to K-8 MKT.

An Example: MKT-FT and Task Design

Teacher education has long noted that task design may be a significant component in the development of knowledge for teaching pre- and in-service teachers. For example, Stylianides and Stylianides (2006) asserted that it is crucial for activities to be *teaching-related mathematics tasks,* so future teachers learn important school mathematics while at the same time making connections between how learning the content relates to its teaching. For Seaman and Szydlik (2007), well-designed tasks deepen the "mathematical sophistication" of future teachers, which they define as occurring as a result of enculturation into the mathematics community signified by teachers exhibiting the ways of knowing and values of mathematicians as their own. A broader example comes from the *Journal of Mathematics Teacher Education* issue devoted to the important topic of task design (Zaslavsky, Watson, & Mason, 2007). Papers in this special issue discussed different aspects of good task design in courses for teachers. For instance, according to Chapman (2007), effective tasks facilitate new understandings of familiar concepts and prompt reflection and discourse, while Bloom (2007) argued that quality tasks enhance mathematical habits of mind among college learners who are future teachers.

Yackel, Underwood, and Elias (2007) demonstrated the profound effect that attention to task design and reflection on task implementation can have on MKT and MKT-FT development of those who teach future teachers. One of their instructors commented,

> I found it interesting that adult students also go through some of the same progressions that children do. In particular, I often noticed that many students initially needed to use [iconic representations] to perform calculations, such as explicitly drawing boxes, rolls, and pieces…Having never taught young children, I had never seen this first hand. *Base 8 gave me the opportunity to experience this part of children's learning*

[emphasis added]. I think this is valuable to college instructors because most, like myself, will never have an opportunity to work with elementary school children closely. (p. 364)

Hence, we see that task design becomes a part of Knowledge of Content and Teaching for teacher educators: it is part of a teaching move designed to facilitate PSET learning of MKT. This example also reinforces the nonlinearity of our model for MKT-FT, as the instructor above mentions building the Knowledge of Content and Students (both for primary and adult learners) by engaging with their Knowledge of Content and Teaching.

As another example of the pluralistic nature of MKT-FT, consider subject matter knowledge itself: as Ball noted, MKT becomes common content knowledge for mathematics teacher educators. However, MKT-FT specialized content knowledge includes an awareness of and responsiveness to the educational literature as a means of helping PSETs understand why certain mathematical practices or pedagogical practices are favored (e.g., in the Common Core Standards). Horizon knowledge for teacher educators includes recognition of district, state, and national mathematics standards.

And what about the knowledge of discourse discussed earlier? Well, for mathematics teacher educators, MKT-FT knowledge of discourse subsumes the same knowledge of discourse that teachers have, and draws on knowledge of communicating about MKT and the teaching of mathematics in different sociocultural situations.

As Hauk, et al. (2014) point out, the literature on PCK includes both stable and dynamic features. To account for this, they use the edges in their tetrahedron to represent the *ways of thinking* about teaching mathematics that teachers use in practice. These ways of thinking are enacted in the classroom as teachers adapt to varying sociomathematical and cultural contexts that arise over time. In like manner, effective mathematics teacher educators also possess ways of thinking about teaching mathematics and about teaching MKT that change as the social, mathematical, and cultural climates change in their courses for PSETs. Hence, the edges in our fractal tetrahedron also represent these dynamic ways of thinking for faculty who teach future teachers.

At the Conference

In pursuit of applications of this model in current data analysis and in future research designs, at the conference we will present several examples of both knowledge and thinking as we envision them in the model. We have these questions for RUME participants in the session:

1. What would make a compelling argument for you about the connections among the ideas?
2. What kinds of data provide evidence for each?
3. How might we design a study to focus on a subset of the “small” or “large” tetrahedra?
4. Based on your experience, what connections among the ideas in the model are central?
5. How would knowing the answer to the questions we ask help faculty preparation and development? Or, inform practice of teaching adults who are in- and pre-service teachers?
6. What other questions are coming to mind, now that we have had these questions?

Research in Courses before Calculus Through the Lens of Social Justice

Shandy Hauk

April Brown Judd
U. Mary Hardin Baylor

Katie Salguero
WestEd

The terms equity, diversity, inclusion, and social justice have entered the research lexicon. Yet, researchers face significant challenges in gaining a nuanced understanding of the various ideas associated with these words. This theory-focused report presents some recent policy efforts to generate a shared meaning for "social justice" in mathematics education and offers a framework for making sense of (and making sense with) intercultural interactions as an essential component of rigorous research. To anchor discussion, we focus on research on teaching and learning in the courses before calculus (e.g., algebra, pre-calculus, liberal arts math, math for pre-service elementary school teachers, algebra-based statistics).

Keywords: Social justice, Cultural competence

Race.
Yes, that kind, the White and Black and Red and Yellow and Brown kind.
Go ahead.
Experience the shock.

Take a moment for a long, uncomfortable silence.
Yes, we just touched the third rail in American mainstream culture.

Breathe.
Here it comes again.
Race.
You know, of course, that if we have said "race" that "racism" is not far off.
Hovering, stage-right, there it is: Racism.
Its companions join from stage-left:
    Sexism,
    Ableism,
    Genderism,
    Ethnocentrism,
    Classism,
    Fill-in-the-blank-ism
They come together when we consider:
    Social justice.

In the past year two organizations, TODOS: Mathematics for All and the National Council of Supervisors of Mathematics (NCSM; 2016), issued a position paper entitled *Mathematics Education Through the Lens of Social Justice: Acknowledgement, Actions, and Accountability*. In it, social justice in mathematics education includes "fair and equitable teaching practices, high expectations for all students, access to rich, rigorous, and relevant mathematics, and strong family/community relationships to promote positive mathematics learning and achievement." Underlying all of these is a call for attention to the ways power, privilege, and oppressions contribute to and maintain an inequitable learning system.

There is a distinction to be made between perpetuating an "ism" and dealing with the fact that it exists. For example, *racism* refers to the ways in which avoidable and unfair inequalities are perpetuated based on ethnic, cultural, religious, and other characteristics associated with the concept of "race" at interpersonal, institutional, and societal levels (Berman & Paradies, 2010). By comparison, *racialization* refers to the processes by which characteristics identified as "racial" become meaningful in different social situations (Delgado & Stefancic 2001; Walton, Priest, & Paradies, 2013). The two are often conflated, resulting in the contention that any mention of race is racist. This conflation of terms can derive from a variety of views, from a belief in "color-blindness" (Apfelbaum, Norton, & Sommers 2012), a drive to be "color-mute" (in which race-talk is actively silenced or removed in social interactions or written documents; Pollock, 2004) or from a stance that society is past race-based discrimination and can be considered "raceless" (Ono, 2010). Color-muteness and racelessness draw on color-blindness but for different purposes. Paradoxically, to be color-mute is to recognize racial difference in order to actively remove mention of it, while racelessness is a "post-racial" approach, in which it is assumed that race no longer matters (Kempf, 2012).

Racialization, or genderization or other fill-in-the-blank-izations that use language to acknowledge inequities, can be valuable support for making bias explicit (rather than implicit). Research suggests that goals for equity, inclusion, and social justice are undermined when biases remain unexamined, implicit, or "unconscious" (Warikoo, Sinclair, Fei, Jacoby-Senghor, 2016).

Discerning difference, recognizing pattern, and anchoring new knowledge in those already noted differences and patterns are at the core of all human cognition. In other words, making "bias" explicit and challenging it are the essentials that allow humans to think, know, and learn.

Each of the authors has taken a different route in coming to mathematics education as a professional focus. Our experiences are rich in dealing personally with institutional "-isms," both academic and societal. In this theory-focused report we explore tools to increase researcher capacity for nuanced noticing of "isms" while tackling the truth of their existence. To attend to social justice in and through research in collegiate mathematics education means addressing our own needs (as humans who are researchers) for language, concepts, and awareness-building to support intentional decision-making. At the same time, we acknowledge the related, inevitable, struggle, of engaging in challenging conversations. Toward that end, we offer key ideas from education theory and intercultural sensitivity development along with a few examples.

Conversational Tools

As people trained in mathematics, those who do research in undergraduate mathematics education (RUME) know that mathematical sense-making is more than "identify the problem and solve it." As citizens of a first-world country in the 21st century, we are aware of societal injustice. Thus, as a community of researchers, we have an opportunity to dig deeper into a line of thought that has been emerging for a while (e.g., Aguirre & Civil, 2016; Adiredja, Alexander, & Andrews-Larson, 2016; D'Ambrosio et al., 2013; Davis, Hauk, & Latiolais, 2010; Gutiérrez, 2013; Nasir, 2016).

Over the past 10 years, Singleton and Linton's (2006) courageous conversations framework has become a cornerstone in the professional development of teachers around race. The framework is built on four agreements. Each can contradict some tightly held cultural norms relating to race talk. To participate in a "courageous conversation" people agree to: stay engaged, expect to experience discomfort, speak their truth, and expect and accept a lack of closure.

Being courageous about the risk of engaging in "--izations" involves navigating our own meanings for comfort, safety, and bravery. One tool we have found helpful is the Venn diagram shown in Figure 1. The diagram can support being self-aware and communicating with others about how each of us experiences risk in a conversation. We have used the diagram in a variety of settings: with pre-service K-8 teachers or developmental algebra students in creating classrooms where the challenging conversations are about mathematics (and its teaching) as well as with other researchers when the challenging conversations are about the role of race in research design. For example, a person may rarely feel safe having a conversation with people or about people from races other than their own, but can be brave and handle the expected discomfort in order to stay engaged in a valued exchange of ideas.

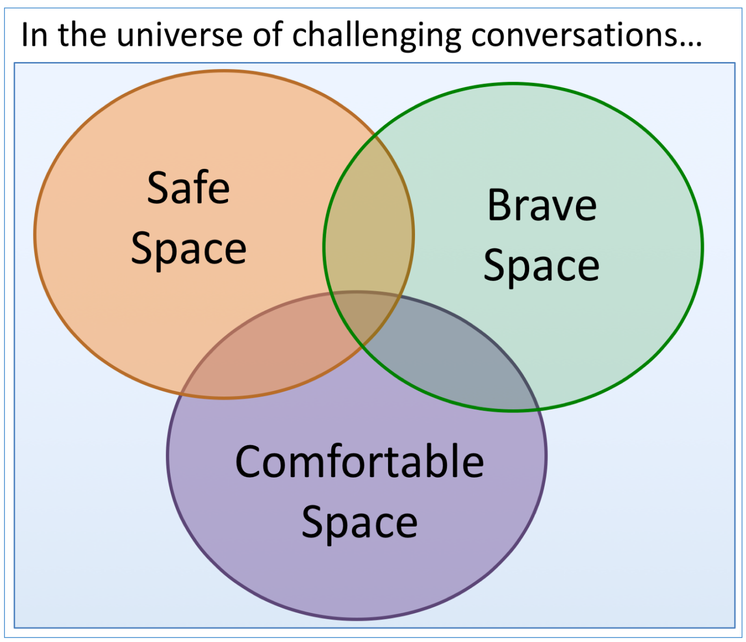

Figure 1. Juxtaposition of three types of experience related to taking risk (personal or professional) during a challenging conversation.

Along with the Venn diagram, we also have found the diagram in Figure 2 (next page) to be a useful tool. Qualitative researchers will recognize the interactions pictured among framework, experience, and reflection. What we have added are specifiers about being aware (mindful) during experience, being purposeful (focused) in reflection, and being rooted in human relationships (intercultural) when framing what we do. In fact, Figure 1 is a tool to support mindful experience. Generating this report resulted from focused reflection and an effort to share our, sometimes stumbling, journey into rehumanizing our work as researchers in collegiate mathematics education.

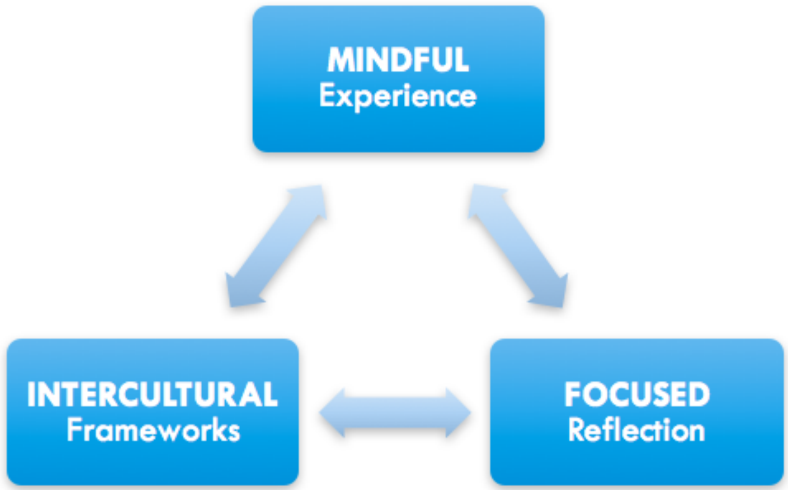

Figure 2. Descriptions and relationships among aspects of building self- and other-awareness.

In what follows, our focus is how the idea of *intercultural frameworks* can support social justice in RUME. We encourage the reader to stay engaged, while also being mindful and expecting to experience discomfort. We will "speak our truth" by illustrating ideas with examples. In offering these ideas, just as each reader may face different degrees of professional and personal vulnerability in reading it (i.e., different experiences of safety, comfort, and bravery), so has each author in creating it. Finally, this theory-based piece is an opening, so we expect and accept a lack of closure.

Moving From Personal Reflection to Professional Action

According to the TODOS-NCSM (2016) position paper, three conditions are necessary to establish socially just and equitable mathematical education for all learners:

(1) **acknowledging** that an unjust social system exists,
(2) **taking action** to eliminate inequities and establish effective policies, procedures, and practices that ensure just and equitable learning opportunities for all, and
(3) being eager for **accountability** so changes are made and sustained.

Taking the three tenets as foundational, we can ask: What is the role of social justice in RUME? What is the role of RUME in social justice? When we conduct research in the U.S. we make decisions about who participants are. What would be different if decisions in a project you know about had included overt and repeated attention to the three tenets?

Read through the three conditions again and think about it for a moment.

How would acknowledging that the social system is unjust shape selection of sites? Participants? Topics? Interpretations of actions and words? How might our next research question be framed so the answer would be evidence to support action to eliminate an inequity? How do we do that? How might the research design or analyses need to be different if the results of the work were held accountable by research peers *and* judged in a court of stakeholder opinion that valued equity as much as excellence in mathematics education?

Short, possibly terrifying answers to these questions exist: observe the world; be purposeful in inviting people into your research who do not look like you or act like you or think like you. But the short answers are deceptive. Such calls for courageous action in the face of our own ignorance can feel motivating *and* can be recipes for disaster. Entering the uncomfortable, not necessarily safe space of research that pays attention to social justice can be rewarding – but we must also stick it out even when it blows up in our faces.

Mathematical training has prepared us for this. The colossal failures before generating an elegant proof are well known to those who have done advanced mathematics. Some may ask: are the stakes as emotionally high in creating a proof? Mathematicians will say yes. For others, a comparable situation might be the personal and professional status that rides on completing and reporting well on a piece of educational research. So why do we do it? In short, to keep our jobs. But, we also may do it because something fulfilling comes from the process that is unavailable elsewhere. The reason we get on our particular professional roller coaster is because we want the thrill of the ride and we feel safe enough, or pressured enough, to be brave enough to take the risk. The idea of social justice in research adds complexity to the roller coaster. The main emotional aspects may be trepidation along with meta-affect of hope, a hope based on a (perhaps hazy) vision of a socially just world. The ideas and language of intercultural competence can help. They provide tools for meta-cognition about the affect and meta-affect.

Framework for Intercultural Awareness and Competence Development

Interactions with other people are shaped by our orientation to noticing and engaging with difference and the approach we take to the interaction itself. Do we anticipate great risk? Do we have the privilege of assuming safety? Social justice-aware research is shaped by what a researcher knows or anticipates about others' experiences. Below, we first offer language and structure for the research community for noticing and discussing difference. Then, we give a vignette and examine it in light of the suggestions.

The ways we are aware of and respond to others, including the particular challenges we each face dealing with the societal realities of racism, sexism, and other inequity-preserving structures, is a consequence of our *intercultural orientation*. This is neither a reference to our beliefs about culture or race nor about views on researching in mathematics education. Rather, intercultural orientation is the perspective about human *difference* each person brings to interacting with other people, in context. For researchers, it includes perceptions about the differences between their own views and values around various types of work in mathematics education, the views of their colleagues, and the views of various stakeholders in research. Intercultural competence is the capability to shift perspective and appropriately adapt behavior to socio-cultural differences and commonalities (Hammer, 2009).

To build skill at establishing and maintaining relationships in, and exercising judgment relative to, cross-cultural situation requires the development of intercultural sensitivity (Bennett 2004). The developmental continuum for intercultural sensitivity has five milestone orientations to noticing, making sense of, and developing response to difference: *denial*, *polarization*, *minimization*, *acceptance*, and *adaptation*.

With mindful experience a person can develop from ethnocentric ignoring or *denial* of differences, moving through an equally ethnocentric *polarization* orientation of an us-versus-them mindset. With growing awareness of commonality, a person enters the less ethnocentric orientation of *minimization* of difference, which may over-generalize commonalities. From there, development leads to an ethnorelative *acceptance* of the existence of intra- and intercultural differences. Further development aims at a highly ethnorelative *adaptation* orientation in which differences are anticipated and responses to them readily come to mind. This summary is represented in Figure 3 and elaborated below.

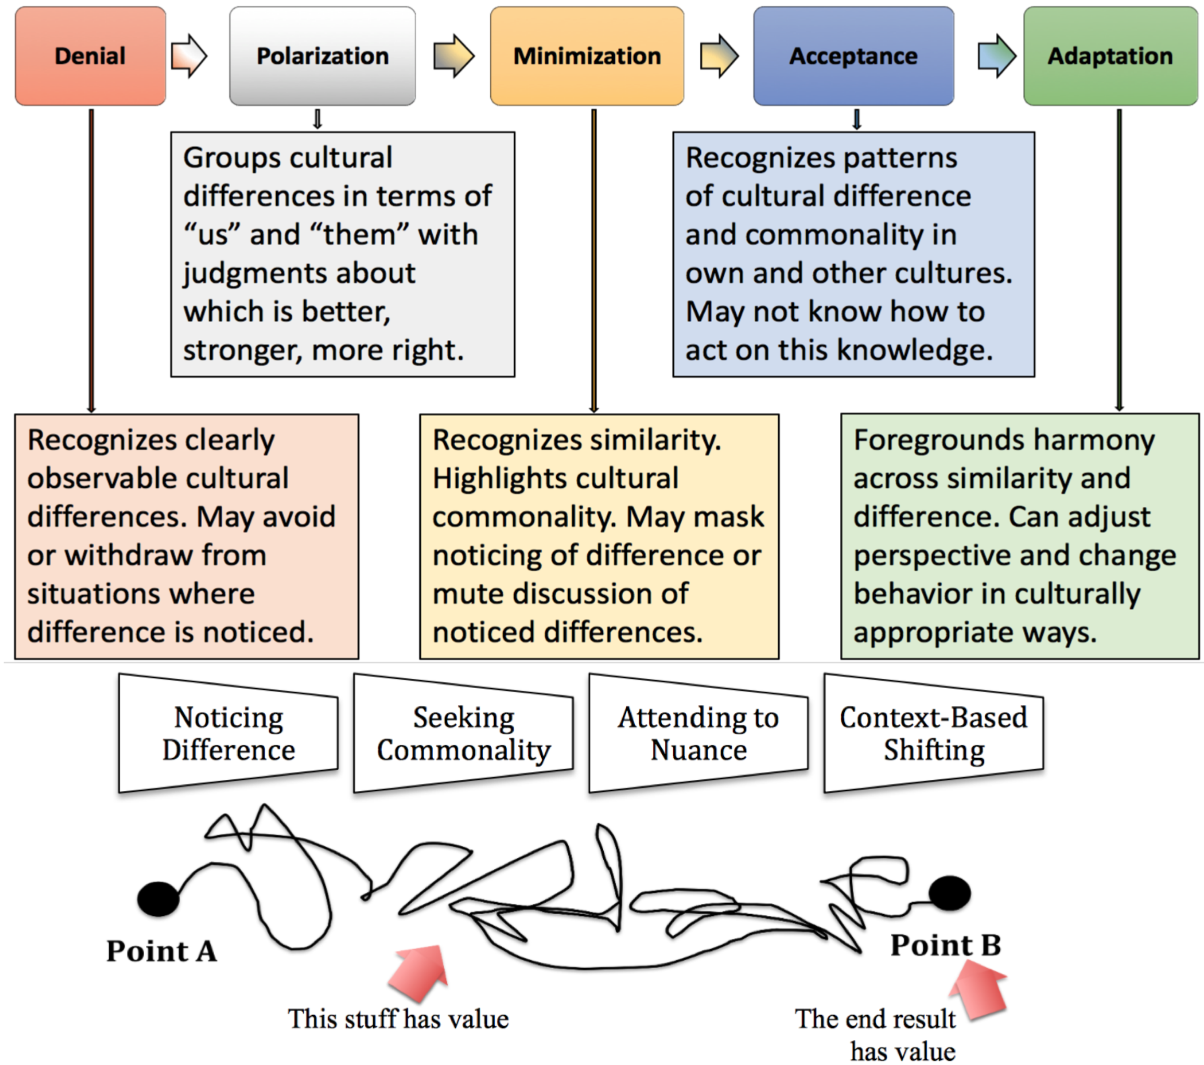

Figure 3. Diagram summarizing intercultural competence developmental continuum. One may start at point A and eventually develop to point B but the path is not linear.

Denial. A central part of awareness is to observe self and others. In the denial orientation, little observation of others happens. Such an orientation is not denial in the sense of “I'm going to say it is not there” but denial as in “I can't even see it.” The view is “we’re all researchers and we all do our work” without attention to what “our work” might mean to others.

Polarization. The polarization orientation might be characterized as: “There's a RIGHT way to do things and there's a WRONG way to do things. And we're going to make sure we use the right way.” For example, depending on the experience and values of the conversant, the “right” way to do research in collegiate mathematics education may or may not include education discourse or the language of assessment, statistical analyses, curriculum, program, or teacher development. Nonetheless, enacting a polarized orientation in mathematics education research would mean seeing that a practice is happening or noticing a norm being developed.

Minimization. From a minimization orientation, people may focus attention on how others' approaches are similar to their own valued ways of designing, conducting, and reporting research. For some, this might be characterized as, "Look how this stuff called equity in math ed is LIKE research on effective mathematics teaching. It has a lot in common with it, even if the way it is said is a little different, I say effective, they say equitable. Let's talk about how it is similar. Let's leverage the fact that we have seen this before." From this perspective, any research in mathematics education is similar to all other research in mathematics education – whether one is reflecting on teaching a class, examining inquiry-based project learning involving the mathematics of institutionalized racism, researching how teachers take up the idea of brave conversations about race, sex, and poverty in professional development workshops, or in researching how graduate students validate proofs.

Acceptance. Through increased attention to nuance in the differences that exist among commonalities, one begins the transition from an orientation focused on minimization of difference to one of acceptance of difference. Here, the word "acceptance" is used in its socio-cultural sense – the action or process of consenting to receive (rather than its psychological one – believe or come to recognize as valid or correct). From this orientation, it might be characteristic for a researcher to notice various ways of determining the "quality" of research and suggest colleagues use whichever makes most sense for them. Additionally, the researcher might encourage peers to accept and understand the differences that exist in ways of prioritizing measures of "quality" in research.

Adaptation. Beyond accepting that there are these differences, adaptation-oriented people seek for themselves, and find ways to give colleagues, opportunities in noticing, articulating, and responding to differences. This might be characterized by statements such as, "I am looking for ways to work with colleagues. I don't have to assert or defend many, or even one method. Quality in research is a relative thing. How my colleagues and I connect ideas and access, organize, or value ideas is not necessarily strictly limited to the ways valued by my perspective." In adaptation, a person can converse well with people of differing mindsets (and with other orientations), understanding and appropriately using discourse familiar to discussion partners.

Intercultural competence is developed non-linearly. And, it is not static. The higher the stakes of a situation the more challenging it can be to maintain what might be one's usual, everyday orientation, towards difference. When the potential for conflict or challenge emerges in a situation (like reading this paper), affect and meta-affective pressures mean we may fold back to earlier developmental levels (e.g., the wandering curve in Figure 3). Being mindful of ourselves – our reactions and orientations – can support developmental growth.

Vignette

A RUME researcher is creating a professional statement that situates her work in the context of social justice in teaching future teachers. Her aim is to give background that explains the trajectory of her professional development and research goals.

As a teacher I want to foster a learning environment in which everyone has equal opportunity to learn. And, I want to foster a research environment where everyone has equal opportunity to contribute to the research. It is about bringing a broader perspective to new researchers that encourages people to change their focus from within to around. I have looked, but haven't really found the research on culture and teaching very useful, so I don't read it much. Just too much blame and shame there.

I recently conducted research on the implementation of a new curriculum for developmental math students. The curriculum had relevant, real-world activities that helped make clear why algebra can be a useful tool. When I am researching general mathematics, I am focused on what is offered by a curriculum that changes mathematics "from a gatekeeper to a gateway." I want students to see the ways society places workers in classes based on how much math they know and can use. We see this in K-12 education, and it is something most students have experience with. I want my research to recognize and capture information on how and if students see that the mathematics they learned in grade school had an impact on their options at the college level and beyond. Getting tracked into a lower level of mathematical learning does not have to limit their expectations and opportunities in life, but it does mean they will need to work harder as an adult to get to where they want to be. When I research lower level college mathematics courses, the enrolled students are often (but not always) those who were tracked into lower level mathematics courses in high school. The tracking students experience in grade school can have long-standing negative effects on the opportunities they see in the future.

Discussion - Connecting the Framework to the Vignette

Given our experiences in conversations with research colleagues, for this report we selected material for the vignette to highlight the minimization orientation. In the vignette, the narrator discussed intentional efforts to notice and include the three tenets of the social justice view. At the same time, her own developmental level of intercultural competence for noticing and responding to difference meant she saw students' opportunities to learn as affected by previous tracking without noticing that the students themselves were participants in whether something was an "opportunity." Her next round of research could include probing students' and instructors' perceptions of scenarios, finding out what is perceived as an opportunity, by whom.

Students in "lower level math" courses are much more likely to have had regular encounters with disruptions to intimacy with mathematics. Every interaction with mathematics may be a risk, with the type and level of risk varying widely depending on the many years of previous experience of adult students. What the researcher or classroom instructor might perceive as an equal opportunity to increase intimate connections with mathematics may not be fair if the risks are vastly different for different students. The narrator had not investigated the literature because it was uncomfortable to read. She has an opportunity to take the kinds of risks that her new curriculum asks students to embrace.

Another opportunity for the researcher is expanding on her reflection that: "Getting tracked into a lower level of mathematical learning does not have to limit their expectations and opportunities in life, but it does mean they will need to work harder as an adult to get to where they want to be."

Conclusion

The feelings and thoughts experienced when reading the first page of this piece may have some indicators for you about where you are on the developmental continuum from denial to adaptation. A large body of research in intercultural orientation has suggested that the majority of the college-educated U.S. population interacts with the world from a perspective somewhere between polarization and minimization. Our own research, among researchers in collegiate mathematics education, mathematicians, and U.S. public school teachers in grades 6 and up has echoed this result several times (Hauk, Toney, Nair, Yestness, & Troudt, 2015; Hauk, Yestness, & Novak, 2011). We take this as a starting point and seek ways to move along the developmental continuum. That means asking questions and finding resources that can support growth of intercultural sensitivity while being aware of the energy and care needed, for ourselves and others, to make brave decisions and to explore beyond the bounds of what we consider comfortable or safe.

The more that researchers in cognition use critical theory features and vice versa, the closer the research community may come to an equality in talk. The problem in this over-reliance on commonality is that equality in discourse style is not equity in discourse. As Marilyn Cochran-Smith and colleagues have recently described it, “With the former, the valence of the terms is primarily about sameness (equality) or difference (inequality), while with the latter, the valence of the terms has primarily to do with fairness and justice (equity) or unfairness and injustice (inequity)” (Cochran-Smith et al., 2016, p. 69).

Remember, we said to expect an absence of closure. To support that, we offer some suggestions for questions to drive a conversation in your near future. Find someone to talk with who agrees to Singleton and Linton’s (2006) four standards and discuss some/all of these questions. The set of questions asks you to do some *acknowledging*, *take some action* (e.g., step into a brave space to read) and be *accountable* at least to yourself and a conversational partner.

(1) Read Bennett’s (2004) article. What new goals do you have for your own intercultural competence development? Review the references below, what might you read next to help make progress on those goals?

(2) Read the article by Aguirre and colleagues (2017). How are your answers to the questions in #1 altered? Why?

(3) Questions for a focused reflection on research identity: What is going on in my community? What do I mean by "my community"? Research thought partners? Fellow faculty? Geographically defined? Socio-culturally defined? Why that?

(4) Questions for a focused reflection on the intersection of research and social justice: If I were conducting research that attended to social justice in college mathematics, what data would be collected? What is problematic about using that data? For example, what does a social justice lens offer in thinking about what constitutes a valid assessment of mathematical thinking, knowing, and/or understanding? Of mathematical knowledge for teaching?

(5) Questions for generating an intercultural framework: Given the potential variability in intercultural development of students, instructors, and researchers, of textbook authors and administrators, and acknowledging institutional inertia, how might we create a developmental continuum for social justice in mathematics education?

(6) Questions to prepare for mindful experience: What is my position within the social justice framework? If you have not already, read Aguirre et al., (2017) and consider: What are next steps I am ready for now? Three months from now? One year from now?

(7) Questions to connect social justice to a framework for research: Read the TODOS/NCSM (2016) position statement and Aguirre et al. (2017) article. The TODOS/NCSM position statement details steps to take to implement the recommendations of acknowledgement, actions, and accountability. On the next page is an example of how the ideas might be translated to RUME. Discuss and create similar tables of parallels, one table for each of the other aspects in the position paper.

Example: Belief Systems and Structures

Actionable Items for Changing Educational Practices in Mathematics (p. 4)	***Potential Actionable Items for Changing Research Practices***
• Interrogate individual and societal beliefs underlying deficit views about math learning and children with specific attention to race/ ethnicity, class, gender, culture, and language.	• Interrogate individual and societal beliefs underlying deficit views about mathematics learning in college with specific attention to race/ethnicity, class, gender, culture, and language.
• Refrain from using deficit discourse in instructional decision making (e.g., placement decision, course offerings).	• Refrain from using deficit discourse in research decision making (e.g., sample, instrument design, interview strategies).
• Show evidence that course taking patterns are changing, remedial/ intervention courses reduced, and advanced mathematics offerings are more robust and plentiful.	• Conduct research to provide evidence about course taking patterns, including remedial/ developmental courses, and report on context for all, from basic to advanced mathematics.
• Increase recruitment and retention of mathematics teachers and leaders from historically marginalized groups.	• Increase recruitment and retention of researchers and research participants from historically marginalized groups.
• Require professional development opportunities that focus on social, cultural, linguistic, contextual, and cognitive facets of mathematics and mathematics learning.	• Require professional learning opportunities that focus on social, cultural, linguistic, contextual, and cognitive facets of mathematics, mathematics learning, and research thereon.
• Create a mathematics vision with accountability mechanisms for the classroom, school, and district that uplifts students to learn rigorous and relevant mathematics.	• Create a research vision with accountability mechanisms for individuals, projects, and professional groups that uplifts research on the learning of rigorous and relevant mathematics.

What Should Undergraduate Mathematics Majors Understand About the Nature of Mathematical Knowledge?

Jeffrey David Pair
Middle Tennessee State University

A primary function of mathematics education is that students understand the subject matter of mathematics. That is, students are supported in understanding mathematical concepts and attaining mathematical knowledge. But there is another function of mathematics education, often unaddressed in research, which deserves more attention. In addition to learning content, students must be supported in developing informed views about the human processes by which mathematical knowledge is produced and the unique characteristics of that knowledge. Through an exploration of humanistic philosophy of mathematics, the purpose of this paper is to identify characteristics of the nature of mathematical knowledge that may be important for undergraduate mathematics majors to know and understand. Four characteristics are discussed: mathematical knowledge is subject to revision; mathematical knowledge is socially validated; proofs are bearers of mathematical knowledge; and informal mathematical work is the foundation of formal knowledge.

Key words: Nature of Mathematics, Nature of Mathematical Knowledge, Philosophy of Mathematics

Students and teachers often have a limited view of the nature of mathematics and may believe mathematics is a static body of knowledge consisting of arbitrary rules and procedures (Beswick, 2012; Erlwanger, 1974; Thompson, 1992). These naïve views may negatively affect the teaching (Thompson, 1992; White-Fredette, 2010) and learning (Erlwanger, 1974) of mathematics. In contrast to these naïve views, many mathematics education scholars view and describe mathematical knowledge as a dynamic human product (Boaler, 2016), and emphasize the human aspects of mathematical work such as creativity (Burton, 1999) and fallibility (Ernest, 1991). These modern views are influenced by cultural approaches to mathematics (Bishop, 1988), humanistic philosophy of mathematics (Ernest, 1991), or perhaps scholars' own experiences doing mathematical work (e.g. Hersh, 1997). The gap between uninformed views of mathematics (largely held by students and teachers) and the informed cultural-historic perspectives held by scholars needs to be addressed within mathematics education.

Lessons from Science Education

In science education, scholars have argued that students and teachers not only need to understand the facts of science, but also need to possess a general understanding of science as a discipline, and the nature of scientific knowledge (McComas, Almazroa & Clough, 1998). Proponents for teaching the nature of science (NOS) are concerned with providing students and teachers a general understanding of the scientific enterprise. As Hurd (1960) noted, "A student should learn something about the character of scientific knowledge, how it has been developed, and how it is used" (p. 34). Driver, Leach, Miller, and Scott (1996) noted "such understanding is necessary in order to appreciate science as a major element of contemporary culture" (p. 19). Research in science education indicates that understanding NOS assists students in learning science content (McComas, Almazroa & Clough, 1998, p. 517). Furthermore, students enjoy learning about NOS and lament when social/historical aspects of science are left out of instruction. McComas and colleagues (1998) wrote, “Incorporating the nature of science while teaching science content humanizes the sciences and conveys a great adventure rather than memorizing trivial outcomes of the process” (p. 519). Perhaps similar positive outcomes would be seen if mathematics students had the opportunity to learn about the nature of mathematical knowledge, but little work has been done in this area (Jankvist, 2015).

Beginning a Systematic Inquiry into the Nature of Mathematics

In science education, scholars have done significant work conceptualizing the construct of nature of science (NOS), and have conducted research to understand how NOS can be taught to students and teachers (Irzik & Nola, 2014). Research on the teaching and learning of nature of science is guided by frameworks or lists that explicitly outline an informed conception of NOS and goals for learning (Lederman & Lederman, 2014). Perhaps a first step in conducting a systematic inquiry into the teaching and learning of the nature of mathematics is to consider the characteristics of the nature of mathematics that students or teachers should understand, and compile them into a framework/list with the purpose of conducting further research into student and teacher understandings of those characteristics.

In this paper we draw from the literature on philosophy of mathematics to formulate an initial list of possible goals for undergraduate mathematics majors’ understandings of the nature of mathematics. Such an understanding will certainly be valuable for students who pursue graduate studies in mathematics or become secondary teachers. I agree with Fried (2014) that those who are “mathematically educated must feel at home with mathematics, appreciate its power, and know it as a part of one’s culture” (p. 30). The conceptions of mathematics that future teachers develop in the university will likely stay with them as they begin to teach, and will likely have an influence on their students’ understanding. If the nature of mathematics cannot be taught at the university, the home of disciplinary mathematics, then where can it be taught?

What is the Nature of Mathematics?

Note that the question “What is the nature of mathematics?” is a philosophical one. Ernest (1991) noted, “The philosophy of mathematics is the branch of philosophy whose task is to reflect on, and account for the nature of mathematics” (p. 3). Philosophers of mathematics primarily seek to understand and describe the discipline of mathematics and the nature of its corresponding knowledge (Kitcher, 1983). Although there are many philosophies of mathematics, humanistic philosophy of mathematics has had a profound influence within mathematics education (Lerman, 2000; Toumasis, 1997). Humanistic approaches are unique in that they take as foundational the notion that mathematical knowledge is a human product. As Hersh (1997) wrote, “To the humanist, mathematics is *ours*—our tool, our plaything” (p. 60). Humanistic philosophy of mathematics (Ernest, 1991; Hersh, 1997; Lakatos, 1976) informs the characteristics of the nature of pure mathematics that are discussed in this paper. When describing these characteristics, I will also contrast humanism with Platonism and formalism. These philosophies have typically served to proliferate the idea that mathematical knowledge is absolute and value-free (Dossey, 1992).

Steen (1988) called mathematics the science of patterns. She described three branches of the mathematical sciences: core (pure), applied, and statistical. There are also many other types of mathematics such as artisanal or commercial-administrative forms (Harouni, 2015).

Mathematical knowledge is certainly not limited to western academic knowledge (Bishop, 1988). Nevertheless, pure mathematical knowledge is particularly relevant to much of the research in undergraduate mathematics education (especially regarding the teaching and learning of proof). In this paper I will narrow our focus and consider what aspects of the nature of pure mathematical knowledge undergraduate mathematics majors should know and understand.

The Nature of Mathematical Inquiry versus the Mathematical Nature of Knowledge

In the domain of pure mathematics, I conceive of two aspects of the nature of mathematics (NOM) that may be fruitful to distinguish: the nature of mathematical inquiry (NOMI) and the nature of mathematical knowledge (NOMK). NOMI refers to the practices that mathematicians engage in when creating knowledge (e.g. conjecturing, proving, communicating, etc…) and the human experience of such activity (e.g. emotion). NOMK refers to the nature of the knowledge that mathematician's produce (e.g., is mathematical knowledge absolute or subject to revision?). It should be noted that this distinction is not always clear cut. For instance, would an understanding of conjecturing be categorized as NOMI or NOMK? One can make the case for NOMI—conjecturing is an important mathematical practice that plays a role in the creation of mathematical knowledge. On the other hand, established theorems were once conjectures. This would place conjectures in the category of NOMK. Although the distinctions between knowledge and practice are not always clear cut, it is important to make the distinction when possible as there has been confusion in science education when scholars have conflated the nature of scientific knowledge and scientific inquiry when discussing nature of science (Lederman & Lederman, 2014). Due to length constraints, the focus of this paper shall be the nature of mathematical knowledge (NOMK).

The Nature of Pure Mathematical Knowledge

Mathematical Knowledge is Subject to Revision

Humanistic philosophers work from the simple assumption that mathematics is a human activity and product (Hersh, 1997). As a human product, mathematical knowledge is necessarily imperfect, fallible, and subject to revision (Ernest, 1991). Imre Lakatos is typically credited with the fallibilist view of mathematical knowledge (Kitcher, 1983). Through the story told in *Proofs and Refutations,* Lakatos (1976) demonstrates the fallible, revisionary nature of mathematical knowledge—as counterexamples are found to what are believed to be solid proofs and theorems, mathematics grows and changes. Fallibilism stands in contrast to Platonism and formalism.

Platonism. According to Dossey (1992), "Plato took the position that the objects of mathematics had an existence of their own, beyond the mind, in the external world" (p. 40). Brown (2008), a modern Platonist, wrote "Mathematical objects are perfectly real and exist independently of us" (p. 12), and we gain access to these objects through "the mind's eye" (p. 14). If mathematical objects are conceived to have a transcendental existence, then mathematical truth exists independently of humans and awaits human discovery.

The Euclidean (Deductivist) paradigm. The Platonic perspective formed the foundation of the Euclidean paradigm that dominated mathematics for 2,500 years (Ernest, 1991). This view is that humans can arrive at certain mathematical knowledge by following the deductive process. A few self-evident truths called postulates are assumed along with some definitions of mathematical terms. Then, beginning from these postulates and definitions, one can proceed by logical deduction to arrive at other certain truths. But mathematicians eventually found they could create new bodies of useful mathematical knowledge, non-Euclidean geometries, by withholding Euclid's assumption about parallel lines (Ernest, 1991). Thus, what were considered postulates could no longer be considered obvious truths, as a different "truth" could be arrived at when one began with a different set of assumptions. According to Hersh (1997), "Geometry served from the time of Plato as proof that certainty is possible in human knowledge…. Loss of certainty in geometry threatened loss of all certainty" (p. 136). Mathematicians responded to this loss of certainty by attempting to ground the foundation of mathematics in logic, arithmetic or set theory, but these attempts led to contradictions (Hersh, 1997). Formalism, the attempt "to characterize mathematical ideas in terms of formal axiomatic systems" (Dossey, 1992, p. 41) emerged in response to these conundrums.

Formalism. Under the formalist paradigm, mathematics begins with a collection of formal axioms and definitions. From these axioms and definitions theorems are logically deduced. If we adopt *Axioms X, Y, Z* we arrive at one branch of mathematics; or we can adopt *Axioms W, X, Y* and arrive at a different branch. Under formalism, neither branch of mathematics is *truer* than the other. In describing today's formalist, Hersh (1997) wrote,

> For him, all mathematics, from arithmetic on up, is a game of logical deduction. He defines mathematics as the science of rigorous proof… All mathematicians can say is whether the theorem follows logically from the axioms. Mathematical theorems have no content; they're not *about* anything. On the other hand, they're absolutely free of doubt or error, because a rigorous proof has no gaps or loopholes. (p. 163)

Hersh (1997) claimed that the working mathematician is caught between Platonism and formalism. "[W]hen he is doing mathematics, he is convinced that he is dealing with an objective reality… But then, when challenged to give a philosophical account of this reality, he finds it easiest to pretend that he does not believe in it after all" (p. 11). Furthermore, "To abandon both, we must abandon absolute certainty, and develop a philosophy faithful to mathematical experience" (p. 43).

Both Platonism and formalism (or a melding of the two) perpetuate the absolutist view that mathematical knowledge "consists of certain and unchallengeable truths" (Ernest, 1991, p. 7). Humanists adopt the fallibilist view: mathematics is an imperfect human activity, and so mathematical knowledge is subject to revision. According to humanistic philosophers, we need not hold onto the idea that mathematical knowledge is absolutely certain, or that mathematics is restricted to axioms, definitions and proof. Hersh (1997) noted, "Mathematical knowledge isn't infallible. Like science, mathematics can advance by making mistakes, correcting and recorrecting them" (p.22). Lakatos's (1976) *Proofs and Refutations* highlighted the way mathematical knowledge can be revised over time as mathematicians find new counterexamples to established proofs (even proofs that were widely regarded as correct may be eventually be refuted). As Hersh (1997) noted, "*For two millennia, mathematicians and philosophers accepted reasoning that they later rejected*. Can we be sure that we, unlike our predecessors, are not overlooking big gaps? We can't. Our mathematics can't be certain" (p. 45).

Burton (1995) noted that if we consider mathematics to consist of a body of absolute truths then "the purpose of education is to convey [the truths] into the heads of learners" (p. 276). When mathematics is presented as "information which should not be questioned" (p. 276), some learners may perceive that mathematics is a subject that only a few people have the ability to understand. Thus an absolutist conception of the nature of mathematics, in addition to being philosophically indefensible (Ernest, 1991; Hersh, 1997), also disempowers learners who do not immediately perceive the "truth" of what the teacher is trying to convey in the classroom. Burton

(1995) advocated for a humanist/feminist view of mathematical knowledge in school, claiming that "Re-telling mathematics, both in terms of context and person-ness, would consequently demystify and therefore seem to offer opportunities for greater inclusivity" (p. 280).

Mathematical Knowledge is Socially Validated (NOMK)

Philosophers presenting a humanistic view of mathematics (e.g. Ernest, 1991; Hersh, 1997; Lakatos, 1976; Tymoczko, 1988) are frequently cited and have been influential in mathematics education (e.g. Ball, 1988; Boaler, 2016; Komatsu, 2016; Lampert, 1990; Larsen & Zandieh, 2008; Weber, Inglis, Mejia-Ramos, 2014). A key feature of humanistic philosophy is the notion that mathematical knowledge is socially validated. Ernest has described in detail the general process by which mathematical knowledge is socially validated in the discipline of mathematics. Ernest contended that mathematical knowledge is created through a subjective/objective cycle. Individuals subjectively create knowledge, and it is validated inter-subjectively by other mathematicians so that it becomes objective knowledge accepted by wider communities (perhaps through publication). This objective knowledge can then inspire more individual thought as it is subjectively reconstructed, and this may lead to further subjective creations, which may then in turn become objective taken-as-shared knowledge.

Hersh (1997), an academic mathematician, emphasized importance of proof in the social validation of knowledge. Hersh noted that for mathematicians, the primary purpose of proof is to convince other mathematicians that a claim is true (Hersh, 1993). But the truth of the statement is not within the proof itself, but in the refereeing. Hersh (1997) claimed, "What mathematicians at large sanction and accept *is* correct mathematics" (p. 50). Furthermore "There are different versions of proof or rigor, depending on time, place, and other things". (p. 22).

How might students come to understand the social function of proof and the socially validated nature of mathematical knowledge? Some authors have designed instructional activities so that students have authority to judge what is correct through classroom discussions, and to negotiate standards of rigor and proof (cf. Ko, Yee, Bleiler-Baxter, & Boyle, 2016). Perhaps students will understand that mathematics is socially validated if they have the opportunity to participate in an inquiry-oriented classroom in which the students (rather than the teacher) are responsible for justification and validation. Speaking on findings from an inquiry-oriented differential equations course, Rasmussen and Kwon (2007) noted, "social norms that empower students to be creators of mathematical ideas, along with the explanations and justifications that support these ideas, provide an opportunity for learners to develop desirable beliefs about the nature of mathematics" (p. 192). But are these students developing desirable beliefs about the nature of mathematics in general, or just what "constitutes mathematical activity in [their particular] classroom" (Yackel & Rasmussen, 2002, p. 324)? Research in science education has found that "doing science" in an inquiry setting is not sufficient for students to develop informed understandings of the nature of scientific knowledge (Bell, Blair, Crawford, & Lederman, 2003). The outcome may be different for mathematics instruction, but we need more research to investigate this question.

Proofs are Bearers of Mathematical Knowledge.

Central to humanistic philosophy of mathematics is the distinction between descriptive and prescriptive philosophy (Ernest, 1991). Philosophy of mathematics traditionally was driven by the notion of what mathematics *ought to be*. For a Platonist or formalist, mathematics is (or should be) the most certain and absolute of human knowledge; thus the purpose of philosophy of mathematics is to justify its absolute nature. For instance, even if most published mathematical proofs contain gaps in logic (Ernest, 1991; Hersh, 1997), proof *ought* (from a prescriptive perspective) to be a rigorous deductive argument from accepted premises to conclusion. Humanistic philosophers work from a descriptive perspective, basing their philosophy on what mathematicians actually do, rather than an ideal vision. Thus humanistic philosophy of mathematics is distinct from traditional philosophy because it incorporates sociological, anthropological, or historic studies of mathematics. Indeed the classroom discussions in Lakatos's (1976) *Proof and Refutations* paralleled an account of the historical events surrounding the development of proof of an Eulerian conjecture. Hersh (1997) wrote "A humanist sees mathematics as a social-cultural-historic activity. In that case it's clear that one can actually look, go to mathematical life and see how proof and intuition and certainty are seen or not seen there" (p. 48). The humanistic emphasis has relevance not only to philosophers, but also for mathematics education scholars who desire to understand the practices of mathematicians so that implications may be drawn to inform the teaching of mathematics.

In his interviews with professional mathematicians, Weber (2010) found that mathematicians read proofs in order to learn new methods and techniques that could be used in their own work, in essence, filling their mathematical toolbox with tools that can be valuable in their own work. For this reason, Hanna and Barbeau (2008) claimed that proofs are bearers of mathematical knowledge (Rav 1999). Hanna and Barbeau (2008) noted that like mathematicians, students can fill their mathematical toolbox as they work to comprehend unfamiliar proofs. Undergraduates can find value in reading classmate's proofs in order to get new ideas to aid in their own proof construction (Pair & Bleiler, 2015). Students should be aware that proofs are bearers of mathematical knowledge, and a key function of proof for mathematicians is the transmission of methods (Weber, 2010). Students may also benefit from learning about the other roles proof serves for the discipline of mathematics (de Villiers, 1990).

Informal Mathematical Work is the Foundation of Formal Knowledge.

An allegiance to formalism may result in the delegitimization and rejection of informal mathematics. For instance, Brown (1996) described a formalist mathematics instructor in a graduate course. This instructor explained that the only valuable objects in mathematics were the formalisms: axioms, definitions, and logically deduced theorems. During the writing of a proof at the board, he became temporarily stumped and resorted to draw a diagram. After using the diagram to obtain the insight needed to finish the proof, the teacher hurriedly erased his diagram and resumed the formalist presentation. Lakatos (1976) wrote, "This [deductivist] style starts with a painstakingly stated list of *axioms, lemmas* and/or *definitions.* The axioms and definitions frequently look artificial and mystifyingly complicated. One is never told how these complications arose" (p.142). Axioms are presented to students as having a divine status that is not to be questioned (Brown, 1996). Instead, students should have the opportunity to understand the concepts related to axioms and how mathematical axioms are formulated.

Hersh (1991) elaborated on the importance of informal mathematical work when he claimed that mathematics has a front and a back. The front is what is typically seen, in journals, and in textbooks (e.g. axioms, definitions, theorems, proofs). The front of mathematics is the polished, finished form of mathematics. But just as important and meaningful is the behind the scenes work, the creative emotional activity that serves as the basis for formal mathematical knowledge. Hersh noted that mathematics, being a human activity, is influenced by economic and social pressures. He explained that mathematics as an institution benefits from a presentation that hides the human struggle.

> The standard exposition purges mathematics of the personal, the controversial, the tentative, leaving little trace of humanity in the creator or the consumer. … If mathematics were presented in the style in which it's created, few would believe its universality, unity, certainty, or objectivity. These myths support the institution of mathematics. For mathematics is not only an art and a science, but also an institution, with budgets, administrations, rank, status, awards, and grants. (p. 38)

Students within a mathematics classroom, especially an undergraduate setting, should understand the nature of the informal work that ultimately leads to polished theorems. Lakatos (1976) claimed mathematics is a quasi-empirical discipline. De Villiers (2004) summarized the notion of quasi-empiricism: "[T]he objects in mathematics, though largely abstract and imaginary, can be subjected to empirical testing much as scientific theories are. Quasi-empiricism will, therefore, refer here to all non-deductive methods involving experimental, intuitive, inductive, or analogical reasoning". (p. 398). Lakatos (1976) showed how quasi-empirical methods (e.g. using a counterexample to refute a theorem statement), are implemented in practice and contribute to the development of mathematical knowledge. Mathematicians often use examples to look for patterns and make conjectures (de Villiers, 2004); it is this informal work that ultimately leads to the formal theorem. In interviews in which mathematicians were asked to determine if a proof was valid, Weber (2008) found that mathematicians used inductive examples to make sense of deductive inferences within a proof. Students should understand that mathematics is not only axioms, definitions and the following of deductive steps. Inductive methods also play a crucial role in creating (Lakatos, 1976) and validating (Weber, 2008) mathematical knowledge.

Summary and Implications

In this paper we have discussed four characteristics of the nature of mathematical knowledge: mathematical knowledge is subject to revision; mathematical knowledge is socially validated; proofs are bearers of mathematical knowledge; and informal mathematical work is the foundation of formal knowledge. Scholars in undergraduate mathematics education will find it valuable to consider whether these or other characteristics of the nature of mathematical knowledge may be worthy to serve as goals for student understanding. Research will be needed to identify and understand the instructional methods that can be used to support undergraduate mathematics majors in coming to know and understand these characteristics.

Making RUME for Institutional Change

Daniel L. Reinholz
San Diego State University

Overwhelming evidence favors the use of active learning in undergraduate STEM classrooms. Thus, the issue faced by educators is no longer what to do in classrooms, but how to enact what is known to be effective. This poses a challenge, because faculty teaching is embedded in the context of departments, universities, and the broader disciplinary culture. Thus, improving education requires knowledge of how systems work and how to enact systemic change. While organizational change has studied these issues for decades in nonprofit and business settings, the application of this knowledge to higher education is relatively new. Accordingly, this theoretical paper provides an introduction to the organizational change literature in the context of higher education and provides an example of its application through Departmental Action Teams (DATs). By highlighting five principles from organizational change, this paper serves as a reference for change agents wishing to improve undergraduate mathematics education.

Keywords: Institutional change; Faculty development; Culture; Active learning

There is now considerable evidence for the use of active learning techniques in STEM classrooms. Broadly speaking, active learning aligns with sociocultural and constructivist views, which posit that learning involves constructing meaning through engagement in social practices (Lave & Wenger, 1998; Smith, diSessa, & Roschelle, 1993). As such, active learning courses involve students as active participants in classroom sessions, through activities such as: groupwork, peer instruction, class discussions, and personal response systems. Active learning is generally contrasted with "pure lecture," in which students passively listen to lecture and take notes. While active learning courses often involve some lecture (or mini-lessons), the distinction is that lecture is one of many modes used for instruction, rather than the only one.

A recent meta-analysis of 225 studies demonstrates the benefits of active learning; pure lecture increases failure rates in STEM courses by 55% when compared to active learning (Freeman et al., 2014). This evidence is so strong that the authors of the study described teaching solely through passive lectures as akin to educational malpractice. Moreover, the use of active learning can help reduce existing disparities between students from dominant groups and those historically marginalized in STEM classrooms (President's Council of Advisors on Science and Technology, 2012). Finally, these benefits appear to extend beyond just the courses incorporating active learning, to support students to do better in future courses as well (Kogan & Laursen, 2014). Thus, STEM education research has identified improved instructional techniques (i.e. active learning), scientifically proven to be more beneficial for students than traditional methods. As such, RUME (Research in Undergraduate Mathematics) is confronted with a new challenge: how to foster the use of active learning in undergraduate mathematics classrooms.

Research shows that simply providing faculty with evidence of the value of active learning is insufficient (Foertsch, Millar, Squire, & Gunter, 1997; Reese, 2014). This has been studied extensively in physics, where despite the wealth of instructional advances and widespread awareness of them, they are not widely used (Dancy & Henderson, 2010; Henderson & Dancy, 2007; Lutzer, Rodi, Kirkman, & Maxwell, 2005). Even when new pedagogies are adopted, sustainability is a challenge (Henderson, Dancy, & Niewiadomska-Bugaj, 2012). As such, recent calls for educational improvement have begun to shift their focus from developing new learning techniques to understanding how to scale and sustain the use of existing techniques (PCAST, 2012). This theoretical paper focuses on exactly this issue: how to enact and sustain educational change. Ultimately, I argue that change efforts should draw on the vast literature of organizational change. I highlight five principles from this literature to support change agents in their own local efforts, and provide an example of their application through Departmental Action Teams (DATs).

Theoretical Framing

Educational improvement requires attention to the university as a holistic system (Corbo, Reinholz, Dancy, Deetz, & Finkelstein, 2016). A recent meta-analysis of 191 STEM education improvement efforts showed that 85.3% of efforts focused on only a small part of the system, and that they were "clearly not effective" (Henderson, Beach, & Finkelstein, 2011). As such, researchers must draw from organizational change, to better understand how to change *systems*. Indeed, if the RUME community seriously considers the seven recommendations of the recent study of college calculus programs (Bressoud, Mesa, & Rasmussen, 2015), the need for systemic change is clear. Thus, change agents must expand their work with individual faculty members to consider how their efforts are embedded in departments, universities, and disciplinary culture. While there are interactions between each of these levels, the academic department itself is often considered the key unit of change, due to its relative coherence as a unit (AACU, 2014).

Given its roots in educational psychology, most educational research is grounded in experimental science. The logic of experimental science is that variations in treatments and contexts can be accounted for statistically, to generalize results across settings. In contrast, organizational change is better understood as an improvement science (Bryk, Gomez, & Grunow, 2011). Given the complexity of organizations, improvement scientists argue that context is too important to be "averaged out" statistically; instead, one must develop a "system of profound knowledge" for how to enact change within a given context (Lewis, 2015). While some educational research aligns with this perspective, such as in action research (Zeichner & Noffke, 2001) and design-based research (Cobb, Confrey, Disessa, Lehrer, & Schauble, 2003), these approaches have not yet been widely adopted.

What follows is a brief description of principles extracted from a synthesis of improvement efforts in higher education (AACU, 2014; Elrod & Kezar, 2015; Henderson et al., 2011), intended to provide undergraduate mathematics educators with powerful ideas that they can use immediately to support their own educational improvement efforts. For a general overview of this literature, consider the book *How Colleges Change* (Kezar, 2013). While it is beyond the scope of this paper, improvement science offers tools for assessing the impact of systemic change efforts, such as: program improvement maps, driver diagrams, and Plan-Do-Study-Act (PDSA) cycles (Bryk et al., 2011). In what follows, I describe five ideas from organizational change and their application to RUME.

Five Good Ideas

These ideas draw the reader's attention to concepts that are often overlooked in educational improvement. The five ideas are: (A) building a shared vision, (B) supporting agency and ownership of a change, (C) promoting the use of evidence, (D) creating opportunities for early wins, and (E) designing for sustainability. As the authors of a recent effort for systemic change on university campuses note, “almost all of these process – organizational learning, addressing politics, creating a shared vision and unearthing cultural assumptions – were extremely hard for STEM leaders…These processes are often messy and non linear” (Elrod & Kezar, 2015, p. 7). In other words, while these principles are supported by the organizational change literature, they can be difficult to enact, and are not yet widely used.

Building a Shared Vision

Suppose a group of faculty aims to improve student interactions in their department. A common approach is to generate a list of barriers, such as: large class sizes, an overstuffed curriculum, lack of department funds, and many students commuting to campus. Having identified these problems, the group identifies possible solutions (e.g., classroom response systems, curricular change) and debates their relative merits. Yet, this “problems focus” tends to result in a fixation on specific problems and preferred solutions to them. For instance, one group member may fixate on large lecture courses, and the use of classroom response systems as a “solution.” Most individuals have such preferred solutions, and this often leads to inflexibility.

Rather than operating in “problem-solving mode,” discussions are more effective when they focus on positive outcomes to be achieved (Cooperrider, Whitney, & Stavros, 2008). Suppose the same group of faculty works to generate a shared vision for student interactions in the department. They decide upon the goal: students will feel like a part of a community with their peers and work together productively to succeed as mathematicians. This opens the conversation to many other possibilities, including: improving department culture, running community events, and creating space for student collaborations outside of class. Such an approach builds flexibility, helps reduce conflict, and thus increases collaboration. An “outcomes focus” changes the nature of the conversation, allowing group members to see possibilities (e.g., creating a welcoming departmental culture) where before they saw only obstacles.

Agency

Change is not something that can be “done to others.” Yet, very often, educators have a new curriculum or teaching techniques that they would like others to adopt. In other words, the change agents would like to change others. However, as the research on dissemination approaches highlights (Henderson et al., 2011), this is generally not effective. Instead, a change agent should work with others, to help them achieve their goals. This process often begins with developing a shared vision for what the participants want to achieve, affording participants agency in the process. Agency relates to the ability of individuals to influence their circumstances (Bandura, 2006). When individuals have agency over a change effort, they are more invested in the work, as they develop ownership over their change effort. Because of this investment, the individuals are more likely to expend more effort, rather than giving up, when obstacles are inevitably encountered.

Evidence

Psychological research shows that individuals use shortcuts to make decisions (Kahneman, 2011). According to the availability heuristic, individuals usually rely on the most accessible or salient examples to make decisions, regardless of how representative of the larger population they are. Consider a faculty member trying to explain why a student is doing poorly in their class. The faculty member may notice a student has skipped a few class sessions, and infer that the student is lazy or unmotivated. In general, it is easier to center the locus of control within the student, than to consider systemic factors, such as departmental culture or the student's life circumstances (e.g., working a full-time job to pay for college).

The above explanations are ascriptions of motive, intended to describe the underlying causes of the student's behavior. These ascriptions can be placed on a spectrum from person- to system-focused (Blum & McHugh, 1971; Simpson & Vuchinich, 2000). Person-focused explanations (e.g., laziness) tend to be readily available, so faculty members are more likely to adopt them "by default." Yet, person-focused explanations are also outside of the faculty member's control, so adopting these explanations means that the faculty member has little agency to change the situation. In contrast, systemic factors (e.g., departmental culture) can be changed, so focusing on them increases faculty agency.

When conversations focus on "anecdata," they tend to revolve around person-focused explanations. Thus, to shift conversations towards systemic factors, change agents can use evidence that highlights the systemic nature of issues. In accordance with building a shared vision and promoting agency, change agents should help faculty gather data to answer their questions, rather than presenting data to argue for a preformed agenda.

Early Wins

Change is a time-consuming. For instance, work in teacher professional development shows that effective interventions are longterm and must be holistic (Darling-Hammond, Wei, Andree, Richardson, & Orphanos, 2009; Wilson & Berne, 1999). Similarly, work at the department or campus level can be expected to take many years (Elrod & Kezar, 2015). Yet, when change work takes years to come to fruition, it is easy for participants to disengage or processes to become stalled. Thus, it is key to build in "early wins" to the process (Kotter, 1996).

The idea of early wins is simple; to begin a change process, a group identifies a vision for what it would like to achieve. Again consider the group that aims to build greater community for its students. While changing the community and the culture of the department is a many-year project, there are also many waypoints or markers of change that would provide evidence of improvement. For example, the group could: survey students about their experiences (collecting data), run community events, run faculty professional-development for inclusive teaching, or seek external funding. By conducting these activities, the group creates concrete "successes" towards the larger goal of building community. This is important internally, for the motivation of the group, and externally, with respect to department and campus politics.

While there may often be early wins on the way to a larger goal, from the perspective of a change agent, they can be strategically built into the change process. For instance, creating early wins is built into the cyclical nature of PDSA cycles in improvement science (Bryk et al., 2011). PDSA cycles are iterative improvement cycles that focus on implementing and analyzing ideas quickly, to enact efforts in a way that is sensitive to the local context. Thus, once a shared vision has been developed, PDSA cycles are one way to identify short-term goals that can be achieved in service of the larger goal, to ensure that the process does not stall.

Sustainability

Change agents often talk about "solving" educational problems, or having courses that are "transformed." This language implies that educational improvement is something that can be "done" and then it will be sustained. Yet, it is difficult to sustain even largely successful change efforts when external funding is removed (cf. Chasteen et al., 2015). Thus, efforts should focus on continuous learning and sustainability from the offset (Senge, 2006).

One key aspect of sustainability is focusing on culture. Culture is a "pattern of shared basic assumptions learned by a group…which has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think, and feel" (Schein, 2010, p. 19). As such, a department's culture consists of these beliefs, values, customs, rituals, practices, artifacts, and institutional structures. These various components of culture interact with one another to provide a relatively coherent system. Thus, if one attempts to change only a single component of the cultural system, without addressing other components, it is unlikely that the change will be sustained over time.

As described above, dissemination efforts often do not result in sustained use of new teaching techniques (Henderson et al., 2012). Because these efforts focus only on practices, a single component of culture, there are numerous forces acting in opposition to the use of the new teaching techniques. For example, traditional beliefs about teaching and learning will influence *how* the practices are used, which may limit their efficacy. Or, reward structures may be such that the time required to learn to use the new techniques is not perceived as worthwhile.

Departmental Action Teams

Departmental Action Teams (DATs) were developed as one component of the STEM Institutional Transformation Action Research (SITAR) Project, which fostered and studied systemic change in STEM departments at one research-extensive university (Corbo et al., 2016). A DAT consists of 4-8 participants (primarily faculty) working collaboratively to improve education in a single department. DATs are externally facilitated; facilitators bring expertise in educational research, help coordinate logistics, and draw on principles from organizational change (i.e. the key ideas identified above). In what follows, the process of facilitating a DAT is described in more detail to provide change agents with concrete examples of how to implement organizational change principles in their own educational improvement efforts.

A DAT begins with members developing a shared vision around an issue of common interest in their department (key idea A). Participants have agency to choose an issue that is meaningful to them (key idea B); the role of the facilitators is to help the DAT work on the issue in the most productive way possible, not to tell participants what issue to work on. As the DAT works to achieve its vision, it gathers and analyzes relevant data (key idea C): so it can make informed decisions about potential actions, and so it can build political will from external stakeholders (e.g., a department chair). Along the way, the facilitators and DAT members think strategically about how to build early wins into the process (key idea D) so that progress does not stall. Finally, the types of issues a DAT addresses are crosscutting, and building sustainable structures is a goal from the offset (key idea E).

DATs in SITAR met regularly, typically for an hour every other week for multiple semesters. Between meetings, DAT members assign their own "homework," determining what needs to be done to continue moving the group forward. DAT members may also schedule additional meetings as necessary. Thus, while DATs are externally facilitated, they are departmentally-driven. To date, the DAT model has been used to facilitate 6 working groups through the SITAR project. In what follows, I provide examples of the five key ideas in action. Data are drawn from from four STEM departments: Alchemy, Potions, Prophecy, and Runes (actual department names redacted for confidentiality).

Shared Vision

Once the group has been established, a DAT begins by building a common vision for its work. To help participants build a common vision, the facilitators use a “sticky note” activity (adapted from http://serc.carleton.edu/departments/degree_programs/idealstudent.html). Each DAT member is given a pad of large sticky notes, and asked to write individually their responses to the following prompt:

> Imagine you are writing a letter of recommendation for a student graduating from your department. Ideally, what would you like to be able to say in response to the following questions: (1) what kind of person will they be? (2) what will they be able to do? (3) what will they know? (4) what skills will they have? (5) how will they behave? (6) what will they value?

After writing their responses, the DAT members stick their responses on the wall, the group organizes them looking for common themes, and then they have a whole group discussion about vision. These prompts are designed to help faculty focus on students (not just themselves), and to seek areas of overlap in what all participants value. These prompts appear to work effectively even with DAT participants that have very different views on education.

Agency

While the external facilitators help shape discussions, they do not tell DAT participants what to do. As described above, it is DAT members who determine the vision and direction of the group, not the facilitators. Moreover, the participants determine homework, whether or not to schedule additional meetings, and many other key features of how the work gets done. As a result, DAT members perceive the change effort as theirs. For example, as a participant in the Runes DAT described:

> I really think they did a fabulous job of letting all of us kind of speak our piece and keeping it harmonious and letting us kind of find our own way. I think- Like I said, I think, I'm hoping that everybody's as excited about this as I am, because I think we've struck on something that'll really work for our department.

While this is a quote from just one member of one DAT, it is generally consistent with the perceptions of other DAT members that they “owned” their efforts.

Evidence

Gathering evidence to support decisions was a common thread across DATs. In the Runes and Prophecy DATs, both focused on curricular integration, participants gathered and analyzed institutional data about the course taking patterns and success of their students. In the Potions and Alchemy DATs, both focused on diversity and inclusion in their departments, a wealth of data about the retention, success, and experiences of students from diverse groups were collected and analyzed. These data were used to determine plausible actions for the DATs, and on multiple occasions were used in presentations at faculty meetings or to departmental committees to gather support for the actions of the DATs.

Early Wins

The Potions DAT spent the majority of its first year analyzing data related to diversity in the major, which resulted in a detailed report to the department. Yet, beyond curating data, the DAT also engaged in a number of actions, such as: targeted recruiting of admitted students, building collaborations with other diversity organizations on campus, and leading the department's response to a campus diversity initiative. All of these actions supported the DAT to be seen as a positive force in the department, and ultimately supported it to be institutionalized in the form of a standing committee. Similarly, the Alchemy DAT has begun to focus on concrete actions in parallel to collecting and analyzing data.

Sustainability

Both the Runes and Potions DATs (the only multi-year DATs, to date) have successfully created new departmental structures to sustain their efforts. In Runes, new curriculum coordinator positions have been created (and funded by the department) to revisit curricular integration issues on an ongoing basis. In Potions, the DAT has been formalized as a standing committee. Moreover, the facilitation practices used by the external facilitators have been adopted, and the Potions DAT is continuing to use them in its ongoing work.

Summary

STEM education has identified research-based approaches for improving classroom learning. Yet, actually enacting these approaches remains a challenge. Fortunately, there is a wealth of organizational learning theory, traditionally applied to businesses and nonprofits, that can be adapted to support higher educational change. Accordingly, this paper has two primary aims: (1) broaden the focus of RUME to emphasize systemic change perspectives, and (2) provide practical tools that RUME practitioners can use to increase the impact of their work.

A systemic change perspective provides a new lens for RUME practitioners engaged in improvement efforts. For example, it highlights the systemic nature of educational improvement, operating at multiple levels: students, classrooms, departments, universities, disciplines, and society. As such, improving education requires thinking about these multiple levels. It also highlights the political nature of change, such as the need to develop processes that will effectively engage a variety of stakeholders. Finally, this perspective highlights the need for sustainability. When sustainability is built into a process from the offset, rather than considered as an afterthought, it is much more likely for continuous improvement to result.

This paper provides a number of practical tools that the RUME community can draw upon. For instance, simply organizing improvements around outcomes rather than problems, can result in much more productive conversations. Similarly, building in early wins can help make progress visible, rather than resulting in improvement efforts stalling. By affording participants with agency and the ability to make decisions around evidence, rather than anecdote, it is more likely that innovations in education will be used and sustained. In sum, organizational change provides useful theoretical background to promote systemic change. As researchers adopt this perspective, theory of organizational learning can be adapted and contextualized to RUME.

Although many policy documents include equity as part of mathematics education standards and principles, researchers continue to explore means by which equity might be supported. Teaching practices that include active learning have been proposed to address this issue (e.g., CBMS, 2016; NCTM, 2014). In this paper, we theoretically explore the ways in which active learning teaching practices that focus on teaching for inquiry (e.g., Inquiry-Based Learning (IBL) or Inquiry-Oriented Learning (IOL)) support equity in the classroom. Specifically, we claim that some characteristics of inquiry (Student Ownership, Knowledge Building, Peer-Involvement, Doing Mathematics, Student-Instructor Relationship, and Student Success) put forth by Cook, Murphy, and Fukawa-Connelly (2016) may align with the Four Dimensions of Equity (Access, Achievement, Identity, and Power) proposed by Gutiérrez (2009). Therefore, inquiry teaching may be a first step for a focus on equity without compromising the excellence (Gutiérrez, 2002) or material that is often prescribed in undergraduate mathematics courses.

Key words: Active Learning, Equity, Inquiry-based Learning, Inquiry-oriented Learning

Many policy documents and institutions both highlight the importance of equity and caution educators with possible consequences of not attending these issues in research and teaching. Most recently in their *Statement on Active Learning* (2016), the Conference Board of the Mathematical Sciences stated, "Pervasive problems caused by issues of equity and access, starting long before students begin post-secondary study, prevent or discourage many students from continuing in their study of mathematics and other STEM disciplines" (p. 3). More strikingly, Nasir, Shah, Gutiérrez, Seashore, Louie, and Baldinger (2011) reported that three decades after the release of *A Nation at Risk* (1983), which "cautioned that America's economic future depended on the mathematical and scientific literacy of all of its citizens" (p. 1), there are still "substantial disparities both in resources and in achievement" that are "organized along troublingly clear lines of race, ethnicity, and socioeconomic status" (p. 1).

Although many policy documents include equity as part of standards or principles of mathematics education, ways in which this goal can be achieved are not explicit. For example, at the K-12 level, the *Principles for School Mathematics* provided by the NCTM have included *Equity* since the early 1990's. The American Mathematical Association of Two-Year Colleges (2006) states, "All students should have equitable access to high-quality, challenging, effective mathematics instruction and support services" (p.10). Yet, as Gutiérrez (2007) indicates, "[m]ost members of the mathematics education research community would agree that equity is a valued goal, maybe even the reason behind their research. However, much less consensus arises when the question is raised: how do you think we should address equity?" (p. 2).

Teaching practices that include active learning have been proposed to address this issue (e.g., CBMS, 2016; NCTM, 2014). We explore the ways in which active learning teaching practices, with a focus on teaching for inquiry (e.g., Inquiry-Based Learning (IBL) or Inquiry-Oriented Learning (IOL)), can provide a pathway to equity in the classroom without compromising the excellence (Gutiérrez, 2002) or material that is often prescribed in undergraduate mathematics courses. We claim that characteristics of inquiry align with the Four Dimensions of Equity proposed by Gutiérrez (2009). That is, we claim these four dimensions explicate how inquiry pedagogy promotes equity in mathematics courses. This particular framing helps us to identify how the inquiry instruction can promote a more equitable experience for all students within the context of the curriculum that is usually required in undergraduate mathematics courses.

Equity

In general, equity teaching promotes a mindset where all students are capable of learning mathematics (Bullock, 2012; Gutiérrez, 2002; Jett, 2012). Equity research seeks to surface teaching practices that enable these mindsets (Gutiérrez, 2002) among instructors and students alike (Oppland-Cordell & Martin, 2015). It is important that instructors bracket prejudices about student participation and achievement levels based on race, gender, social class, proficiency in the dominant language, or ethnicity (Gutiérrez, 2002). Similarly, judgments based on a student's prior performance, particularly if s/he has performed poorly in the past should not be seen as personal weakness, rather as a consequence of the complex social, economic, and cultural factors (Frankenstein, 1983) that affect individual experiences while learning mathematics.

Gutiérrez (2009) argued that teaching for equity includes four dimensions: *Access*, *Achievement*, *Identity* and *Power*. *Access* and *Identity* are considered precursors to *Achievement* and *Power*, respectively. *Access* addresses the resources that students have available to them to participate in mathematics such as "quality of teachers, adequate technology and supplies, classroom environment that invites participation, infrastructure for learning outside the classroom" (p.5), and the opportunities to draw upon their "cultural and linguistic resources" (p. 5). *Achievement*, on the other hand, is an outcome affected by students' opportunities to learn and can be measured by "participation in class, course taking patterns, standardized test scores, majoring in math, having a math-based career" (p. 5). Adiredja, Alexander and Andrews-Larson (2015) summarized this description by offering that learning outcomes can range from the "knowledge on specific content to students' ability to productively use mathematics to participate in society" (p. 64).

On a different axis, *Identity* attends to the "balance between self and the global society and ways students are racialized, gendered and classed" (Gutiérrez, 2009, p. 5) and to pay "attention to whose perspectives and practices are 'socially valorized'" (p. 5). The goal is to "strike a balance between opportunities to reflect on oneself and others as part of the mathematics learning experience" (p.5). *Power* can mean to empower students towards high academic achievement, but Gutiérrez explained it as students using their math knowledge to reach "personal goals of excellence such as helping their community to solve a local problem" (p. 6). Adiredja et al. (2015) added that learning focused on this dimension attends to "disrupting the existing power distribution and dynamics in a society based on race, gender, and social class" (p. 64). To achieve this, students can be involved in decision-making on "what counts as productive mathematical knowledge" (Adiredja et al., 2015, p. 64), pacing of content (Laursen, Hassi, Kogan, and Hunter, 2011), and starting points for curriculum (Frankenstein, 1983). This type of learning requires a social transformation as measured by whose voice can be heard in the classroom and "opportunities to use math as an analytics tool to critique society" (Gutiérrez, 2009, p. 6).

Gutiérrez (2009) situated these four dimensions more broadly, namely, “in society” or in a “community” (p. 6). In discussion of power, Gutiérrez (2002) positioned the distribution of power in the contexts of the classroom, future schooling, everyday life, and the global society. In this paper, we use the classroom as a stepping-stone to discuss alignment of inquiry pedagogies to dimensions of equity. As such, we utilize these four dimensions of equity as a framework to discuss how active learning pedagogies, and inquiry learning in particular, have the potential to increase access, lead to higher achievement, provide opportunities for students to reflect on their identities, and attune students to power dynamics in their mathematical community: the classroom. We acknowledge that just using inquiry learning alone may not fully address equity, especially if there is not a change to the system outside the classroom or if students do not have opportunities to question power distribution and dynamics in the greater society. The purpose of our theoretical exploration is simply to investigate inquiry learning as an entry point towards a more equitable classroom, in order to move towards a more equitable society.

Active Learning

While this paper reports on teaching through inquiry, we see this pedagogy as a subset of a collection of pedagogies termed *active learning*. Although many different definitions exist, Prince (2004) noted “active learning is generally defined as any instructional method that engages students in the learning process” (p. 223). However, pedagogical techniques used in active learning vary between instructors and may include group work, think-pair-share, student presentations, project-based learning, and many other teaching techniques. Freeman, Eddy, McDonough, Smith, Okoroafor, Jordt, and Wenderoth, (2014) reported that active learning techniques have a strong positive impact on student learning as a result of the meta-analysis of 225 studies in STEM education. In addition, Kogan and Laursen’s (2014) study indicates that “the benefits of active learning experiences may be lasting and significant for some student groups, with no harm done to others. Importantly, ‘covering’ less material in inquiry-based sections had no negative effect on students’ later performance in the major” (p. 197). There is even strong evidence that active learning promotes student engagement and achievement when coupled with lecture; lecture is defined as “continuous expositions of a speaker” (Bligh, 2000, p. 4) where student activity is “limited to taking notes and/or asking occasional and unprompted questions of the instructor” (Freeman, 2014, p. 5). Prince (2004) found that incorporating several short active learning segments into lecture on a topic in an engineering course improved students’ retention of the material and exam scores on that topic.

Overview of Inquiry Learning

Some major goals of inquiry learning are to “deeply engage [students] in rich mathematical tasks, [give students] ample opportunities to collaborate with peers (where collaboration is defined broadly)” (Academy of Inquiry-Based Learning, n.d.), “enable students to learn new mathematics through engagement in genuine argumentation, … empower learners to see themselves as capable of reinventing mathematics, and to see mathematics itself as a human activity” (Rasmussen and Kwon, 2007, p. 190). Despite the numerous studies on inquiry-based or inquiry-oriented learning, there is not a consistent definition of these pedagogies. However, one defining feature of inquiry learning seems to be the modified role of the instructor in the classroom, which Cook et al. (2016) label the *Student-Instructor Relationship*. Thus, in an inquiry course, part of the job of the instructor is to ask about student thinking (Kuster, Johnson, Keene, & Andrews-Larson, submitted). Laursen, Hassi, Kogan, and Weston (2014) found that students in IBL courses often reported being able to express their own ideas while the instructor listens. Another facet of inquiry is student participation in authentic mathematical experiences, which Cook et al. (2016) refer to as *Doing Mathematics*. Kuster et al. (submitted) argue that "questions that require students to engage in problem solving activity affords the instructor opportunities to inquire into student thinking and reasoning" (p. 8). Thus, doing mathematics contributes to the student-instructor relationship.

Cook et al. (2016) also describe *Student Ownership* as the action of encouraging learners to create, generate, and developing their own knowledge. This knowledge is built from their prior knowledge, which is labeled *Knowledge Building*. Kuster et al. (submitted) also see this as a fundamental part of IOL and they refer to it as "building on student contributions". As part of knowledge creation, students are given opportunities to provide explanations and justifications of their thinking while others listen to and attempt to understand the ideas being discussed or presented, termed *Peer Involvement* by Cook et al. (2016). In Laursen et al. (2014), students in IBL courses reported often participating in activities such as asking questions, evaluating other students' work, and working together in class. Kuster et al. (submitted) also identified students' "being engaged in one another's thinking" as a characteristic of IOL.

According to Cook et al.'s (2016) exploration of existing studies, an outcome of their aforementioned features of inquiry is that inquiry-based or inquiry-oriented learning is better aligned to how people learn. Similarly, in a study that gathered data from over 100 sections of IBL and non-IBL courses taught between 2008 and 2012, Laursen et al. (2014) reported higher "cognitive gains in understanding and thinking, affective gains in confidence, persistence, and positive attitudes about mathematics, collaborative gains in working with others, seeking help and appreciating different perspectives" (p. 409) in students from IBL courses compared to those in non-IBL sections of the same courses. Notably, Laursen et al. (2014) also found that in IBL courses, both men and women's attitudes about mathematics improved as well as their interest in pursuing mathematics, but the women had greater gains in these areas than men. Cook et al. (2016) categorized this as *Student Success*.

In surveying authors of the papers that they reviewed, Cook et al. (2016) identified three foci in participants' definitions of inquiry. The first focus is on the student-instructor relationship and how it is different from a lecture-based course, which is an extension to the aforementioned *Student-Instructor Relationship* theme. Participants stated that the students should not look to the instructor as the sole mathematical authority in the classroom. The second focus is similar to the theme *Peer-Involvement*; that is, the class should include opportunities for peers to interact. The last focus is different from the aforementioned themes as it highlights the importance of valuing and nurturing curiosity in the students. This last focus (valuing and nurturing curiosity) and the first five themes (*Student-Instructor Relationship, Doing Math ,Student Ownership, Knowledge Building*, and *Peer Involvement*) can be classified as Classroom Climate, whereas the last theme (*Student Success*) is related to an outcome of the classroom climate.

The themes that we consider in this paper are not an exclusive list of IBL/IOL teaching practices; they are still under development and undergoing revisions. Hence, our theoretical exploration is only a preliminary start of a framework that aims to explore the alignments between IBL/IOL features with the Four Dimensions of Equity by Gutiérrez (2009).

Alignment of IBL/IOL with the Four Dimensions of Equity

With this proposed framework, we put forth the claim that, as a pedagogical practice, inquiry learning can be used to promote equity by providing students access and chances to explore their identities, with the hopes of both a shift in both power and achievement in the course. Our exploration originated from several reports, particularly Laursen et al.'s (2014) assertion that

"IBL benefits all students even as it levels the playing field for women" (p. 415). Their study documented ways in which IBL can increase achievement and attitudes among students. To explicate how described features of IBL/IOL provide a more equitable experience for students studying mathematics, within the Four Dimensions of Equity we describe some selected related features of IBL/IOL.

Access

Gutiérrez's (2009) definition of equity included a "classroom environment that invites participation" (p. 5) as a tangible resource to access. Civil (2006) reinforced this definition and stated: "equity to me is related to access by **all** students to opportunities to engage in rich mathematics" (p. 56). IBL/IOL pedagogies revolve around a classroom environment that invites and encourages all students' participation in doing, discussing, and presenting mathematics (*Peer Involvement*). When all students are given opportunities to be active participants in the mathematical community of the classroom (*Doing Math*), students are given an additional access point to learn because they are given the chance to provide explanations and justifications of their thinking processes while others listen and attempt to understand the ideas being discussed or presented. We believe that these opportunities give all students the chance to be exposed to other ways of thinking which can result in richer learning experience for them.

Nasir et al., (2011) provided characteristics of classroom practices that support equity: "Powerful classroom practices include those that foster student-centered discourse, student exploration of mathematical ideas, and on-going feedback (Davis, et. al., 2007; Boaler, 2002b; Fullilove & Treisman, 1990" (Nasir et al., 2011, p. 17). Inherent in the on-going feedback is the *Student-Teacher Relationship*: the instructor's responsibility of inquiring into student thinking and "fostering and facilitating productive student discourse" (Nasir et al., 2011, p. 17).

Achievement

Gutiérrez (2009) refers to Achievement as a measure of "how well students can play the game called mathematics" (pg. 6). In other words, this dimension relates not only to student performance on exams and standardized tests, but also considers a student's mathematical "story." This can refer to measures such as whether students continue taking mathematics courses or whether they choose a mathematical career.

When all students are encouraged to create, generate, and develop their own knowledge (*Student Ownership*), confidence in doing mathematics and participation in class may be positively affected. Laursen et al. (2014) demonstrated that participation in IBL courses does increase student performance as well as other measures related to this definition of achievement. Learning gains were found in IBL sections over non-IBL sections of the same course; not only improvements in course performance, but gains in confidence, persistence, and enjoyment of mathematics (*Student Success)*. Some of these outcomes may lead to Gutiérrez's (2009) measures of Achievement, namely "course taking patterns, majoring in math, and having a math-based career" (p. 5). Kogan and Laursen (2014) also reported that all students in IBL courses were positively impacted to enroll in more mathematics courses.

Identity

We claim that the *Peer Involvement* theme of IBL/IOL aligns with Gutiérrez's (2009) definition of Identity. When students are actively engaged with each other and each other's thinking (*Peer-Involvement*), it can lead to a shift in mathematical identity. Hassi's (2015) qualitative study of students reflecting on their IBL learning experiences supports our claim. In that study, students talked about “the role of the social environment in an IBL class for gaining or verifying their self-esteem or self-confidence” (p. 60). In addition, Oppland-Cordell & Martin (2015) write that “the ways in which individuals continuously construct identities of participation and non-participation over time in [Communities of Practice] is related to how they position themselves, how others position them, and how such positionings are related to their histories and experiences in the broader contexts in which [Communities of Practice] are embedded” (p. 24). At the secondary level, Boaler and Greeno (2000) contrasted students who learned by working through rote problems in a textbook with students who learned through mathematical discussions (*Peer Involvement*). They found that in discussion-based classes, students were required to contribute more aspects of their selves (as compared to non-discussion-based), which can be done through reflecting on community participation and family relationships.

Power

Gutiérrez (2009) thinks of student voice as a fundamental part of the power dimension; inquiry is changing whose voice is primarily present in the classroom. Instructors are responsible for facilitating student discussion and presentation of the problems (Yoshinobu and Jones, 2012; Cirrillo, 2013). When given opportunities to provide explanations and justifications of their thinking while others listen to and attempt to understand the ideas being discussed or presented (*Peer Involvement*), power shifts to the students because they decide on “what counts as acceptable knowledge” (Adiredja et al., 2015, p. 66).

The instructor is the primary architect of the problems worked on (Laursen et al., 2011), and when the tasks assigned include problem-posing, students create and solve their own problems (*Doing Math*). In this scenario, students have power in deciding the curriculum.

The instructor’s main role is not as a problem-solver, but as an expert participant (Levenson, 2013) that guides students to generate, create, and develop their own knowledge (*Student Ownership*). In this way, the instructor signals that the students’ thoughts, beliefs and contributions are a valued part of the learning process and removes her/himself as the sole source of knowledge in the classroom. If we agree that *Doing Math, Peer Involvement*, and *Student Ownership* are components of inquiry teaching, then this represents a substantial shift of the power dynamic from instructor to students.

Future Steps

“Equitable classrooms are reflections of a pedagogical, political, and moral vision.”
(Lotan, 2006, p. 526)

We acknowledge that changing the curriculum to include ways for students to use mathematics to critically analyze the society in which they are gendered, raced, and classed extends past our theoretical framework to provide a richer equitable experience. However, for instructors who are not ready to (fully) change the curriculum of their class, we claim that by merely engaging in practices of IBL/IOL, we can start to move towards teaching for equity and thinking equitably. That is, engaging in practices of IBL/IOL is a good entry point for people who are ready to begin embracing equitable practices.

We also see room to frame IBL/IOL in terms of culturally responsive pedagogy. Hernandez (2013) reviewed literature by seminal culturally responsive pedagogy researchers (Banks, Gay, Ladson-Billings, Nieto, Villegas and Lucas) and found five main themes within the research. To demonstrate how the inquiry themes posited by Cook et al. (2016) or the dimensions of equity theorized by Gutiérrez (2009) may align with the five themes of culturally responsive pedagogy, we have added the inquiry themes in brackets to the definitions below:

- Content Integration: inclusion of content from many cultures, the fostering of positive teacher-student relationships, holding high expectations for all students, and the use of research-based instructional strategies [*Student Success*] that reflect the needs of a diversity of backgrounds and learning styles [*Knowledge Building*]
- Facilitation of Knowledge Construction: the teacher's ability to build on what the students know [*Knowledge Building*] as they assist them in learning to be critical, independent thinkers who are open to other ways of knowing
- Prejudice Reduction: teacher's ability to use a contextual factors approach [*Student-Teacher Relationship*] to build a positive, safe classroom environment [*Access*] in which all students are free to learn regardless of their race/ethnicity, social class, or language
- Social Justice: teacher's willingness ''to act as agents of change'' (Villegas), while encouraging their students to question and/or challenge the status quo in order to aid them in ''the development of sociopolitical or critical consciousness'' (Ladson-Billings) [*Power*]
- Academic: teacher's ability to ''create opportunities in the classroom'' (Villegas) [*Access*] that aid all students in developing as learners to achieve academic success [*Student Success, Achievement*] (p. 811-814) [emphasis added].

In preliminary efforts to give empirical evidence of our framework, we found some data that did not fit into the themes presented by Cook et al. (2016) describing IBL/IOL. For example, "limited involvement by instructor" or "instructor acts as facilitator/mediator" didn't seem to fit in the *Student-Instructor Relationship* category, which puts the instructor as an inquirer into student thinking or not as the sole authority. Additionally, the theme of *Doing Mathematics* seemed to intersect with the other themes so often that we may need to create a hierarchy of themes. Thus, we plan to continue refining the themes of inquiry, and the subsequent connections to equity, from student data we have collected and as other research emerges.

The theoretical framework we put forth in aligning inquiry pedagogies to equity teaching is merely a start to providing equitable experiences for all our students regardless of race, gender, ethnicity, social class, sexual orientation, or language. To deepen equity in the field of mathematics, educators can integrate content that uses mathematics to critically analyze the ways in which students are gendered, classed and raced. For example, to address the contentious "All Lives Matter" movement, students in a proofs or logic class can analyze the statement, "If you are black, then your life matters" to help people understand that saying "Black Lives Matter" does not mean that other lives do not matter. In the future, we aim to deepen our alignments of inquiry teaching and learning with equity through interviewing students who have experienced inquiry pedagogies. We also hope to explore pedagogical techniques to better integrate content that allows students to use mathematics to critically analyze social justice issues. Both future goals are considered with the intent to extend our theoretical framework beyond the classroom and towards the global society.

Leveraging Real Analysis to Foster Pedagogical Practices

Nicholas Wasserman
Teachers College, Columbia University

Keith Weber
Rutgers University

William McGuffey
Teachers College, Columbia University

Although it is frequently a required course, many secondary teachers view real analysis as unnecessary and unrelated to teaching secondary mathematics. In accord with a proposed model for improving the teaching of advanced mathematics courses for teachers, we implemented a course that framed real analysis content by 'building up from' and 'stepping down to' teaching practice. In this paper, we describe how this model was implemented in a single module and analyze secondary mathematics teachers' engagement in and reflections on the desired pedagogical aims, which provide evidence that they saw what they learned in the real analysis module as being useful for informing their pedagogical practice.

Key words: Real Analysis, Secondary Teaching, Teacher Education, Pedagogical Practice

In the United States, prospective secondary mathematics teachers usually are required to take a substantial number of courses in advanced mathematics, including real analysis. However, while mathematical organizations believe that a mastery of advanced mathematics is important for teaching secondary mathematics (e.g., CBMS, 2012), research has also shown that completing courses beyond a fifth course in university studies – which is where advanced mathematics courses fall – yields very minimal gains in a secondary mathematics teachers' efficacy (Monk, 1994). Indeed, many students do not perceive any relevance between advanced mathematics and the teaching of high school mathematics (e.g., Zazkis & Leikin, 2010). In this paper, we address the following broad question: Given that prospective teachers are required to complete courses in advanced mathematics, how can we design these courses so that they productively inform teachers' future pedagogy? We look specifically at one module in a real analysis course designed according to this aim, and consider how the prospective and practicing teachers (PPTs) engaged in and reflected on a particular pedagogical practice.

Literature and Theoretical Perspective

A Model for Teaching Secondary Teachers Advanced Mathematics

From our point of view, the belief that completing a course in real analysis will improve a PPT's ability to teach secondary mathematics has been based on a traditional view of transfer from the cognitive psychology literature (e.g., Perkins & Salomon, 2002). More specifically, there is an assumption that as a byproduct of learning advanced mathematical content, PPTs will better understand secondary mathematics content and will consequently respond differently to instructional situations in the future – a tenuously presumed "trickle down" effect (Figure 1a). Given the notorious difficulties in achieving this type of transfer, it is not surprising that PPT's experience in real analysis often does not improve their teaching. In Figure 1b, we propose an alternative instructional model (Wasserman et al., 2016). This model is based on two premises. The first is the knowledge that PPTs learn should be inherently practice-based and applicable to the actual activity of teaching (e.g., Ball, Thames, & Phelps, 2008). The second is that PPTs will be more likely to make connections between real analysis and pedagogical practice if what they learn is situated within the context of teaching (e.g., Ticknor, 2012). Our model is composed of two parts: building up from practice and stepping down to practice. To *build up from (teaching) practice,* the real analysis content is preceded by a practical school-teaching situation. The building-up portion provides a context that sets the stage for the study of real analysis content in ways that are both relevant to teachers' practices and particularly well-suited to being learned in real analysis. The second part, *stepping down to (teaching) practice*, then uses the mathematical ideas from real analysis as a means to reconsider the pedagogical situation that began the module, as well as other relevant pedagogical situations. Stepping down to practice explicitly clarifies the intended mathematical and pedagogical aims. In between building up from and stepping down to practice, the real analysis topics are covered in ways true to its advanced character with formal and rigorous treatment, but the tasks make explicit what connections and implications these have for both secondary mathematics and its teaching.

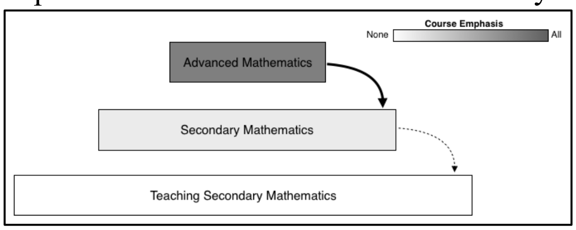

Figure 1a. Implicit model for advanced mathematics courses designed for teachers

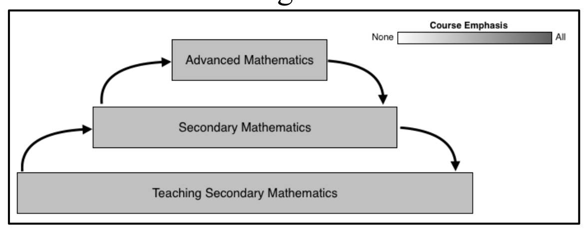

Figure 1b. Our model for advanced mathematics courses designed for teachers

An Example of our Model: Considering Derivative Proofs as "Attending to Scope"

In their professional work, teachers must explain content, practices, and strategies (e.g., TeachingWorks, 2016); we regard a particularly important facet of providing an explanation as being attentive to the scope of that explanation. For example, in trying to help elementary students understand subtraction, some teachers may state: "you cannot subtract a larger number from a smaller one." This explanation has a limited scope—it is only accurate when one is considering positive numbers – and can hinder students' future mathematical learning (e.g., Ball & Bass, 2000). Real analysis, with its rigorous proofs and its attention to the number sets to which a statement applies (e.g., the Intermediate Value Theorem requires the completeness axiom and consequently applies to **R** but not **Q**), is a domain in which attention to scope can be learned. In a real analysis course, students are expected to study and produce rigorous proofs of the common differentiation rules, such as the power rule and the product rule. (See, for instance, the textbooks of Abbott, 2015, and Fitzpatrick, 2006.) In the module that we describe, we use these real analysis proofs to highlight the importance of attending to the scope of a statement, and leverage them to help foster developing this desirable pedagogical practice.

Building up from practice. We began the module by presenting PPTs with the following situation: "Mr. Ryan teaches everything from Pre-Algebra to Calculus. The following scenes are snapshots from his classes at different times during the year." Using cartoons (which are not included for space purposes), two of Mr. Ryan's statements throughout the year were depicted: the *Exponents statement,* "Exponents are just repeated multiplication," and the *Power rule statement,* "If you see a function with an exponent, to take the derivative, you bring down the exponent to the front and subtract one from the exponent" [on the board was written $f(x)=2x^3$]. From this cartoon, PPTs were first asked to "Evaluate the pedagogical quality of each one of these explanations." We note that these two statements are *limited in scope*: exponents can only be viewed as repeated multiplication if the exponent is a positive integer, and the power rule only works for power functions. Next, students were shown a typical proof of the power rule for differentiation, using the binomial expansion of $(x+h)^n$. They were asked to identify for which sets the proof would be valid (**N, Z**, **Q,** or **R**), with the point being that this proof, which was likely familiar and is often presented to calculus students, is only valid for natural numbers.

Real analysis. The real analysis portion of the course consisted of the presentation of proofs of the power rule, the product rule, the quotient rule, the chain rule, and the inverse function rule. A progression of proofs of the power rule (for $f(x)=x^n$, $f'(x)=nx^{n-1}$) was presented that differed depending on the scope (i.e., for *natural*-numbered exponents, for (non-zero) *integer*-numbered exponents, etc.), and the proofs of the product rule, quotient rule, chain rule, and inverse function rule were provided so that they could be used for the power rule proofs.

Stepping down to practice. After the real analysis was presented, PPTs were invited to revisit the classroom scenario presented earlier. They were also asked on their homework to evaluate the pedagogical quality of two other explanations that were limited in scope, which we called the *Perimeter statement* ("The perimeter is just the sum of all the side lengths") and the *Add zero statement* ("Remember, to multiply a number by ten, just add a 0 to the end."). Finally, PPTs were asked write a journal entry in which they reflected on: "What, if anything, did you find helpful for your teaching in this week's class? If there were helpful aspects, specify in what ways they might influence your teaching – if nothing was helpful, explain why."

Methodology

Research Context, Participants, and Data Collection

We designed an experimental real analysis course in which each session was designed using the model presented in Figure 1b and described above. We implemented this course with 32 PPTs, 31 of whom agreed to participate in our research study. In this paper we focus on the Attention to Scope module, which took place across two 100-minute sessions. We collected and analyzed three sources of data: (i) we audio- or video-recorded all students collaboratively working on the module's activities; (ii) we collected their homework responses to the *Perimeter statement* and the *Add zero statement*; and (iii) we collected their reflective journal assignments for what they learned from these modules.

Analysis

We coded each source of data in the following way. For (i), to analyze PPT's in-class activity, we had recordings from five tables (T1, T2, T3, T4, T5), each containing about six students. When the groups were analyzing Mr. Ryan's exponent and power rule explanations, we used an open coding scheme in the style of Strauss and Corbin (1990) to capture the aspects of the classroom scenario to which the PPTs attended. When asked to cite the limitations of the proof of the power rule using the binomial expansion, we recorded each group's answers and the justification for their answers. For (ii), when coding the homework responses, we determine if the PPTs mentioned a limitation in scope for the statement and whether this limitation in scope was mathematically accurate. For (iii), we used an open coding scheme to document the category of responses that were present in PPT's reflective journal entries.

Results

We organize the presentation of results from our analysis in terms of their support for three particular claims: Claim 1) When evaluating the pedagogical quality of a teacher's statement, PPTs increased the attention they gave to the mathematical scope and limitations of a statement; Claim 2) PPTs valued the idea of attending to the scope and language of an explanation for their teaching; and Claim 3) Our model contributed to the goals of the module, particularly via the use pedagogical discussions to motivate the real analysis and vice versa.

To document Claim 1, we argue that PPTs showed limited attention the scope of Mr. Ryan's explanations at the start of the module, but that PPTs showed increased attention to scope on their homework assignment. When considering Mr. Ryan's explanations at the start of the module, we note that all tables were engaged with the task, and all evaluated the pedagogical quality of the exponents statement and the power rule statement negatively and gave reasons for their justification. At each table, a number of pedagogical concerns were raised. These included, for example, concerns about what students might understand 'repeated multiplication' to mean (e.g., "2x3x5x7" (T1)), and whether 'bringing down the exponent to the front' might be unclear (e.g., "It could be 23, not 6" (T3)). However, for some tables, this was the extent of their evaluations – focusing on the '*explanation* of the mathematics' and not the '*mathematical* aspects of the explanation.' Indeed, specifically in consideration of scope, only two tables (T3 and T4) attended to the limitations of scope for both statements, one table (T5) considered the limitation of scope with the exponents statement but not the power rule statement, and the other two tables (T1 and T2) did not attend to scope at all. That is, only 2 of 5 tables were consistent in their attending to the limited scope of both explanations. In contrast, however, on the homework assignment, both for the Perimeter and the Add Zero statements, all 31 PPTs correctly noted the limited scope of these statements. In addition, the quality of their attention to mathematical scope in the HW responses also increased. Even for the two tables that did so initially (T3 and T4), the exploration of the mathematical limitations of the statements was relatively narrow – they did not attempt to exhaust the possible scenarios. Each table only identified *one* instance where the power rule statement was limited (i.e., $\sin^2(x)$) – neither table discussed, for example, the derivative of e^x. In the HW exercises, however, the quality of the PPTs exploration of mathematical limitations was richer and more exhaustive. Both within individual responses as well as collectively across all PPTs, there was greater variety of limitations referenced (i.e., straight/curved, closed/open, exterior/interior lines, single/composite figures, 2D/3D) – indeed some of their discussions went beyond what was initially anticipated. We regard both the increased number of PPTs as well as the improved quality of responses as supporting Claim 1.

We document Claim 2 based on PPT's written reflections on what they learned from this module. In general, a common theme from PPT's written reflections was that they specifically valued the desirable pedagogical idea of attending to the scope and language of an explanation for their teaching – primarily addressing the mathematical precision of their language with students. Of the 27 PPTs who submitted reflections, 25 identified this idea as both: i) specifically stemming from the real analysis module; and ii) valuable for their teaching. We see both of these aspects in the following response that is representative of their reflections: "This lesson made me realize that as a teacher I must pay close attention to what I am saying. When I make statements that have errors, I need to know what loopholes or misconceptions held in my statement and be conscious of these as I create examples and answer questions" (S1). Here, it is worth reminding the reader that the PPTs were not obliged to say that they learned anything useful from the real analysis class (an option that some PPTs chose when reflecting on other modules). Within their statements, a few subthemes about implementation considerations arose: 1) scaffold definitions, beginning simple but getting increasingly rigorous (6 responses); 2) make sure explanations were not just procedural (5 responses); and 3) take into account the teaching context when considering the rigor and accessibility of explanations used (7 responses). In summary, we take this as evidence that PPTs saw pedagogical value in this module.

Lastly, we consider Claim 3 about the contribution of the model toward these aims. Notably, the data supporting this claim is anecdotal; however, we regard reflection on the model as important, and the responses from some students as suggestive about its contribution. First, we explore the possible value that the pedagogical situation may have added to the real analysis. Within PPTs' evaluation of Mr. Ryan's statements initially, pedagogical quality hinged somewhat on the mathematical scope and limitations. Thus, when transitioning to the real analysis proofs, PPTs appear to have given additional gravitas to considering mathematical limitations because of the related professional value, and their sense of the proofs may have been similarly tied to these limitations. As one instance, upon realization that the first power rule proof was limited to **N**, one student concluded: "This proof takes anything that I've ever believed in... Like here's a proof. Not anymore! Like this is the proof that I've always taught. And now, I'm like, everything about this is wrong" (T3). That is, the negative pedagogical evaluations appear to have prompted further mathematical motivation. Second, we explore the potential value that the real analysis may have added to accomplishing the desired pedagogical aims. Notably, the sequence of real analysis content explicitly modeled this attention to scope. And although one might do this without real analysis, at least some PPTs made this link and reflected on the value: "Seeing the connection between the analysis content and two very different concepts taught in high school was particularly useful.... the progression we took in the proofs from each set of numbers was a very elegant way of showing the different methods of proof, showing the flaws within each…" (S6). We see these – and other – comments as supporting the idea that the interaction between pedagogical discussion and real analysis was mutually beneficial to developing both.

Discussion and Conclusion

The analysis and reporting in this paper of one module from an experimental real analysis course – a single case study – sought to explore the broad issue of how advanced mathematics courses can be designed to inform PPTs pedagogical practice. In particular, the data from the study support the claim that, after engaging in the 'Attending to Scope' module from the real analysis course, the PPTs both increased their attention to (Claim 1) and valued (Claim 2) the desirable pedagogical practice of attending to the mathematical scope and limitations in teachers' explanations. By design, the real analysis content was both tightly connected to and framed by this pedagogical practice; however, as was evident from some of the tables of PPTs (i.e., T3, T4), one does not have to learn real analysis to be able to attend to the scope and limitations of secondary mathematics explanations. However, since a real analysis course already sort of inherently models this idea in both the precision of statements and progression of proofs, it seems sensible to exploit this connection for teachers. Indeed, the teachers in this study, overall, increased their attention to and valued this pedagogical practice. The anecdotal evidence for Claim 3 also seems to support at least one of the ways in which the model may have facilitated these goals. Thus, we see this as evidence that by framing real analysis content with pedagogical situations, in addition to learning real analysis, PPTs can also learn important teaching ideas. Further work studying how best to mathematically prepare secondary teachers is needed, including the degree to which this particular model is productive and/or needs refinement, and could help guide improved design and implementation of advanced mathematics courses for secondary teachers.

Characterizing Mathematical Digital Literacy: A Preliminary Investigation

Todd Abel
Appalachian State University

Jeremy Brazas, Darryl Chamberlain Jr., Aubrey Kemp
Georgia State University

This preliminary report offers initial results from a study designed to begin identifying characteristics of digital literacy in mathematics. Undergraduate students in a three-course honors calculus sequence were provided with tablet computers as part of a digital literacy initiative and digital tasks were integrated into the courses. Student work was analyzed and coded for type of ICT tool use and possible components of mathematical digital literacy. The specific types of tasks developed for and integrated into the class will be discussed below with specific illustrative examples highlighted. The aspects of mathematical digital literacy illuminated by student work will be outlined, with some initial conclusions and conjectures about the nature of digital literacy in mathematics.

Keywords: Digital Literacy, Technology, Calculus, Preliminary Report

Introduction and Background

The ever-increasing role of technology in everyday life and work prompts questions about the skills and understandings needed for effective use of that technology. The range of information and communication technology (ICT) tools grows ever greater, and the ability to obtain, manage, synthesize, analyze, and communicate information is constantly changing and adapting. As technological capabilities rapidly change, the accompanying skills and understandings necessarily shift in response. Competence and knowledge with technological tools is described by and named with a variety of terms, the most prevalent of which is *digital literacy*, a term first defined by Gilster (1997) as "the ability to understand and use information in multiple formats from a wide range of sources when it is presented via computers" (p. 1). It is now frequently used as an umbrella term with a variety of implications, though there is general agreement that digital literacy involves interaction and integration of a number of proficiencies, such as procedural competence with ICT tools, cognitive skills for using them effectively, and social and communication skills (Avriam & Eshet-Alkalai, 2006; Goodfellow, 2011). The use of the word "digital" is itself far from universal, with some sources variously referring to media literacy, digital and media literacy, ICT literacy, or related specialized terms. This paper will use the term "digital literacy" to encompass the wide variety of terms used in order to draw on the valuable contributions of multiple approaches.

Educational Testing Service (2003) characterized seven proficiencies that characterize general digital literacy: Define, Access, Manage, Integrate, Evaluate, Create, and Communicate. Specific applications of the term might include or alter those proficiencies within the context of a particular subject. In education, digital literacy has been increasingly emphasized in general (Gutierrez & Tyner, 2012) and in mathematics specifically (NCTM, 2000, National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010), and has been shown to have a positive impact on student learning (Li & Ma, 2010). ICT tools are also increasingly integrated into the work of research mathematics (Monroe, 2014).

Despite the increased emphasis on and integration of ICT tools within mathematics, *mathematical digital literacy* is not well-defined. The competencies with ICT tools specific to mathematics would be of particular concern to educators, curriculum developers, and many other stakeholders within the field. This presentation describes an investigation into digital literacy among undergraduate students in an honors calculus sequence. By assessing how students engaged with digital tools that were often new and unfamiliar in order to solve mathematical problems and understand mathematical concepts, preliminary characteristics of mathematical digital literacy emerge.

Context and Methodology

Setting and Data Collection

Undergraduates in a three-course honors calculus sequence were provided with tablet computers as part of a digital literacy initiative at their university. These courses (Honors Calculus I - 22 students; Honors Calculus II - 22 students; Honors Calculus III - 18 students) covered the traditional material of the calculus sequences in a "late transcendentals" ordering. In the past, the mathematics program had not emphasized the use of digital tools, so integrating them into the work of the course provided an opportunity to observe emergent digital literacy in mathematics and investigate an initial characterization. The primary digital tools introduced to the students by the instructor were Wolfram Mathematica and the online Desmos graphing calculator.

An initial assignment allowed students to use any tools they might choose and consisted of problems for which digital ICT might be useful, but which focused on concepts already familiar to students. For example, finding the zeros of a sixth degree polynomial or determining the domain of a ratio of logarithmic functions. This served as an initial assessment of how students chose to use such tools. Throughout the semester, two types of digital tasks were used to assess student interaction with and use of ICT tools - digital assignments and digital exams. These were supplementary to the traditional written course content.

Digital assignments were primarily meant to provide students with base-line experience using digital tools to solve mathematical problems and were typically assigned as handouts or pdf files related to the content that had recently been discussed in lecture. A set of instructions led students through the use of Mathematica or Desmos (depending on the content) to visualize and solve a set of problems. Often the instructions would require students to choose parameters to create their own individualized problems. For problems that required more advanced coding, students would be provided with a template file to edit. During in-class digital assignments, the instructor would typically provide demonstrations and move around the classroom to help students with syntax and interpretation. Students submitted their work digitally as either a Mathematica Notebook file or a link to a Desmos graph. Though an indirect consequence of using these ICT tools may have been an increase in student understanding of content, the primary focus of digital assignments was on gaining literacy with digital tools and accessing new problems and information via their use.

Digital exams were completed in the class period following a written exam. The problems on the digital exam often required students to create digitally generated images/animations and to make computations that could not be completed by hand in a reasonable amount of time. The exams were "open resource" - students were allowed to use any digital resource at their disposal except for online help forums, including those not discussed by the instructor. This permitted analysis of the ways in which they chose to use digital tools. The TPACK framework (Mishra & Koehler, 2006) and Howland, Jonassen, and Marra's (2012) five dimensions of learning involving ICT tools served as general guides for designing the integration of digital tools into assignments and exams in each course.

Student work was collected for each digital assignment and digital exam. On the initial assignment and digital exams, students were asked to identify what digital tools they used. At the end of the course, a survey about their attitudes toward and use of digital tools gave additional information. The first digital assignment and the digital exams permitted students the most freedom in selecting and utilizing digital tools and were therefore the first to be analyzed for characteristics of digital literacy. Open coding (Strauss & Corbin, 1990) was used to develop coding schemes that described student use of and interaction with the digital tools.

Examples of Digital Tasks

An example of a digital assignment. Early in the Calculus I course, students were required to complete a digital "Desmos" assignment asking them to explore limits involving trigonometric functions. The first portion of the assignment asked students to consider the limit $\lim_{x\to 0}\frac{sin(ax)}{bx}$ using the function as graphed in an existing Desmos file. Students used the Desmos "sliders" to evaluate the limit for various values of *a* and *b*. Eventually, students choose their own unique values to verify the pattern. The assignment included a similar exploration for 3 other common trigonometric limits: $\lim_{x\to 0}\frac{ax}{sin(bx)}$, $\lim_{x\to 0} ax\, cot(x)$, and $\lim_{x\to 0}\frac{1-cos(ax)}{bx}$.

Apart from the digital assignment, students were provided with a rigorous proof of the first computation. As with many digital assignments, this one provided exploration, experience, and visualizations that would later support formal computations, theorems, and proofs. During the assignment, the instructor reminded students that the use of Desmos itself as a tool was only the secondary purpose of the assignment. The primary purpose of this assignment was to encourage students to begin using technology when presented with an apparently intractable problem.

An example of a digital exam. Figure 1 shows a Calculus II Digital Exam problem on Taylor series that is impractical to solve by hand. To illustrate the ways in which students used digital tools to solve problems and communicate their solutions, samples of student work on this problem are included in Figure 2 below and discussed later.

3. (5 pts) $g(x) = \int \sin(x^2)\,dx$ is not an elementary function but still has a convergent Taylor series. Assume $g(0) = 0$. Find the 15th Taylor polynomial centered at $x = 0$ of this funciton. Use this polynomial to approximate $g(3/2)$ (even though we don't have a formula for g to "plug in").

Figure 1: A Calculus II Digital Exam Problem

The nature of the problems in both types of tasks was varied in order to expose students to different ways ICT tools might be useful and to highlight the various ways students chose to use them.

Preliminary Results

The full analysis of student work provided rich data on use of ICT tools. Below, a very brief overview of the initial results is given. One specific example is used to illustrate how the digital tasks highlighted the variety of uses of digital tools and how the data led to this preliminary characterization of mathematical digital literacy.

Notable Results from Surveys

Thirty-five students responded to the post-course survey. When asked to rate their comfort level with digital tools at the beginning and end of the semester on a scale of 1 (not comfortable at all) to 10 (very comfortable), every student reported the same or greater levels of confidence. The mean change in self-reported comfort level was 1.6 with a median change of 1. All students reported using some technology outside of the digital assignments and course requirements.

When students were asked to describe how they used digital tools in the class, the most common response was for visualization. In particular, students noted the value of Desmos for graphing equations and of Mathematica for graphing three-dimensional solids. They also valued the ability to quickly perform calculations and to check answers, though many noted that learning the syntax for Mathematica was difficult, at least initially.

An Example of Results From Student Work

Analysis of student work on the digital tasks illustrated the different ways in which students engaged with digital tools. For one instance, two examples of student work on the problem from Figure 1 are shown in Figure 2:

Student 1 submission of #3	Student 2 submission of #3

In[1]:= `(* Problem 3 *)`
`p15[x_] = Integrate[Normal[Series[Sin[x^2], {x, 0, 15}]], x]`
`N[p15[3/2]]`
Out[1]= $\frac{x^3}{3} - \frac{x^7}{42} + \frac{x^{11}}{1320} - \frac{x^{15}}{75\,600}$
Out[2]= 0.777928
	`(*3*)`
	`Clear[f, a];`

Figure 2: Samples of student work on Calculus II Digital Exam problem #3

Both students chose Mathematica for this particular problem. This is not surprising given the nature of the problem and the tools with which most students were comfortable. However, their processes differ. Student 1 submitted a concise and correct solution. Student 2 also submitted a correct solution but copied previously used code provided by the instructor to find the 8th Taylor polynomial. Note that Student 2 did not bother to change p8 to p15 even though the problem is to find the 15th Taylor polynomial. A comparison suggests that Student 1's solution exhibited greater digital literacy since they were comfortable enough with the content and syntax to simplify their code whereas Student 2 attempted to mimic a previous application of digital tools.

Toward an Understanding of Mathematical Digital Literacy

Students tended to use digital tools in the following major ways:

1. *Determine which tool should be used to solve a given problem*.
2. *Learn and apply syntax of technological tool (sometimes based on template)*.
3. *Decide how to translate mathematics into input in chosen tool*.
4. *Interpret technological results to find a proposed solution.*
5. *Use technology to justify that a proposed solution is correct*.
6. *Display and submit answer and supporting work digitally.*

Though there was much variation in the particular ways students engaged in these activities with ICT tools, they fell into these six main categories of use. Such a categorization permits some initial conjectures about components of mathematical digital literacy:

Component 1: Ability to assess and choose tools based on potential use along multiple proficiencies

Component 2: Translation between digital and mathematical contexts, including multiple representations (notational, graphical, syntactical) and digital and mathematical troubleshooting

Component 3: Using ICT tools to enhance or complement (rather than replace) mathematical understanding

Component 4: Using ICT tools to communicate mathematics

These components are related to the seven proficiencies with ICT tools described by ETS (2003), but are specific to mathematics. A more nuanced and detailed analysis is underway and will be described in greater detail in the proposed presentation.

Conclusion

Work remains to be done to fully characterize digital literacy for mathematics. However, this preliminary study supports the idea that a focus on learning and doing mathematics within digital environments increases student facility and comfort with ICT tools. The ways students utilized digital tools provides some initial indications of important components of digital literacy.

The Proposed Presentation

The proposed preliminary report would include the information summarized in this proposal in addition to more specific examples of student work and more careful and nuanced descriptions of components of digital literacy. As a preliminary report, the authors hope to use this as an opportunity for feedback from experienced and engaged mathematics educators to shape future research and analysis on this subject. In addition to welcoming critical assessment and feedback of this preliminary research, the authors propose the following questions to be considered by the audience:

1. How do we, as a research community, move toward a fuller understanding and description of what digital literacy means in mathematics? What research designs might be useful or beneficial?
2. How does such an understanding remain responsive to changes in availability and capability of digital tools?

3. How might we begin to understand the relationship between mathematical digital literacy, mathematical conceptual understanding, and proficiency with mathematical practices?

Blended Processing: Mathematics in Chemical Kinetics

Kinsey Bain, Purdue University
Adam Zabih, Purdue University
Alena Moon, University of Michigan
Marcy H. Towns, Purdue University

This work investigates the following research question: How do non-major students understand and use mathematics to solve chemical kinetics problems involving integrated rate laws? Personal constructs, a blend of personal and social constructivism, serves as the theoretical framework for this study. Semi-structured interviews with 36 general chemistry students, 5 upper-level physical chemistry students, and 3 chemical engineering students were conducted using a think-aloud protocol. Audio and written data were collected using a Livescribe pen. The audio data were transcribed, and screenshots of students' written data were inserted into the transcripts; these transcripts were refashioned into problem-solving maps. Open coding of the problem-solving maps reveals initial themes regarding students' understanding and use of mathematics when solving chemical kinetics problems. Blended processing was used as a methodological framework to guide the coding process. Through this analysis, distinctive types of blended processing have emerged.

Key words: Rates, Problem Solving, Blended Processing, Chemistry, Kinetics

Understanding fundamental chemistry concepts is intrinsically tied to understanding mathematical symbolism and operations, as well as the ability to translate between equations and physical reality. This nature has led researchers, such as Becker and Towns (2012), to investigate students' understanding and use of mathematics in scientific contexts. These lines of inquiry are providing insight to researchers and practitioners on how to best enhance students' abilities to interpret and use mathematical expressions with conceptual reasoning.

Multiple studies have shown that students need a rich conceptual understanding of algebra and calculus in order to succeed in the physical chemistry classroom (Derrick and Derrick, 2002; Hahn and Polik 2004; Nicoll and Francisco, 2001). Thompson and colleagues showed that students struggled when writing mathematical expressions to describe a physical process (Bucy, Thompson, and Mountcastle, 2007; Thompson, Bucy, & Mountcastle, 2006). Conversely, students also demonstrated difficulty interpreting physical meaning from mathematical equations. In another study, students seemed to hold an isolated understanding of topics in physics and mathematics (Pollock, Thompson, and Mountcastle, 2007). This was studied further by Wemyss, Bajracharya, and Thompson (2011) who showed that when students are given analogous questions in the context of mathematics and physics, they perform better on the former. This finding is in line with other studies on students' understanding of mathematics in the context of science (Bassok & Holyoak, 1989; Beichner, 1994; Black & Wittmann, 2007; Christensen & Thompson, 2012; Cui, Rebello, & Bennett, 2005, 2007; Cui, Rebello, Fletcher, & Bennett, 2006; Orton, 1983a, 1983b; Shaffer & McDermott, 2005; Zandieh, 2000).

Problem solving is also a key component in the learning and practicing of chemistry (Bodner & Herron, 2002; Summerfield, Overton, & Belt, 2003). As Maloney (2011) found, there are many problem-solving strategies or steps required to solve quantitative problems. In quantitative problem solving, there is often an initial qualitative analysis to understand what the problem is asking (Reif, 1983). This conceptual reasoning step is not only important and beneficial to students, but also demonstrates problem-solving expertise (Hull, Kuo, Gupta, & Elby, 2013; Kuo, Hull, Gupta, & Elby, 2013; Reif, 1983). Such research has led to the development of problem-solving strategies to help students mirror expert-like behaviors (Heller, Keith, & Anderson, 1992; Huffmann, 1997; Reif, 2008; Van Heuvelen, 1991). However, examining how students use and understand the equations when problem solving in science contexts has rarely been studied.

Chemical kinetics was chosen as a rich context to study quantitative problem solving among chemistry students because of its highly quantitative nature. Furthermore, this work contributes to two key gaps in the literature. In their recent review, Bain and Towns (2016) revealed that research in the area of chemical kinetics at the undergraduate level are rare, unlike other chemistry content areas. Additionally, the National Research Council reported that research on upper-level students and courses were scarce in discipline-based education research (DBER) (Singer, Nielsen, & Schweingruber, 2012). This study targets these literature gaps by investigating how both introductory- and upper-level students use and understand mathematics in the context of chemical kinetics problems. Therefore, the following question serves as the guiding research question for this work: How do non-major students in a second-semester general chemistry course, a physical chemistry course, and a chemical engineering course understand and use mathematics to solve chemical kinetics problems involving integrated rate laws?

Theoretical Underpinnings

The theoretical framework that guides this study is Kelly's (1955) theory of personal constructs. This theory is a combination of personal and social constructivism that posits that while individual's knowledge constructions may differ, they can be similar to one another because of social interaction. The theory of personal constructs provides an appropriate theoretical lens to investigate how individuals understand and use mathematics to solve kinetics problems in that each participant has their own individually constructed understanding of the content.

Blended processing serves as the methodological framework for this study. This framework builds on the basic tenant of constructivism, knowledge as being constructed in the mind of the learner, by describing how an individual's different knowledge constructions interact, or "blend" (Bodner, 1986; Bodner, Klobuchar, & Gleelan, 2001). Blended processing is a framework stemming from the field of cognitive science that explores human information integration (Coulson & Oakley, 2000). It provides a way to describe and understand individuals' mental spaces (knowledge constructions) and their interactions (Bing & Redish, 2007; Hu & Rebello, 2013). When multiple mental spaces are activated by external stimulus, knowledge elements from each space interact and are organized in a "blended space", allowing an individual to make sense of cognitive input in an emergent fashion (Bing & Redish, 2007; Coulson & Oakley, 2000; Fauconnier & Turner, 1996, 1998, 2002; Hu & Rebello, 2013).

Methods

The methods outlined below were chosen as they are consistent with the theoretical underpinnings guiding this work and allow for the investigation of student problem solving in chemical kinetics.

Data Collection

Semi-structured individual interviews were selected as the primary mode of data collection. A stratified purposeful sampling technique was employed, providing a participant sample of second-semester general chemistry students and upper-level physical chemistry students (Patton, 2002). The upper-level students were sampled from two courses: a physical chemistry for biological and life science majors course and a chemical reactions engineering course. Non-major science, technology, engineering, and mathematics (STEM) students served as the target study sample because they are a larger population both at the introductory- and upper-level. Additionally, because the ability to integrate different knowledge domains when solving a problem demonstrates expert-like reasoning, this exploratory study aimed to explore how students in interdisciplinary fields (like engineering) solve problems.

A pilot study comprising of four second-semester general chemistry students was conducted initially to test the viability of the interview protocol (Table 1). Audio and written data were collected via a Livescribe pen. The pilot interviews were conducted by a team of two graduate-student researchers in order to develop a shared understanding of the interview environment, prompts, and probing style. After preliminary analysis and discussion by the research team, the full study interviews were conducted independently by one the two graduate-student researchers. This data collection occurred over two semesters, yielding 36 introductory-level and 8 upper-level interviews (Table 1).

Table 1

Interviews by population and semester

Study population	**Number of students interviewed**	
	Fall 2015	**Spring 2016**
Pilot study (second-semester general chemistry)	4	-
Second-semester general chemistry (non-chemistry STEM majors)	17	19
Physical chemistry for biological and life science majors	-	5
Chemical reaction engineering (chemical engineering majors)	-	3

The interview protocol consists of four prompts. Two prompts provide the participants with an integrated rate law equation and ask them to describe it. The other two prompts are chemical kinetics questions that are reminiscent of homework- or exam-style questions. These prompts provide students with data and information about a chemical reaction scenario, asking them to reason about a relevant chemical kinetics quantity.

Data Analysis

The data were transcribed verbatim. Participants' written work were inserted into each transcript where appropriate. In order to make the data more manageable for analysis, problem-solving (PS) maps were generated for each interview. Discrete problem-solving steps in student responses were identified. These steps and the corresponding transcript and written data were organized into tables chronologically. Table 2 includes an excerpt from one of the pilot study PS maps.

Table 2

Excerpt from Trip's PS map (he was prompted to explain the second-order integrated rate law)

Student's problem solving	**PS Steps**
"Okay, so, this is the second-order integrated rate law."	Recognizes equation
"And so, it starts with, you have your rate equation for a second order reaction. And then you, if you integrate both sides with respect to time. dt. Then you end up, and then you rearrange it and you get this." $\int rate\,dt = \int k[A]^2\,dt$	Recognizes origin of equation
"So, basically, the purpose of this is so you can have a function of concentration versus time. Instead of just concentration versus rate. That way it's easier to use in like the lab."	Highlights purpose of equation

Keeping the methodological framework of blended processing in mind, multiple rounds of open coding of the PS maps were conducted (Patton, 2002). Often times codes were assigned to excerpts of data as they were organized as steps in the map, meaning a single problem-solving step received one code. Other times multiple codes were assigned to the data in a single step; further, there were instances in which multiple, consecutive steps received a single code. This coding process is ongoing, where the code book is continually being refined via constant comparison methodology (Patton, 2002).

Preliminary Results

Preliminary analysis shows variation in how students integrate knowledge domains to make sense of concepts to solve kinetics problems. A non-blended understanding has the potential to limit students' problem-solving abilities, while a blended understanding serves to support more productive problem solving. Our data suggests that blended processing is not a binary phenomenon; rather, it is dynamic spectrum. For example, when discussing the purpose of a rate law, a general chemistry participant, Hazel, argued that the equation is useful for solving for a third variable whenever you are given two of the values. This type of understanding could limit a student's ability to understand and make sense a more authentic problem. In contrast, more blended understandings of concepts, such as those demonstrated by other general chemistry participants, Trip and Damien, where the rate law is interpreted in terms of relationships and changes between variables, are likely to be more supportive of successful problem solving.

Preliminary analysis has also revealed distinctive types of blending processing in students' problem solving: mathematics blending, chemistry to mathematics, and mathematics to chemistry. Mathematics blending describes student blending of conceptual and formal mathematical reasoning. The second type of blending describes when students take chemistry concepts/information and translate that to mathematical concepts/symbolism. Alternatively, there is also evidence of mathematics to chemistry blending. This is the most common type of blending demonstrated by the pilot study interview participants. While we have only done preliminary analysis on the general-chemistry-level interviews, we do see similar types of reasoning with upper-level physical chemistry students.

We have also noted a variation in problem solving approaches, varying from very simple approaches utilizing one method with little reasoning to more complex approaches trying multiple methods, often with conceptual predictions and justifications. The latter represents a more sophisticated approach to problem solving, as it draws on multiple types of understanding and explicitly incorporates justification for problem solving steps. We plan to explore the relation of 1) success in problem solving and 2) complexity of problem-solving approaches to blended processing.

Conclusions and Questions

While our preliminary results suggest that there is evidence of blending among our student participants, this evidence is sparse and irregular. Chemistry faculty members want mathematics to be connected to (blended with) the chemistry represented in these problems. Ultimately, meaningfully blending and integrating mathematical understandings to science and engineering concepts and problem solving will help students develop a deeper understanding of STEM disciplines. Therefore, practitioners must explicitly model the cognitive practices of blended processing. Furthermore, they should provide students the time and space to practice blending and assess blended processing on course assessments.

The following questions outline potential avenues for investigation.

1. How is student problem-solving success related to blended processing?
2. How is student problem-solving sophistication/complexity related to blended processing?
3. What is the nature of chemical kinetics assessment in the participants' courses?
4. How do we foster this blending across disciplines in our classrooms?

Raising reasoning through revision: A case study of an inquiry-based college geometry course

Janessa Beach
Texas A&M-Commerce

Rebecca-Anne Dibbs
Texas A&M-Commerce

Geometry is the subject where U.S. students are weakest on international assessments, but college geometry is an area of proof that is understudied. Since geometry is secondary students' only exposure to proof, it is vital our secondary teachers can prove effectively in this content area. The purpose of this case study, drawn from a larger project, was to understand how, if at all, pre-service teachers' proof schemes became more axiomatic throughout a one-semester inquiry-based college geometry course. Participants in this study, Kayla and Lindsey, were pre-service teachers enrolled in an inquiry based college geometry course. Although Kayla had two prior proof courses and Lindsey had none, both participants were using a perceptual proof scheme at the beginning of the semester. However, by the end of the semester, the chance to revise their proofs and discuss problems with their peers helped both students advance to more axiomatic geometric thinking.

Key words: College geometry, inquiry based learning, proof

Compared to other nations, the students of the United States of America are floundering in geometry. The Trends in International Mathematics and Science Study (TIMSS) evinced that twenty-one educational systems, including China, Japan, Israel, and England, have higher geometry scores than the U.S. (Mullis, Martin, Foy, & Arora, 2012). This deficiency is because pre- and in-service teachers possess an inadequate understanding of the structure of geometry. Despite this difficulty for students and educators, college geometry remains severely under-researched (Speer & Kung, 2016).

Geometry arises from a set of undefined terms and axioms through which all other theorems and definitions are constructed. Hence, a thorough understanding of geometry involves a deep understanding of proof; yet, teachers possess a narrow understanding of proof. Studies indicate that pre- and in-service teachers believe proof only helps explain ideas used in mathematical concepts, and they do not recognize the ability of proof to systemize results (Mingus & Grassl, 1999; Knuth, 2002b). Teachers lack the geometry content knowledge required for geometry proofs, and they are convinced by empirical evidence as well (Jones, 1997; Knuth 2002a). Consequently, teachers with inadequate proof and geometry understanding cannot be expected to impart adequate proof and geometry knowledge to students.

Pre-service teachers in undergraduate proof courses do not thoroughly understand what arguments qualify as proof (Weber, 2001). They lack comprehension of the mathematical language and concepts necessary to proof (Selden, 2012), and they possess an incomplete understanding of definitions and theorems (Weber, 2001; Selden & Selden, 2008). In typical direct-instruction, lecture proof courses, students are expected to develop proficient proof skills with little guidance. Without recurrent feedback, students will likely cultivate ineffective strategies (Weber, 2001). These ineffective strategies are typically proof schemes dependent upon external and empirical convictions, such as the authoritarian, ritual, and perceptual proof schemes (Harel & Sowder, 2007). In order to successfully write a proof, students need to employ effective strategies or proof schemes with arguments based on axioms and logical deductions, such as the intuitive and structural axiomatic proof schemes.

A typical proof learning environment is dominated by the instructor with little student participation – an instructor-centered environment (Selden, 2012; Padraig & McLoughlin, 2009). This learning environment affects teachers' conceptions of proof, conceptions already determined to be limited (Mingus & Grassl, 1999; Knuth, 2002b). The typical instructor-centered learning environment, where students copy instructors' proofs, does not induce the logic and proof techniques needed to construct a proof in all students (Harel & Sowder, 1998). Alternatively, a proof course should consist primarily of student-student and student-teacher interactions (Selden & Selden, 2008). One potential approach is an inquiry-based learning pedagogy where students are active learners, and the instructor is responsible for facilitating students' learning (Padraig & McLoughlin, 2009).

The purpose of this study was to evaluate the effects of an inquiry-based learning environment on students' development of proof comprehension throughout an undergraduate geometry course. Through this study, we can determine whether or not this type of instructional environment is a potential solution to pre-service teachers' shallow understanding of proof and geometry. Mathematicians and teacher educators can then make more informed decisions on how to structure college geometry courses. We argue that the revisions present in an inquiry based classroom were vital to help students develop from a perceptual to a more axiomatic proof scheme.

Methods

The theoretical perspective used in this project was the reduced Toulmin model of argumentation. In mathematics education literature, there are two formats in which the model appears. I will distinguish them as the reduced Toulmin model (Figure 1) and the extended Toulmin model. The reduced model consists of three types of statements that represent different pieces of the argument, and the extended model consists of six statements. The three statements in the reduced Toulmin model are as follows: The data (D) is the foundation on which the argument is based. The conclusion (C) is the statement the arguer intends to convince. The warrant (W) justifies the relationship between the data and the conclusion. When students are asked to prove a claim, the conclusion is correct because it is given to the students. However, the data is typically a mixture of right and wrong. This amalgamation occurs because of the warrant the student applies – their reasoning from a piece of information to the conclusion. Although a warrant is specific to an argument, a warrant-type is a category of warrants with similar properties.

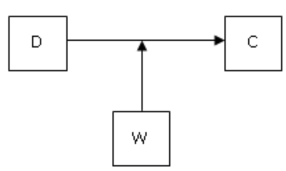

Figure 1. Reduced Toulmin model. Adopted from (Inglis, Meija-Ramos, & Simpson, 2007).

This study took place at a midsized, rural, research university in the South, and the students who participated were those enrolled in a college geometry course based upon Miller (2010) geometry course notes. The data collected was part of a larger study; this study is a case study of two students – Kayla and Lindsey. Both Kayla and Lindsey are Caucasian females whose majors were math education. Kayla was classified as a senior and had two prior proof courses, and Lindsey was classified as a freshman with no prior proof experience. Students in the course were provided with course notes that presented open-ended problems related to a specific learning goal. For each new assignment, students were assigned a specific problem from the provided course notes and a group. If a group appeared to be making little progress or moving in an unproductive direction, the teacher would use guided questioning to redirect students' thoughts. If multiple groups stopped progressing, the teacher would initiate a whole class discussion.

To determine students' proof comprehension, researchers examined the assignments students turned in. Students were allowed to revise and resubmit all assignments, and these were analyzed as well. Researchers also used observations to gain further understanding of students' proof comprehension. As students discussed their ideas, a researcher sat behind them listening and taking notes on their interactions.

The submissions were analyzed by assignment, and all the drafts from an individual participant were analyzed at the same time. After this initial reading of blinded assignments, researchers would journal their impressions of the coding and the trajectory exhibited in the multiple submissions. These journals were used to operationalize the proof schemes in Harel & Sowder (1998) and Harel (2007), and to construct the standards of evidence (Table 1).

Table 1

Standards of evidence

Proof Scheme Warrant	Identifiers
Authoritarian (1)	Argument produced after intentional scaffolding or direct instruction from the teacher/student did not participate in the group's reasoning, and/or writing process/The correct pieces of reasoning were discussed in class, and the argument does not arise from the students' data.
Ritual (2)	Student misapplies multiple axioms and theorems/Argument mirrors the format of a known correct argument, but the argument does not arise from the axiomatic system/Student restates the axiom or theorem as it is originally written despite the fact that the terminology does not relate to the context of the proof.
Perceptual (3)	Student refers to or provides only a diagram as justification for reasoning/The argument is driven by students' perceptual observation of the figure he or she drew and not by the implications of axioms and theorems.
Low Analytical (4)	The argument follows the correct deductive process, but the student does not establish the definitions, theorems, or axioms the process utilizes/The argument follows the correct deductive process, but there is one instance in which the student relies on another lower warrant/The argument follows the correct deductive process, but at least one clarification statement is necessary for validity/The argument follows the correct deductive process, but an axiom or theroem is misinterpreted and misapplied.
Intuitive Axiomatic (5)	The argument is built from undefined terms and axioms, definitions, and theorems of an axiomatic system that is intuitively grasped such as Euclidean geometry.
Structural Axiomatic (6)	The argument is logical and made up of systematic application of axioms and theorems/If any portion of the argument could be clarified, the clarification is not necessary for the argument's validity.

Findings

After analyzing the data, we mapped Kayla's and Lindsey's warrants throughout the course. Figure 2 presents a chronological summary of their proof scheme warrants. On all assignments, except Midterm Problem 3biii, students worked on the solutions with a group during class.

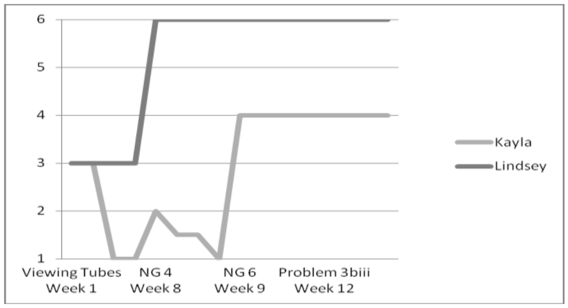

Figure 2. Proof schemes used throughout the semester

The Viewing Tubes assignment asked students to determine the formula to find the area of the wall that can be seen through a tube. To accomplish this, students needed to establish that the two triangles resulting from the situation are similar. Kayla and Lindsey both started this assignment utilizing the perceptual proof scheme. In their claim that the triangles are similar, the students produced and were convinced by a diagram. As they received feedback on their arguments, Lindsey maintained the perceptual proof scheme and Kayla's reasoning regressed to the authoritarian proof scheme.

Neutral Geometry Worksheet 4 (NG 4) required students to prove each point belongs to at least two different lines. Kayla's warrant on her first draft of NG 4 is the ritual proof scheme. This first draft mirrors another worksheet utilizing the Neutral Geometry (NG) axioms, and Kayla successfully completed this previous worksheet. Kayla's revisions to this assignment come from statements directly made by the teacher or a class discussion. Hence, as her drafts of NG 4 progress, Kayla's reasoning becomes solely authoritarian. Lindsey's exploration of the NG Axiom System, however, allowed her to garner a better understanding of how axioms develop and argument. The warrant on Lindsey's first NG 4 draft is then the structural axiomatic proof scheme because she applies the axioms to form a valid deductive argument.

Table 2

Kayla & Lindsey's initial NG proofs

Kayla NG 4 Draft 1	**Lindsey NG 4 Draft 1**
Let there exist 3 different points, (Calvin, Hobbes, One) (Figure 1).	Assumption: Let there be a point, A.
	By Axiom 3, there exists at least one line, L. CASE 1: If the point A lies on Line L, then at least point is not on L, point B, by Axiom 2.
If there exits at least one line (Calvin, One), (Hobbes, One), or (Calvin, Hobbes) by Axiom 3, there must also exist a pair of points (Calvin, One), (Hobbes, One), (Calvin, Hobbes) that are connected by L. (Figure, 2, 3, 4)(Axiom 1)	Since points A and B are two different points, then by Axiom 4, another line, Line M contains points A and B. Because B does not lie on L, line L and line M are two different lines. Therefore, point A belongs to two different lines, Line L and Line M.
	CASE 2: If point A does not line on Line L, then by Axiom 1, at least two points, points B and C belong to Line L. By Axiom 4, since A and B are two different points, there exists a line containing both A and B, line M.
By Axiom 2, there must also exist a point that does not belong to L. In Figure 2, (Calvin, One) belong to L while Hobbes does not exist on L. This similarly applies to Figure 3 and Figure 4 when L consists of (Calvin, Hobbes) or	By Axiom 2, there exists another point not on Line M, point D. Since Point A and Point D are two different points, then by Axiom 4, there exists a line

<table>
<tr><td>(One, Hobbes). Given Figure 4, Calvin also exists on a line consisting of (Calvin, Hobbes). Thus Calvin exists on 2 lines (Calvin, One) (Figure 2) and (Calvin, Hobbes) (Figure 4).</td><td>containing points A and D.</td></tr>
<tr><td rowspan="2">Figure 1, L containing (Calvin, One), there must exist a Hobbes not on L (Axiom 2). For all L containing two points there will be a third point not on L. By Axiom 4, any two points can be connected by a line. For the three points, Calvin, Hobbes, One, therefore there can be at least three lines (L, M, and N) (Figure 4)</td><td></td></tr>
<tr><td>Because points A and D are two different points, and point D does not belong to line M or Line L, then Line M, N, and L are different lines. Therefore, point A belongs to 2 different lines. Line N and Line M.</td></tr>
</table>

Neutral Geometry Worksheet Problem 3 (NG 6) assignment asked students to prove there exists a line not containing a given point on the NG Axiom System. Kayla, for the first time, exhibits analytical reasoning, and her warrant for her drafts is the low analytical proof scheme. Her argument follows a correct deductive process, but she does not utilize the axioms to establish truths. Also, she partially relies on the ritual proof scheme because she continues to use the complex notation from she mirrored in NG 4. Lindsey' warrant is the structural axiomatic proof scheme be she produces a valid deductive argument.

The last assignment analyzed in this study was Midterm Problem 3biii (Problem 3biii), and students were to prove, using the NG axiom system, that for any given point there exist two other distinct points such that the collection of points is non-collinear. Kayla maintains the reasoning she previous exhibited, and her warrant is the low analytical proof scheme. Again, she develops a correct deductive argument, and she is finally able to move past her ritualistic beliefs about arguments in the NG axiom system. For a portion of the argument, however, she still relies on the perceptual proof scheme. Although her reasoning exhibits an analytical characteristic, it is still hindered by preconceptions about proof. Lindsey maintained her reasoning level from NG 6. Her warrant on Problem 3biii is the structural axiomatic proof scheme – she produces a valid deductive argument.

Discussion

Overall, both students began the semester as perceptual provers, and admitted they focused more on trying to remember high school geometry than on engaging in the problems. Kayla's preconceived notions about proof inhibited her ability to move past a perceptual proof schema; whereas without any prior proof courses, Lindsey had no preconceived ideas to overcome and was quickly able to move her reasoning to an axiomatic level. The non-Euclidean geometries used in all assignments after Viewing Tubes forced Kayla and Lindsay to fully engage with the problem to understand its solution. Kayla reported that she had never revisited an assignment in her previous proof courses, and it appears that the revisions they completed helped them to begin to reason more axiomatically; this was Lindsey's first proofs class. Lindsey, who earned an A in the course, needed less time and fewer revisions to begin axiomatic reasoning than did Kayla, who earned a B. Although more inquiry is needed to determine if non-Euclidean is the most effective way to help pre-service teachers understand definitions and proof in their college geometry course, we recommend that revision of partially correct proofs be a incorporated into college geometry classes.

Exploring Mathematics Graduate Teaching Assistants' Developmental Stages for Teaching

Mary Beisiegel
Oregon State University

Traditional training programs that address mathematics graduate teaching assistants' (MGTAs) teaching practices are offered when they first arrive to campus, when they have little, if any, teaching experience. However, not much research has investigated how MGTAs' thinking about and facility with teaching change over the course of their graduate programs and, consequently, how their need for training changes over time. The goal of this study is to understand MGTAs developmental stages for teaching and how understanding these stages can inform the creation of a multi-year training program. Eleven MGTAs from a large, doctoral granting institution were surveyed and interviewed over the course of an academic year. Survey and interview responses were examined using a specific model of teacher development. Preliminary analyses, suggestions for multi-year MGTA training programs, and questions for future research are discussed.

Keywords: Graduate Teaching Assistants, Professional Development, Training for Teaching

Background

Years of research have provided evidence that the form of instruction in science, technology, engineering, and mathematics (STEM) disciplines in post-secondary institutions is significantly problematic for undergraduate learners. In particular, Seymour and Hewitt (1997) found that undergraduates in STEM courses were most likely to point to poor pedagogy as the reason for dropping out of a STEM discipline. More recently, researchers have found that students in traditional lectures have higher failure rates than students in classrooms that support active learning and student engagement in mathematical work (Chen, 2013; Freeman et al., 2014; PCAST, 2012). Mathematics instructors' and professors' teaching practices have an impact on students, as do graduate teaching assistants, with undergraduate students' interest in a subject experiencing a greater decline when they are taught by a graduate teaching assistant (Bettinger & Long, 2004).

As a result of these findings and the understanding that mathematics graduate teaching assistants (MGTAs) represent the future instructors and professors of mathematics, researchers have investigated the teaching practices of MGTAs (Belnap, 2005; Latulippe, 2007; McGivney-Burrelle, DeFranco, Vinsonhaler, & Santucci, 2001; Speer, 2001). In particular, researchers have developed courses and other training programs with the goal of providing MGTAs with a new vision of instruction that would offer undergraduate learners more meaningful ways of engaging in mathematics that lecture-based, direct-instruction does not provide (DeFranco & McGivney-Burrelle, 2001; Harris, Froman, & Surles, 2009; Speer, 2001). However, these studies found that MGTAs' instructional practices did not change as a result of these programs. Despite investigations of the efficacy of training programs, the field of MGTA professional development has not yet reached a consensus on the breadth and scope of training programs for MGTAs, with training programs varying from a few hours, to an intensive week, to training incrementally spread over the course of an academic term (Deshler, Hauk, & Speer, 2015; Harris et al., 2009; McGivney-Burrelle et al., 2001).

Of particular note about MGTA training programs, however, is that most are implemented solely in MGTAs' first year of graduate school; more specifically, when MGTAs first arrive to their programs, when they know little about teaching and likely have not had experience teaching. This is of concern because, over the course of their graduate programs, MGTAs' knowledge of teaching and mathematics will change significantly. Yet, in general, MGTAs will not have explicit attention paid to the development of their teaching practices as their knowledge and beliefs change, and as they encounter particular obstacles to instructional change and innovation. Such obstacles include MGTAs' own histories as mathematics learners (Deshler et al., 2015), the social context of the department (DeFranco & McGivney-Burrelle, 2001), belief among faculty members that attention to teaching is a distraction from research (Harris et al., 2009), and the structures of teaching assistant work (Beisiegel & Simmt, 2012).

Little is known about how MGTAs develop their teaching practices over the course of their graduate programs, even though their teaching practices have a significant, negative impact on undergraduate learners (Bettinger & Long, 2004). Researchers have pointed to the development of MGTA training programs as needing to be informed by many factors and should take into account such needs of the graduate students at different stages of their development (Park, 2004). Additionally, DeFranco and McGivney-Burrelle (2001) note that such training programs should be "viewed as ongoing professional development experiences that support [MGTAs] through the long and complex process of changing their teaching practices" (p. 688). With this in mind, the purpose of the study is to understand MGTAs' transitions, possible stages and changes in their thinking about teaching and learning as they progress through their programs. The research questions that guide this study are:

1. Do MGTAs go through developmental stages as teachers over the course of their graduate programs?
2. What implications do these stages have for how MGTAs are trained and supported over the course of their graduate programs?

The long-term goal of this study is to use this new knowledge to create a well-informed, scaffolded training program that will attend to the stages MGTAs go through as their teaching and thoughts about teaching evolve.

Theoretical Framework

Besides what has been learned through the study of training programs that address MGTAs' teaching practices, little is known about what stages MGTAs go through and how they can be supported as their views of teaching and learning evolve over the two to six years they are in a graduate program. Looking to the K-12 literature, researchers have studied schoolteachers' experiences in order to gain an understanding of teachers' transitions over time. For instance, Katz (1972) described four developmental stages, which include: (1) *survival* of the first year of teaching, with particular focus on classroom management and the routines of classrooms and schools; (2) *consolidation*, in which teachers begin to understand which skills they have mastered, and what tasks they still need to master; (3) a period of *renewal*, when teachers become tired of their routines and start to think of how things might happen differently; and (4) reaching *maturity*, where teachers think more broadly about the contexts of schools and students' learning (p. 52-53). Importantly, Katz (1972) notes that the third stage of renewal, of beginning to question standard teaching practices, does not begin until the third or fourth year of teaching. If MGTAs experience similar developmental stages, then the current programs that address their teaching practices only at the beginning of their graduate programs are likely inadequate and more thought should be given to MGTAs' possible developmental stages and their needs at those stages.

Context of the Study

In order to understand the MGTAs' transitions in teaching over time, two beginning-of-the-academic-year surveys were developed, one for new and one for experienced MGTAs. Additionally, protocols for mid-year and end-of-year interviews were created. Surveys are used at the beginning of the year because of logistical issues, such as varied arrival times to campus, and to also capture baseline information. The surveys include open-ended questions that inquire about MGTAs' thoughts about teaching and learning mathematics, how they would describe a well-taught mathematics lesson, and what had influenced the way they think about teaching. Additionally, Likert-Scale items include those that address MGTAs' epistemic beliefs and self-efficacy. Mid- and end-of-year interviews allow a deeper view their teaching practices, MGTAs' most recent teaching experiences, whether they feel that they are receiving adequate support, and what other support they they feel they need. The intention of the study is to survey and interview participants for the duration of their graduate programs in order to capture, longitudinally, any changes to their views of teaching and their need of support for teaching.

In 2015, the MGTAs were recruited from a department of mathematics in a large, doctoral granting institution. Approximately 5,000 students enroll in a lower-division mathematics course (such as Pre-calculus, Differential, Integral or Vector Calculus, Business Calculus, or Differential Equations) each year at this university, with the structure of most courses having three hours of lecture with 150-250 students per class and taught by an instructor. MGTAs are generally assigned to run recitations (1 hour workshops) of smaller groups of students from the large lecture sections. MGTAs are not assigned to courses based on knowledge, skill, or experience. Rather, assignments to courses depend mostly upon scheduling, although MGTAs are asked what their preferences are. At the beginning of the academic year, newly arrived MGTAs receive 2 ½ days of training for their teaching assignment, with a primary focus on how to support active learning and student engagement in mathematical work during recitations and lectures. During the summer after their first year, MGTAs are offered the opportunity to teach their own course as the instructor of record. Only informal mentoring happens before and during the summer sessions.

Eleven of 60 MGTAs agreed to participate in the first year of the study. Participants include 3 first-year, 2 second-year, 4 third-year, 1 fourth-year, and 1 fifth-year MGTA. At the time of submitting this proposal, each of the participants had completed the beginning-of-the-year survey as well as the mid-year and end-of-year interviews. The participants who remain in the mathematics graduate program will complete surveys and interviews in the upcoming academic year and new participants will be recruited. Participants' responses to survey and interview questions were analyzed using thematic analysis (Braun & Clarke, 2006), with a deductive approach that looked for instances of the participants' experiences that could be elucidated with Katz's (1972) four-stage model of teacher development. At the end of the first year of this study, data has not yet been collected that would illustrate each participant's transitions during the course of their programs. However, comparisons will be made between the first- and later-year MGTAs in order to gain a preliminary understanding of their developmental stages.

Preliminary Findings

The first year MGTAs alluded to *surviving* the first year as teaching assistants. For example, one first year MGTA described her initial experience teaching in this way: "The first [term], I was completely on my own and I didn't know what I was doing." In this statement, I see that, despite the training the MGTA had received, she was still fairly uncertain about her teaching. The newness of teaching was a disorienting and isolating, and she did not seem to rely on what she had heard or learned during her training. As another example, a first year MGTA stated this about his first term:

> By that point the quarter was just getting really hectic and I wasn't able to plan as much as I usually like to plan for courses. Sometimes I was looking at the material for about two hours before I started that day whereas usually I like to look at it the day before or during the weekend or something. And so sometimes, though, the classes that I went to where I was kind of doing it on the fly, where I was literally looking at it like an hour or two before class. A lot of times it's just more like get the notes done, go in, and do it.

In this participant's statement, I observe that the busy life of a new mathematics graduate student was enough to counteract the training that he had received when he first arrived. He noted that he had intended to devote more time to preparing for teaching, even creating revised drafts of lessons, with the aim of posing several open-ended questions during class. However, under the time constraints of his life as a graduate student, he switched to survival mode, with a routine of going through notes and presenting material and not implementing teaching strategies that would promote active learning.

One first-year MGTA spoke about his experience of being assigned to teach a course during the summer term at the end of his first year in the graduate program:

> I've never taught a day in my life – and when I went to – I originally just asked [two instructors] three questions. I asked them, "What worked in your classroom and what didn't?", "What advice do you have?" and some other questions. And so they answered that and then they said, "Hey, if you want to sit down and talk, we can." And, if that hadn't happened – that was out of their own kindness – and, if that hadn't happened, I feel like I'd be drowning right now because I wouldn't know what to do.

This MGTA noted that he would not be surviving, but would instead be drowning, in his first teaching experience had he not independently sought out advice and course materials from instructors. Another interesting thing to note is his statement that he had "never taught a day in his life." He had led multiple recitations during the two terms immediately prior to teaching his own course, and yet neither that experience nor the initial training seemed to provide him with enough resources to feel comfortable in his role as an instructor.

Later-year MGTAs spoke differently about their teaching experiences. For example, one third-year MGTA summarized her transition from the *survival* stage to the *renewal* stage:

> I think previously, I was more focusing on, "I just want to survive my first teaching experiences." So, now that this is my fourth time teaching, I feel a little bit more comfortable trying to incorporate more active learning in my classroom, and trying non-traditional techniques whereas previously, when I taught, for example, my first time teaching my own class and I taught Calculus, I did mostly lecture because I just wanted to do what I felt most comfortable with – what I felt I could be successful at.

From her statement it is not clear that she had tired of her routine of lecturing, as suggested by Katz (1972), for the transition from survival to renewal. Yet, it is clear that she is now comfortable enough in the classroom that she is beginning to think of what she might do differently; in this case, incorporate active learning. This is interesting as the MGTA training she had received three years prior had promoted active learning and it was only at the end of her third year that she was ready to consider and enact active learning strategies.

The third- and fourth-year participants' statements illustrated their transition into *maturity*, as they were thinking more broadly of educational issues (Katz, 1972). For example, one MGTA noted that she had become more aware of different learning styles:

> I've learned to understand more deeply some of the things students have going on in order for me to be more conscious of. I've also been very aware of different learning styles. I'm making sure to – some people are visual. I am visual. So I make sure to have everything written down. But I also know people are auditory learners. So I also read everything.

Another later-year MGTA spoke of her awareness of multiple choice assessment questions and potential biases within multiple choice questions, noting her observation that questions are "biased for gender and ethnicity and culture." This particular MGTA had also begun to think about the intersection of teaching mathematics and social justice issues.

Discussion

Katz's (1972) developmental stages are useful for defining and understanding the stages that MGTAs go through. Through this framework, I observe that MGTAs think about different, and progressively more sophisticated, aspects of instruction as they progress through their graduate programs and developmental stages. These findings suggest that MGTAs are not necessarily ready to enact more demanding instruction (e.g., active learning) in their first experiences running recitations, when they are teaching for the first time and likely in survival mode. The findings of this study also suggest that MGTAs have more advanced thoughts about teaching in their third and fourth years, thoughts that go beyond what is typically offered in initial MGTA training programs.

One conclusion is that MGTA training programs should be multi-year training programs that address these stages and the MGTAs' needs in each of these stages. A third-year MGTA illustrates how the initial training did not impact her at first and that follow-up training in her third year might be useful. Here she refers to the teaching strategies she had learned in her initial training:

> I probably couldn't recall them all, right? They're just somewhere in the recess of my head. It might be good to hear them in the context of now having three years' experience. And certainly what I thought was important before I had ever taught is going to be different than hearing it after three years' experience. So maybe even if I heard the same thing, it would carry more weight now. I would have a better understanding for the context it would fit in.

Katz (1972) noted the stage of *renewal*, of thinking of how teaching might happen differently, does not being until a teachers' third or fourth year in the classroom. Thus, with Katz's finding and the participant's statement, I suggest that training programs that extend into third and later years might gain more traction in helping MGTAs enact more demanding forms of instruction, such as active learning. Once MGTAs have more experience teaching, the instructional practices espoused by training programs can become more relevant, relatable, and practicable.

Intended Questions for the Audience

For the presentation at RUME, questions that I intend to pose and discuss with the audience are:

- Does Katz's (1972) framework seem adequate for understanding and describing the developmental stages for MGTAs?
- How might the results of this study be useful to and inform training programs for MGTAs?
- What other questions and ideas should be answered in order to better inform the development of a multi-year MGTA training program?

Flip vs. Fold: What is so important about the Rigidity of a Motion?

Anna Marie Bergman, Portland State University
Dana Kirin, Portland State University
Ben Wallek, Portland State University

This report will investigate the mathematical and pedagogical consequences of flipping versus folding in the identification of reflection symmetry. Preliminary results are presented from a teaching experiment aimed at exploring the development of one undergraduate student's understanding of symmetry. The analysis indicated that throughout the teaching experiment, the student held two distinct versions of reflection symmetry. One version was what most would identify as reflection, while the other was an iterative process based on the participant's ability to fold the figure. In this report, we share what this student identified as symmetries and how she justified her methods. In addition, we discuss why the definition of isometry necessitates a rigid motion and how the motion of folding is insufficient for identifying symmetries correctly. Lastly, we consider why understanding a rigid motion is advantageous for students who want to consider symmetries in more sophisticated mathematical contexts such as group theory.

Keywords: Symmetry, Abstract Algebra, Intellectual Need, Teaching Experiment

Introduction

Symmetry can be thought of in two different ways (Larsen, 2010). Consider the following definitions of symmetry from different textbooks, "an object or design has symmetry if part of it is repeated to create a balanced pattern" (Lappan, Fey, Fitzgerald, Friel, & Phillips, 1998, p. 206) and "a symmetry of a figure is a rigid motion which leaves the figure unchanged" (Farmer, 1991, p. 27). The first definition describes symmetry as a property of a figure, and the second as a motion preformed on a figure. Throughout their K-12 experiences, students are introduced to both conceptions of symmetry as part of their mathematics instruction (Common Core State Standard [CCSS], 2010). In particular, as early as forth grade, students are introduced to the concept of symmetry as a property of a figure and expected to, "recognize a line of symmetry for a two-dimensional figure as a line across the figure such that the figure can be folded along the line into matching parts" (CCSS, 2010). In later grades, students are introduced to the concept of symmetry closer to that of a motion performed on a figure. For example, in 8th grade students are expected to "verify experimentally the properties of rotations, reflections, and translations" (CCSS, 2010). For more advanced courses in mathematics, it is often beneficial that students are able to consider symmetries as strictly isometries. This is especially true in the context of group theory, where students need to be able to think of the property of symmetry in terms of a transformation that can be combined (composed) in such a way that leaves the given figure unchanged (Larsen, 2010).

The context of geometric symmetry has proved to provide a 'rich and natural context for developing the concepts of group theory' (Larsen, 2009, p. 136), since the ideas of symmetry and equivalence are fundamental concepts in group theory (Burn, 1996). However, outside of APOS theory (Asiala, Kleiman, Brown, & Mathews, 1998), little research has been done into how students develop an isometry understanding of symmetry. We have recently begun to investigate how students may develop an understanding of symmetry and symmetry equivalence through a series of task-based interviews. In this preliminary report, we present our findings from a teaching experiment aimed at exploring the development of one undergraduate student's understanding of symmetry. In particular, we report on how this student identified symmetries of various figures and how she justified her methods.

Theoretical Perspective

In the context of our research we are considering symmetry as an isometry, or a rigid motion, and therefore it must be a motion that does not deform the shape. Yet since it is not uncommon for students to have been taught to fold a figure in the context of symmetry (CCSS, 2010), we have found ourselves faced with an interesting question, "If symmetry is a motion, what does it matter if one flips or folds?" We are interested in not only the mathematical consequences of the different motions, but also the pedagogical ones. If students are in fact more accustomed to a folding motion, as per Harel (2013), the issue we must address is that of how we might *necessitate* one a flip motion (rigid) over a fold (non-rigid). In other words, as we help to facilitate students through the Measuring Symmetries Task (Larsen & Bartlo, 2009), we must be cognizant of how we can make flip, instead of fold, a solution to what students recognize as a problem.

Methods

The first author conducted a teaching experiment (Steffe & Thompson, 2000), exploring how an undergraduate student, Birdie, developed an understanding of symmetry over a series of 5 task-based interviews. Birdie is a high achieving sophomore civil engineering student who had recently completed Calculus 3 at a large urban university in the western United States. Data collection consisted of all Birdie's written work as well as video recordings of each interview, which were later transcribed. Throughout the interviews, the student explored her ideas of symmetries by working through the Measuring Symmetry Task (Larsen & Bartlo, 2009). The task is designed to build on the student's aesthetic sense and intuition to help the development of formal ideas of symmetry, and later focuses on the idea of symmetry equivalence. The task begins by asking the student to consider the following figures, see Figure 1, and to rank them from least to most symmetric.

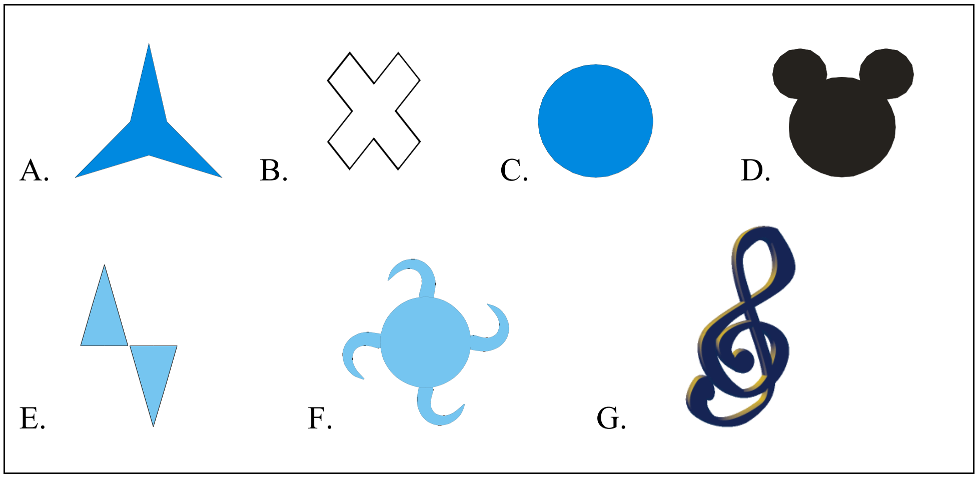

Figure 1. Figures (A – G) given in the Measuring Symmetry Task

Through the course of the teaching experiment the student was also asked to:

- Measure (i.e., assign a number to) the symmetry of a figure in a way that is consistent with the ranking
- Define the various types of symmetries they had counted
- Negotiate between their definition and counting system for inconsistencies
- Consider equivalence of symmetries

Ongoing thematic analysis (Braun & Clarke, 2006) is being conducted in an attempt to identify Birdie's various ideas of symmetry. As one of the main research goals of the teaching experiment is to discover how Birdie developed an isometry understanding of symmetry, we are particularly interested in what parts of the definition of symmetry she could recreate on her own. There did not seem to be a point in the Measuring Symmetry Task that necessitated a flipping motion instead of folding, which was the catalyst in trying to find the true distinction between the motions.

Initial Results

From the first time Birdie offered an explanation as to why she ranked the figures in the way that she did, she offered 2 distinct versions of what she eventually called, "line symmetry." When considering figure D (see Figure 1), Birdie assigned a ranking of 1. She explained:

> Birdie: Um, this (motions to figure D) I can at least cut once, and I guess this is asymmetry (in reference to figure G)...
> Interviewer: Can you describe what you mean by cut?
> Birdie: So if I were to fold it in the middle right here I can fold it once and it would be symmetric on that line.
> Interviewer: Can you use the transparency to show me what you mean by fold? ...(she folds the transparency in half) like actually fold it in half, ok. And then it lines up like that, ok.

This is precisely the reflection symmetry one would expect for figure D, and mathematically accurate, one reflection about a vertical axis down the middle of the figure.

As Birdie continued to describe her ranking for the figures, she quickly offered a different version of line symmetry when considering figure E (see Figure 1). In early interviews, Birdie gave figure E a rank of between 2-6 symmetries as she developed and negotiated her ideas of line symmetry. Notice that mathematically figure E has only a trivial and non-trivial rotation, and no reflections. The following transcripts show her initial thoughts on a second version of line symmetry.

> Birdie: Um, this one's (figure E) kinda the same situation where, if I fold it in the middle, it lines up to be something that's more symmetric in my mind.
> Interviewer: Ok, what parts are lining up when you fold it in the middle?
> Birdie: Um, actually it's not lining up, but it also has rotational symmetry.
> Interviewer: Ok.
> Birdie: Alright, well when I fold it, it lines up to be something that can be folded again into great symmetry.
> Interviewer: Ok so maybe by a compound fold?
> Birdie: Yeah, I don't know what the rules are here, but I'm just assuming it won't be...

Interviewer: We haven't established any so it's whatever you want to do at this point.

Birdie continued to develop and refine both versions of line symmetry as the experiment continued and was able to begin to articulate them in her written description of what she was counting (symmetries). Figure 2 presents Birdie's written description of symmetry.

Symmetry is broken up into two groups for me, line & rotational. Line symmetry being if you draw a straight line through the object from one side to the other & fold it on that line the two sides will match up perfectly (perfectly being without any one the reflected side not matching a half) & either create the same shape or a new one. Which then can then be done again with another 'fold' aka drawing another straight line and so forth until it will no longer match up with the reflected side no matter where the line is drawn.

Figure 2. Birdie's written description of her conceptions of symmetry.

Her description in Figure 2, suggests that Birdie recognized that while one version of symmetry considered the original shape, the other considered new shapes as the result of folding. This iterative folding was a sort of process in which she was considering the resulting shape from a fold, and if it had line symmetry in addition to the original figure. Birdie was always aware that one process deformed the original shape. The following transcript shows Birdie's distinction between these two methods when asked to clarify her assigning 4 folds to figure B (see Figure 1), which only has 2 reflection symmetries:

> Birdie: I guess the argument is more, are you counting it as the same shape or as a different shape, each time you fold it? I mean, technically it's a different shape just looking at itself, but considering the past of it, it's the deformed shape that you create from the original shape.

We explore the mathematics behind both of Birdie's motions for identifying line symmetry; the single folding motion that Birdie eventually identifies as equivalent to 'flipping' and the iterative process of 'folding.' Flipping can be described as a reflective symmetry. Reflective symmetry is absolutely a type of isometry, and therefore a distance preserving injection. The 'folding' motion however is not an injection, as it sends the figure to a proper subset of the original domain. The folding motion deforms the figure and so it is also not distance preserving.

By using an iterative folding process Birdie was able to identify line symmetries that were not mathematically accurate. The figure below (Figure 3) shows Birdie folding two different figures, each of which she counted more symmetries than the figure would have by the formal definition.

E. 		B. 	This figure has 0 reflection symmetries	Birdie identified up to 4 line symmetries	This figure has 2 reflection symmetries	Birdie described 6 line symmetries through iterative folding

Figure 3. Examples of Birdie's additional line symmetries from iterative folding.

Conclusion

The word ‘symmetry’ is given multiple definitions, and while that makes both symmetry as the property of a figure and symmetry as a motion preformed on a figure valid, only the second will be advantageous when thinking of symmetry as a more abstract mathematical object in contexts such as group theory. Our work with Birdie has suggested that students beginning to work with symmetries as isometries may be (heavily) influenced by the notion of symmetry as a property and the motion of folding. There is no doubt that symmetry has been found to be a rich and natural context for developing group theory (Larsen, 2009), where students can rely on their intuition and aesthetic sense, that provides rich opportunity for student discourse (Larsen & Bartlo, 2009). Yet our research has shown that to fully develop an isometry understanding of symmetry required a student to negotiate between their pre-existing idea of symmetry and the folding motion/s that she had associated with it.

Questions for the audience / Related ideas we’re still exploring

- While we know that the deforming motion of the fold is not the same as the rigid motion of the flip and therefore will not create the same group structure under composition we are curious what kind of algebraic structure if any can be used to describe the folding motions, and what the operation might be.

- Under what circumstances does a fold motion accurately identity reflection symmetry? Birdie had two kinds of line symmetry one of which was a single folding motion and the other was a series of iterative folds. The single folding motion was successful at identifying reflective symmetries even though it was not a rigid motion. Would it always be? Why?

- What kinds of situations necessitate a flip over a fold that are experientially real for students that helps facilitate their recreation of a mathematically accurate definition of symmetry that includes a rigid motion?

Examining Students' Procedural and Conceptual Understanding of Eigenvectors and Eigenvalues in the Context of Inquiry-Oriented Instruction

Khalid Bouhjar, Muhammad Haider, & Christine Andrews-Larson
Florida State University

This study examines students' procedural and conceptual understanding as evidenced by their written responses to two questions designed to assess aspects of their understanding of eigenvalues and eigenvectors. This analysis draws on data taken from 126 students whose instructors taught using a particular inquiry-oriented instructional approach and 129 comparable students whose instructors did not use this instructional approach. In this proposal, we offer examples of student responses that provide insight into their reasoning and summarize broad trends observed in our quantitative analysis. In general, students in both groups performed better on the procedural item than on the conceptual item. Additionally, the group of students who were taught with the inquiry-oriented approach outperformed the group of students who were taught using other approaches.

Key words: eigenvalues, eigenvectors, linear algebra, inquiry-oriented, student thinking

Linear algebra is a mandatory course for many science, technology, engineering, and mathematics (STEM) students. The theoretical nature of linear algebra makes it a difficult course for many students because it may be their first time to deal with this kind of abstract and conceptual content (Carlson, 1993). Carlson (1993) also posited that this difficulty arises from the prevalence of procedural and computational emphases in students' coursework prior to linear algebra, and that it might therefore be difficult for students to connect new linear algebra topics and their previous knowledge. To address this issue, researchers have developed inquiry-oriented instructional materials and strategies to help students develop more robust, conceptual ways of reasoning about core topics in introductory linear algebra (e.g. Wawro, Rasmussen, Zandieh, & Larson, 2013). In this proposal we examine assessment data to identify ways in which students reasoned about eigenvectors and eigenvalues. In particular, we identify differences in the performance of students whose instructors taught with a particular inquiry-oriented approach to teaching eigenvectors and eigenvalues and comparable students whose instructors did not use this approach.

In this work we draw on data from an assessment that was developed to align with four core introductory linear algebra concepts addressed in the IOLA instructional materials: linear independence and span; systems of linear equations; linear transformations; and eigenvalues and eigenvectors (Haider et al., 2016). The focus of this study is to identify the ways students understand and reason about eigenvalues and eigenvectors. In the assessment, there were two questions, question 8 and 9 that addressed eigenvalues and eigenvectors. Question 8 was a procedural item related to the eigenvalue of a given matrix and question 9 focused on the conceptual understanding of the eigenvectors. The research questions for this proposal are:

- How did students reason about eigenvectors and eigenvalues in the context of questions designed to assess aspects of student's procedural and conceptual understanding?
- How do the performance and ways of reasoning of students whose instructors adopted an inquiry-oriented approach to teaching linear algebra compare to the performance and ways of reasoning of other students?

Literature & Theoretical Framing

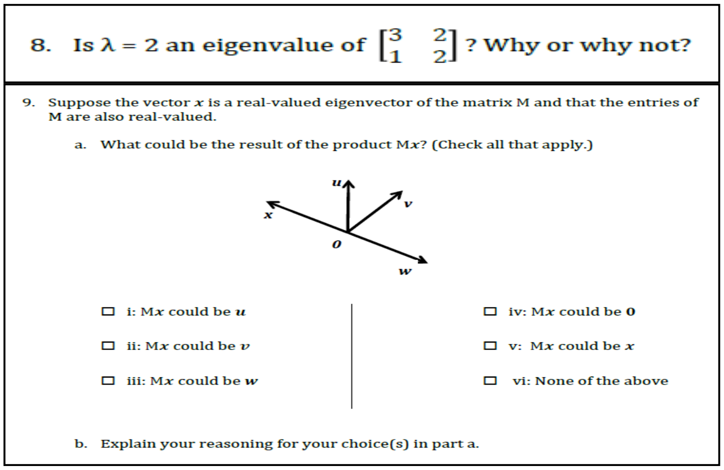
Many have argued that the shift from a predominantly procedural approach to mathematics many students experience before college to a more conceptual approach causes a lot of difficulties for students as they transition to university mathematics; linear algebra is a topic in which students struggle to develop a conceptual understanding (Carlson, 1993; Dorier & Sierpenska, 2001; Dorier, Robert, Robinet & Rogalski, 2000; Stewart & Thomas, 2009). Across the literature on the teaching and learning of eigenvalues and eigenvectors, procedural thought processes are featured prominently. For example, Stewart and Thomas (2006) highlighted the example of the conceptual processes and difficulties students find in learning about eigenvalues and eigenvectors, where a formal definition may be immediately linked to a symbolic presentation and its manipulation. Thomas & Stewart (2011) highlighted a difficulty students find when faced with formal definitions for eigenvalues and eigenvectors. Since these definitions contain an embedded symbolic form ($Ax = \lambda x$), students often move quickly into symbolic manipulations of algebraic and matrix representations such as transforming $Ax = \lambda x$ to $(A - \lambda I)x = 0$ without making sense of the reasons behind these symbolic shifts. Schonefeld (1995) used eigenpictures ("stroboscopic" pictures) to show x and Ax at the same time by using multiple line segments on the x-y-axis. He observed that graphical representations of eigenvalues and eigenvectors got little attention in the literature and that a picture may benefit more than algebraic presentations. It is also documented that students struggle to coordinate algebraic with geometric interpretations (e.g. Stewart & Thomas, 2010; Larson & Zandieh, 2013) and the students' understanding of eigenvectors is not always well connected to concepts of other topics of linear algebra (Lapp, Nyman, & Berry, 2010). To support students in developing a better understanding of the formal definition and the geometrical interpretations of the eigenvalues and eigenvectors, researchers have developed a variety of instructional interventions (e.g. Tabaghi & Sinclair, 2013; Zanidieh, Wawro, & Rasmusen, 2016).

Researchers often make reference to conceptual understanding and procedural understanding when discussing student's thinking about mathematical concepts (Hiebert, 1986). To operationalize our distinction between concepts and procedures, we draw on Vinner's (1997) distinction between conceptual and analytical behavior. According to Vinner (1997), students are in a conceptual mode of thinking if their behavior provides evidence that they are attending to concepts, their meanings and their interrelations. On the other hand, students are in an analytical mode of thinking when solving routine mathematical problems if they act in the way expected and certain analytical thought processes occur. In case they do not act in such ways but succeed in making the impression that they are analytically involved in problem solving then they are in pseudo-analytical mode of thinking. Vinner (1997) argued that in most problem solving situations when students are asked to solve a problem their focus usually is on which procedure should be chosen and not on why a certain procedure works. Based on this, we draw on Vinner's (1997) definition of conceptual versus analytical (procedural) as an analytic tool for interpreting student's answers to the questions involving eigenvalues and eigenvectors.

Data Sources

In our previous work, we have developed an assessment that covers the four focal topics of linear algebra mentioned earlier (Haider et al. 2016). This assessment was administered at the end of linear algebra course at different public and private institutions across the country. This was a paper-and-pencil assessment that includes 9 items and the students were allocated one hour to complete. It was designed to measure students' understanding of introductory linear algebra topics. Every item of the assessment contained a component of open-ended justification for students to elaborate their conceptual understanding of the topic.

Figure 1. Question # 8 and 9 (Eigenvalues/Eigenvectors) of the assessment



8. Is $\lambda = 2$ an eigenvalue of $\begin{bmatrix} 3 & 2 \\ 1 & 2 \end{bmatrix}$? Why or why not?

9. Suppose the vector x is a real-valued eigenvector of the matrix M and that the entries of M are also real-valued.

   a. What could be the result of the product Mx? (Check all that apply.)

- ☐ i: Mx could be u
- ☐ ii: Mx could be v
- ☐ iii: Mx could be w
- ☐ iv: Mx could be $\mathbf{0}$
- ☐ v: Mx could be x
- ☐ vi: None of the above

   b. Explain your reasoning for your choice(s) in part a.

We have collected assessment data from two groups of students: students whose instructors received instructional supports to teach linear algebra using a particular inquiry-oriented approach as part of the NSF-supported TIMES research project (who we will refer to as TIMES students), and students whose instructors did not receive these supports (who we will refer to as non-TIMES students. The instructors who participated in the TIMES project attended a 3-day summer workshop, participated online workgroup conversations for one hour per week for a semester, and implemented inquiry-oriented curricular material in their linear algebra class. We have collected the assessment data of 126 Times students across six TIMES instructors and 129 non-Times students across three non-TIMES instructors from different institutions in the US. Non-TIMES instructors were recruited from linear algebra instructors either at the same institutions as TIMES instructors or at other similar institutions (e.g. similar geographic area, similar size of student population, similar acceptance rate at institution) to collect assessment data for comparison of TIMES and non-TIMES students. In this study, we focused on in-depth analysis of students' reasoning on the assessment questions related to eigenvalues and eigenvectors. Both items are shown in the figures above.

The inquiry-oriented approach to learning eigenvalues and eigenvectors associated with this study is characterized in detail elsewhere (Zandieh, Wawro & Rasmussen, 2016). This approach supports students in coming to first learn about eigenvalues and eigenvectors as a set of "stretch" factors and directions that can be used to more easily characterize a geometric transformation. In this sequence of tasks, students first work to describe the image of a figure in a plane under a transformation that is easily described in a non-standard coordinate system. Students then work to label points using standard and non-standard coordinate systems corresponding to the previous task; they also find matrices that transform points from one coordinate system to the other. The instructor works to link this work to the matrix equation $A=PDP^{-1}$ and subsequent tasks aim to leverage this conceptual basis as students learn more traditional computational methods associated with computing eigenvalues and eigenvectors.

Methods of Analysis

To identify different types of students' approaches to eigenvectors and eigenvalues assessment items, we conducted our analysis in three stages: (I) developed a coding scheme for both the descriptive (open ended) part and the non-descriptive (multiple-choice) part of the items, (II) coded assessment data by following the coding scheme, (III) ran statistical analysis of coded data for descriptive statistics and t-test to compare the performance of TIMES and non-TIMES students.

At the first stage, we decide the coding scheme for non-descriptive part of the problems. Later, we looked into the descriptive parts of the problems. We identified different correct students' approaches for both problems, which helped us to refine our coding scheme. The coding scheme for question 8 and 9 is given in the table below:

	Points Awarded and Criteria	Comments
Question 8	3 Points: For any of the following answers. 1: $\det(A-\lambda I)=0$ implies $(x-1)(x-4)=0$ implies $x=1$ or $x=4$ implies $\lambda=2$ is not an eigenvalue for the matrix A. 2: $\det(A-2I)=-2\neq 0$ implies $\lambda=2$ is not an eigenvalue of A. 3: $(A-2I)\begin{bmatrix}x\\y\end{bmatrix}=0$ implies $x=0$ and $y=0$ which is the trivial vector, implies $\lambda=2$ is not an eigenvector for the matrix A.	Fully correct answer
	2 Points: if any answer with computational mistakes and with good justification and conclusion will be credited with 2 credits (computational mistaken attempt cannot be awarded full credit like a fully correct answer)	Partially correct answer
	1 Point: if any answer missing any of the three rules (correct answer, correct computation and correct explanation) will be missing credits depending on the number of rules missed.	Some procedural knowledge
Question 9	3 Points: Writing $Mx=\lambda x$ or mentioning Mx as a constant multiple of x/scalar multiple of x with or without mentioning what the values of this constant/scalar; 0, 1 and -1 and giving the options x, w, and 0.	Fully correct answer
	2 Points: If a student mentions $Mx=\lambda x$ and miss any of the possible values of constant/scalar; 0, 1, and -1 and/or miss one of the given options x w, and 0.	Partially correct answer
	1 Point: Writing $Mx=\lambda x$ and/or miss two of the possible values of constant/scalar; 0, 1, and -1 and/or miss two of the given options x, w and 0.	Some understanding

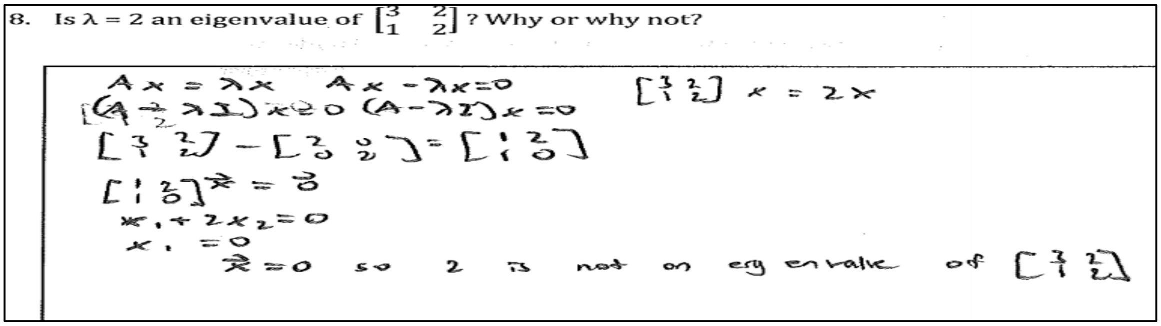
Table 1. Criteria for Awarding Points for question 8 and 9

At the second stage of analysis, we coded assessment data by following the above grading scheme. Two researchers looked at every students' attempt and decide a score independently and then matched with each other. If both researchers assigned different score to a particular student, then they discussed according to the grading scheme and agreed on a common score for that student. If both researchers have disagreement about a particular score, then a third researcher was consulted to make a consensus. At the third stage of statistical analysis, we checked the descriptive statistics to see the overall performance of students on the eigenvalue and eigenvectors questions. We also compared TIMES students with Non-TIMES students for both questions. We used t-test to compare the difference of means between questions 8 and 9 for both groups.

Initial Findings

In this section we summarize how students reasoned about the eigenvectors and eigenvalues items and how they med on both questions. We will provide some examples to show how they reasoned then point out using the quantitative data how the TIMES students performed compared to Non-Times students.

The following example shows that the student has a conceptual and procedural understanding in the sense that he/she by solving $(A - 2I)x = 0$, finding only the trivial solution and concluding that 2 is not an eigenvalue which is a nonstandard solution.



8. Is $\lambda = 2$ an eigenvalue of $\begin{bmatrix} 3 & 2 \\ 1 & 2 \end{bmatrix}$? Why or why not?

$Ax = \lambda x \quad Ax - \lambda x = 0 \quad \begin{bmatrix} 3 & 2 \\ 1 & 2 \end{bmatrix} x = 2x$

$(A - \lambda I)x = 0 \quad (A - \lambda I)x = 0$

$\begin{bmatrix} 3 & 2 \\ 1 & 2 \end{bmatrix} - \begin{bmatrix} 2 & 0 \\ 0 & 2 \end{bmatrix} = \begin{bmatrix} 1 & 2 \\ 1 & 0 \end{bmatrix}$

$\begin{bmatrix} 1 & 2 \\ 1 & 0 \end{bmatrix} \vec{x} = \vec{0}$

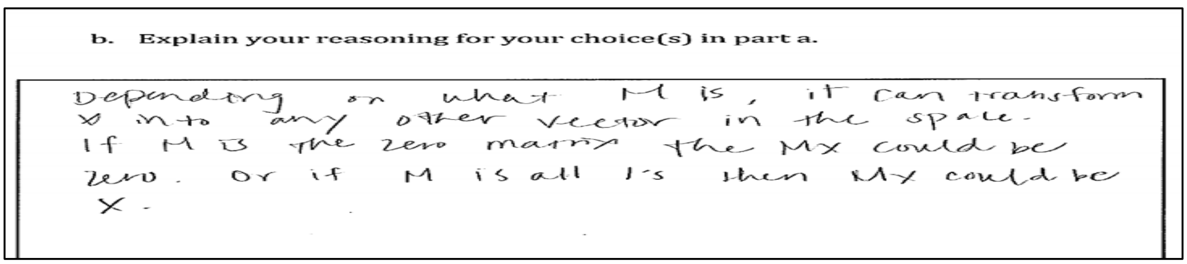
$x_1 + 2x_2 = 0$

$x_1 = 0$

$\vec{x} = 0$ so 2 is not an eigenvalue of $\begin{bmatrix} 3 & 2 \\ 1 & 2 \end{bmatrix}$

Figure 2: A student's example for Q8

Another example of a student who is interpreting the matrix M as something that can change in interpreting the eigenvector equation.



b. Explain your reasoning for your choice(s) in part a.

Depending on what M is, it can transform x into any other vector in the space. If M is the zero matrix the Mx could be zero. Or if M is all 1's then Mx could be x.

Figure 3: A student's example for Q9b

To see the difference in the students' performance we paid attention to the mean and standard deviation of the coded data. We also used t-test to compare the difference of means between both groups.

Question	All Students	TIMES Students	Non-TIMES Students
Q 8: Maximum Possible Points 3	Mean: 1.85 SD: 1.31	Mean: 2.0 SD: 1.23	Mean: 1.71 SD: 1.37
Q 9 (a & b): Maximum Possible Points 9	Mean: 1.50 SD: 0.82	Mean: 1.59 SD: 0.89	Mean: 1.42 SD: 0.74
Q 9 (b part only) Maximum Possible Points 3		Mean: 1.59	Mean: 0.54
		p-value = 0.0000273 < 0.05	

Table 2. Summary of TIMES and Non-TIMES Students' Performance

When examining the quantitative data to see how the two groups compared we noticed two things that seemed particularly noteworthy. First, both groups did better on the procedural item than the conceptual one. Second, TIMES students did better than non-TIMES on both items, but they outperformed non-TIMES on the conceptual item at a higher rate. In our session we will more deeply explore evidence of conceptual and procedural reasoning as it appeared in students' responses to the two items, and differences between the two groups of students.

Supporting Students' Understanding of Calculus Concepts: Insights From Middle-grades Mathematics Education Research

Steven Boyce
Portland State University

Kira Wyld
Harvey Mudd College

In this preliminary proposal, we report on results from a paired-student teaching experiment focused on college calculus students' developing notions of reversibility and reciprocity through compositions and transformations of linear relations. We anticipate fruitful discussions about relationships between numerical and quantitative reasoning and students' thinking about graphs.

Key words: Calculus, Derivative, Teaching Experiment

Introduction

The main topic of first-term calculus–the derivative–depends on deep, flexible understandings of rate and slope (Dawkins & Epperson, 2014; Zandieh, 2000) rooted in conceptions of rational numbers. Two explicit examples are learning to equivocate "increasing function" and "positive derivative" and learning to reason about reciprocal rates of change of an invertible function and its inverse. However, rational number conceptions are not usually the focus of pre-calculus coursework. In placement testing such as ALEKS, rational number topics are generally limited to arithmetic prerequisites for secondary school algebra. Research shows that development of numerical concepts in the elementary and middle grades can have a lasting effect on the ways students construct algebraic knowledge (Ellis, 2011; Hackenberg & Lee, 2015). We conjecture that differences in calculus students' reasoning about reversible and reciprocal relationships may extend from these differences. We report on our exploration of how differences in numerical conceptions affect college students' understandings of the derivative and how engaging in compositions and transformations of linear relations concurrent to calculus instruction may benefit students.

Theoretical Framework

We take a cognitive constructivist epistemologist perspective in viewing individuals' knowledge as a product of their organizing of their experiences interacting with the world to fit within or to construct mental *schemes* (von Glasersfeld, 1995). As others' thinking is fundamentally unknowable, schemes are researchers' constructs serving to fit their observations of others' activities. Our aim is to explore how ways students have constructed schemes for rational number concepts affect their learning of calculus topics.

A scheme consists of three parts: recognition of a situation, operations (mental actions), and an expected result. An example is the iterative fraction scheme, which is necessary for understanding improper fractions as numbers (Hackenberg & Lee, 2015). A student with an iterative fraction scheme understands the size of an improper fraction as the result of partitioning and iterating the size of '1'. If his or her scheme were *reversible*, the student also understands the size of 1 as the result of partitioning and iterating the size of an improper fraction. Reversible schemes are those for which the result of one sequence of mental operations is recognized as a situation for the reversed sequence of operations. Reversible schemes that are *interiorized* are those for which the recognition of a situation and an expected result of mental activity are experienced as synchronous. For a student with an interiorized iterative fraction scheme, the symbol '9/7' "contains" potential relations with numbers including '1', '1/7', '1/9' and '7/9', depending on the situation. These other numbers would be part of the student's concept image associated with '9/7' that could potentially be evoked (Tall & Vinner, 1981). The ways the associated units are coordinated depend on the student's *units coordinating structures*.

The construct of units coordinating structure has distinguished middle-grades students' reasoning with whole number multiplication, fractions integers, and linear algebraic expressions (Hackenberg & Lee, 2015; Ulrich, 2015). Research with pre-service and in-service teachers suggests that differences in units coordinating structures persist into adulthood (Busi, Lovin, Norton, Siegfried, Stevens, & Wilkins, 2015; Izsák, Jacobson, de Araujo, & Orrill, 2012). To our knowledge, units coordination has not previously been studied with calculus students. Of relevance for calculus students is whether students have constructed *two-level* or *three-level* units coordinating structures.

Students who have constructed only two-level units coordinating structures can assimilate composite units (units of units), but transformations of those units (e.g., forming a third level of units) are non-reversible. Such students can reason with three levels of units *in activity*, but they reason with two levels at a time. For example, a student assimilating fractions with a two-level units coordinating structure could form the size of 9/7 from a given size of '1' by partitioning the '1' into 7 parts and appending two more parts. Assimilating fractions with three levels of units is required for maintaining the relationships between the different units (seven 1/7 units within 1 and nine 1/7 units within 9/7) (Norton, Boyce, Phillips, Anwyll, & Ulrich, 2015). A construct related to units coordination that has been studied with calculus students and has been shown to correlate with success in calculus is *covariational reasoning.* As seen in Table 1, the description of mental actions in the Covariation Framework (Carlson, Jacobs, Coe, Larson, & Hsu, 2002) involve successively more structured coordinations of variables' values. Units coordinating structures constrain students' conceptions of (negative) integers and fractions, suggesting relation to Mental Actions 3 and 4.

Table 1
Stages 3-4 of the Covariation Framework (Carlson, Jacobs, Coe, Larson, & Hsu, 2002)

Mental action	Description of mental action	Behaviors
Mental Action 3 (MA3)	Coordinating the amount of change of one variable with changes in the other variable.	• Plotting points/constructing secant lines • Verbalizing an awareness of the amount of change of the output while considering changes in the input
Mental Action 4 (MA4)	Coordinating the average rate-of-change of the function with uniform increments of change in the input variable.	• Constructing contiguous secant lines for the domain • Verbalizing an awareness of the rate of change of the output (with respect to the input) while considering uniform increments of the input

Methods/Methodology

We assessed volunteer undergraduate students' backgrounds during the first week of their Summer 2016 8-week differential calculus course, using a units coordinating assessment (Norton, Boyce, Phillips, Anwyll, & Ulrich, 2015), and a pre-calculus concept assessment focusing particularly on functions concepts and covariational reasoning (PCA, Carlson, Oehrtman, & Engelke, 2010). We engaged two students in six weekly hour-long teaching sessions, which were video-recorded for ongoing and retrospective analysis by the researcher and a witness (Steffe & Thompson, 2000). The sessions were concurrent but separate from students' calculus classes, without interaction between the classroom instructors and researchers.

Preliminary Results

The two students (Susan and Kris, both pseudonyms) who participated in the teaching experiment were life sciences majors who had successfully completed pre-calculus coursework in college. Both were assessed as coordinating two levels of units: Susan used representations to form responses (coordinating units *in activity*) rather than creating representations to justify and explain interiorized reasoning, whereas Kris did not correctly coordinate three levels of units with fractions. Their responses on the PCA were similar, as Susan answered 16 of the 25 items correctly and Kris answered 14 items correctly. The eight items they each missed suggested interpreting graphs, function composition, domain and range, and covariational reasoning were pertinent topics for exploration. Following are descriptions of activities and reasoning exhibited during the teaching experiment.

Reasoning about linear relations

In the first session Kris and Susan were given Cartesian graphs depicting linear relations between time and volume, and volume and height, of water in a container (see Figure 1).

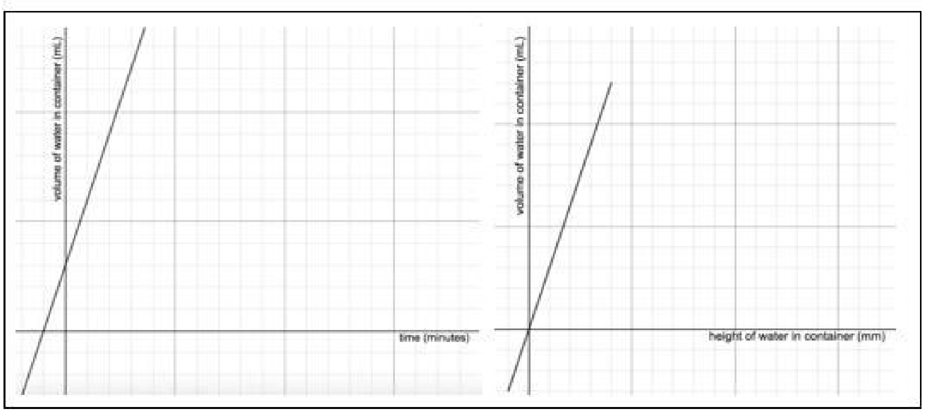

Figure 1. Graphs given to Kris (left) and Susan (right)

After establishing common interpretations of unit grid marks, the teacher asked for the height at 5 minutes. Susan used her time/volume graph to find the volume at 5 minutes and then found the height from Kris' graph. The teacher next asked how long it would take for the water in the container to reach a height of 27 mm, anticipating that they might represent and compose the two relations algebraically since they could not read the values directly from the graph. Susan instead focused on the graphs' slopes. "First we need to find out how much volume needs to be added, and then how much time that volume takes….From my graph we know there's 1 mm per 3 mL and from [Kris'] graph we know there's 3 mL per 1 minute." She was perturbed when multiplying $\frac{81\ mL}{27\ mm} \cdot \frac{1\ min}{3\ mL}$ resulted in 1 min/mm; it seemed she had anticipated a time corresponding with 27 mm. She did not consider the non-zero volume at time t=0 and insisted that knowing the slopes should be enough "since they were constant."

The sessions switched to the Desmos "Water Line" app, in which water is depicted flowing at a constant rate into different containers and students graph water height over time (https://teacher.desmos.com/waterline). The first container is a cylinder; the container is then modified in multiple ways (see Figure 2). In this context, Susan correctly explained why graph of the new cylinder's water line would be a positive vertical shift of the old cylinder's graph, despite Kris' conjecture of a negative shift and in contrast to her earlier reasoning.

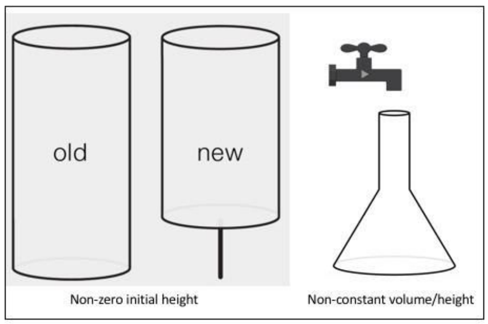

Figure 2. First three waterline containers

Reasoning about non-linear rates of change

Susan's water line graph for the third container indicated a linear component prefaced by an increasing, concave up, non-linear component, which she referred to as "exponential." When asked why she used the term exponential, she first exhibited shape-thinking (Moore & Thompson, 2015) regarding exponential growth , and then, referring to Figure 2, volunteered that "You can't really define this rate, because at each second it's filling at a different rate, because [the glass is] continually sloping inward. So it's going to be an exponential growth curve, because it's changing constantly." When asked what she meant by "it's changing constantly," she replied, "it's constantly getting quicker, and that is indicative of exponential growth." In response, the teacher introduced graphing calculator explorations with sliders to perturb the students' shape-thinking regarding exponential and polynomial functions, as well as activities relating the rate of change of a quadratic relation and its derivative, before returning to modeling water accumulation. *We are continuing to analyze relationships between Susan's and Kris' rational number concepts and calculus understandings. We will solicit feedback from the audience regarding our interpretations of the students' reasoning during the teaching sessions.*

Signed Quantities: Mathematics Based Majors Struggle to Make Meaning

Suzanne White Brahmia
University of Washington

Andrew Boudreaux
Western Washington University

Physics students struggle to make meaning of the negative sign in a variety of mathematical and physical contexts. This study is part of an ongoing concurrent mixed methods exploration of student understanding of negativity in physics. A set of multiple-choice items, modified from a prior study, was administered to over 500 calculus-based college students from diverse backgrounds. Results suggest that when the positive sign is an explicit part of a quantity, students struggle with positive quantity just as they do with negative quantities, and that the language that instructors use may inadvertently impute unintended meaning about signs.

Key words: signed numbers, negative, quantity, physics, vectors

Introduction

While notions of negativity have been part of mathematical thinking for well over a thousand years, many European mathematicians shunned negative numbers as recently as the advent of modern calculus. Negative numbers were seen to *"... darken the very whole of equations and make dark of thinking which are in their nature excessively obvious and simple."*(Maseres, 1758) More recently, mathematicians have isolated a variety of natures of negativity fundamental to algebraic reasoning that go beyond a "position on a number line" nature (Gallardo & Rojano, 1994; Thompson & Dreyfus, 1988; Nunes, 1993). College students are expected to reason with these various natures of negativity that form the foundation of scientific quantification, yet they experience the "darkening" of reasoning foreshadowed by 18th century mathematicians, struggling to separate the physical model from the rules associated with arithmetic. The work presented in this paper argues that the majority of engineering students in the U.S. struggle to make meaning of positive and negative quantities outside of the number line context learned in elementary school, in spite of successfully passing Calculus I and beyond in mathematics.

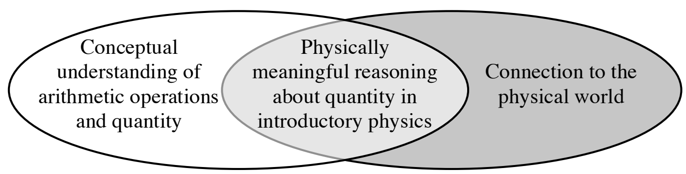
Developing flexibility with negative numbers is a known challenge in math education. In her study of algebra students, Vlassis found that full understanding of the concept of a negative number required that students develop flexibility with the various ways negative numbers are used in context (i.e., with the "negativity" of the number) (Vlassis, 2004).

Few published studies have focused on negativity in the context of the mathematics used in physics courses (Sherin, 2001; Bajracharya, Wemyss, and Thompson, 2012). In our own prior work on negativity (Brahmia & Boudreaux, 2016), we found that engineering students struggled to make sense of negative physics quantities, but struggled less with the unary, or "isolated number" nature of negativity, as compared with other natures. (The unary nature of negativity is embodied by position on a number line.) We found that students have particular difficulty with signed scalar product quantities, commonly associating the sign of the scalar with the direction of one of the factor vectors. We suspect that science contexts overwhelm some students' conceptual facility with negativity, and conclude that students' mathematical understanding is likely more fragile than what physics instructors may commonly assume based on the students' completed prerequisite math courses.

The current study extends this prior research. We wondered if there was something particularly "dark" about negative numbers *per se,* and if students would have a higher success rate had they been asked about signed positive numbers. Additionally, in open-ended versions of the assessment items we saw that students seemed to attribute meaning to particular phrases in the question statement that was not implied. We formulated the research questions below to focus the new study. The remainder of this paper describes our preliminary work in addressing these questions.

1. *Are difficulties with negative quantity associated with negativity per se, or do learners struggle in similar ways with positively signed quantity?*
2. *What assumptions regarding negativity do students make based on language commonly found in physics problems? Specifically, to what extent do students:*
   - *interpret "movement along the x-axis" to imply motion in the +x-direction?*
   - *interpret a negatively signed quantity to imply a motion in the negative direction?*

Figure 1: Double scope quantity reasoning blend



The cognitive blending theoretical framework (Fauconnier & Turner, 2008; Bing & Redish 2007) describes the interdependence of thinking about the mathematical and physical worlds that we feel is necessary for quantifying effectively with signed quantities in physics. Figure 1 illustrates a *double scope quantity reasoning blend*, in which two distinct domains of thinking are merged to form a new cognitive space optimally suited for productive work. Findings by Czocher support this view. She observed students enrolled in a differential equations course solving a variety of physics problems, and found that successful students functioned most of the time in a "mathematically structured real-world" in which they moved back and forth fluidly between physics ideas and mathematical concepts (Czocher, 2013).

Research Methods

Our work adopts a concurrent mixed methods strategy. We have used Vlassis's framework for negativity (Vlassis, 2004) to inform the design of six assessment items, three involving contexts from mechanics (ME), and three, contexts from electricity and magnetism (EM). (See Appendix.) Previously, we used multiple-choice (MC) versions of the items to reveal trends in large populations, and free-response versions to explore students' in-the-moment thinking (Brahmia & Boudreaux, 2016).

For the current study, the items were administered in a three semester, large enrollment, calculus-based physics course sequence at a large, diverse, public R1 university, and in an analogous three quarter sequence at a smaller, less diverse, public regional university. The items were ungraded, and were bundled with concept inventories routinely given as part of course assessment. At the R1 university, the course was composed almost entirely of engineering majors, while at the regional university, the course included not only engineers, but also students majoring in physics, chemistry, biology, and other STEM fields. In each case, students were concurrently enrolled in some level of calculus course.

To investigate the first research question, we administered MC versions of the ME items at the R1 institution in Spring 2016 to 551 students completing the second course in the physics sequence (which includes mechanics applications and thermodynamics). Half of these students (at random) received modified versions of the items, in which the negative quantities used in the original versions were replaced with positive quantities. To investigate the second research question, we extended the study described earlier (Brahmia & Boudreaux, 2016), in which the ME items were administered at the R1 institution in Fall 2015 at the end of both the first course in the sequence (which covers mechanics) and the third course (which covers EM). We examined responses on free-response versions (n=84, ME; n=138, EM), and made changes to the wording and the MC distractors of some items. These changes are described in the footnotes of the appendix. The modified versions of all items were then administered in Winter 2016 at the regional university, at both the start and end of the second course of the three-quarter physics sequence (which covers EM). Table I summarizes the administration of assessment items.

Table I: Administration of items in introductory, calc-based physics courses to assess student understanding of signed quantities. (FR=free-response, MC=multiple-choice)

Institution	**Administered at**	**Math Pre/Co Req.**	**Item context**	**Item format**
R1 University (2015/16)	End of 1st sem. course	PreCalc, Calc I	ME (negative quantities only)	MC and FR
	End of 2nd sem. course	Calc I	ME (neg. and pos. quantities)	MC only
	End of 3rd sem. course	Calc II, III	EM (neg. only)	MC and FR
Regional Univ. (2016)	Beginning and end of 2nd qtr. course	Calc I, II	ME and EM (mod. wording and choices; neg. only)	MC only

Findings

Figure 2 shows results from the positive and negative versions of items ME1-ME3. For all three item pairs, a chi-square test of significance yields p-values > 0.6. For items ME2 and ME3, effect sizes determined from log odds ratios are < 0.8 (Borenstein et al., 2009). The effect size for item ME1 is 0.13, a statistically small effect size. Prior research has found that physics students tend to inappropriately associate negative (positive) acceleration with decreasing (increasing) speed. We suspect that results on item ME1 are related to this difficulty, and thus do not interpret the finding as evidence that students experience inherent difficulty with negatively signed quantities (i.e., relative to positive quantities). Results overall suggest that students struggle to make sense of positive values just as they do with negative values, when the sign is an explicit part of the quantity.

Figure 2: Positive vs. Negative

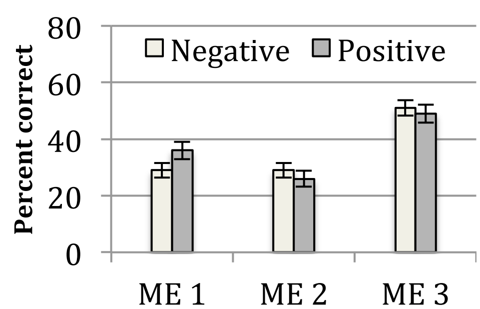


Figure 3 shows results from the original and modified versions of ME1 (see Appendix). We use these results to address the first part of the 2nd research question. Note that on the original version, choice "e" would be correct if the motion were assumed to be in the +x-direction. We note that on the modified version, given at the regional university, 17% fewer of the students selected e, with a corresponding 17% increase in the fraction selecting c, the correct answer. This result, statistically significant with a medium effect size, could indicate that students at the R1 institution tended to interpret "an object moves along the x-axis" to signify motion in the positive direction. An alternative explanation is that students at the regional university were not comparable to those at the R1, perhaps due to differences in course instruction. The statistically identical patterns of the other distractors, however, cast doubt on this explanation. We intend to replicate the experiment with samples drawn from the same population, and to present the findings as part of our talk.

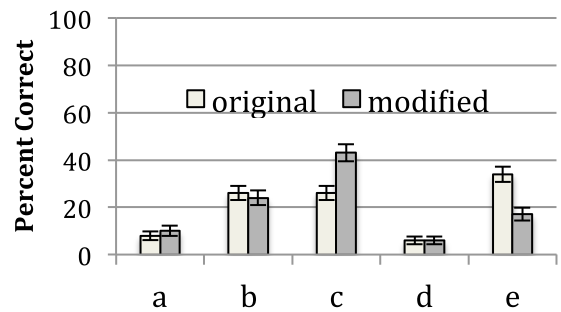
Figure 3: Results from two versions of item ME1.



To address the second part of research question 2, we compared results on the original and modified versions of items EM1 and EM3 (see Appendix). No significant differences in performance were found. We conclude that although on free-response versions of the items, some students associated negatively signed quantities (i.e., quantities other than velocity) with motion in the negative direction, this association is not robust enough to distract students from other sensible choices in the MC format.

Implications for Mathematics Instruction

Based on prior research associated with negativity (Blaire et al. 2012), we suspect that understanding signed quantities increases students' cognitive load in science courses, which explains why, in the absence of a robust cognitive structure on which to hang the new signed quantities, students flounder to make meaning of the quantities and the language surrounding them.

We recognize the value of explicitly addressing mathematization with signed quantities in physics instruction. Here, however, we open a discussion of math instruction, in particular instruction between pre-algebra and calculus, with informal observations from an examination of sample math textbooks:

1. Sign and operation are often conflated using an equals sign (e.g., $5 + (-3) = 5 - 3$), and unsigned numbers are assumed positive. Adding a negative quantity and subtracting a positive one often have different meanings in science contexts. Although these operations yield the same arithmetic results, conflating them may lead students to struggle with the distinctions between sign and operation.

2. Orientation and sense are not always explicit in coordinate systems. Aligning the positive coordinate axis with the direction of motion eliminates the need for signed quantities. This, however, could be a missed opportunity to distinguish between orientation and sense. The opposite coordinate choice can prime students to understand signed numbers in science contexts.

Questions for the RUME community

1. What kinds of knowledge would math education researchers be interested in gaining from subsequent qualitative studies?

2. What audiences would be most interested in learning about this research?

Appendix

Multiple-choice versions of the assessment items and the percentage of students selecting each answer (Brahmia&Boudreaux, 2016). Correct answers are in bold.

	Unary structural signifier	Symmetrical operational sig.	Binary op. sig.
	Dir. of a vector component	Signifies work *by block* not *on block*	Position *rel. to* an origin
MECHANICS ITEMS	[a]***ME1:*** An object moves along the x-axis. The acceleration is measured to be $a_x = -8$ m/s^2. Consider the following statements about the "–" sign in "$a_x = -8$ m/s^2". Pick statement that best describes information the neg. sign conveys: a. The object moves in the negative direction. *(8%)* b. The object is slowing down*(26%)* c. **The object accelerates in the –x-direction (26%)** d. Both a and b *(6%)* e. Both b and c *(34%)*	[b]***ME2:*** A hand exerts a force on a block as block moves along a frictionless, horiz. surface. For a particular interval, the hand does W= –2.7 J of work. Consider the following statements about the "–" sign in "W = –2.7 J". *The neg. sign means:* I. the work done by hand is in neg. dir. II. the force exerted is in neg. dir. III. the work decreases the mechanical energy associated with the block Which are true? a. I only *(17%)* b. II only *(17%)* **c. III only (23%)** d. I and II only *(29%)* e. II and III only *(14%)*	***ME3:*** A cart is moving along the x-axis. At a specific instant the cart is at position x = –7 m. Consider the following statements about the "–" sign in "x = –7 m". Pick statement that best describes information the sign conveys. a. The cart moves in the negative direction *(6%)* b. **The cart is to the negative direction from the origin (67%)** c. The cart is slowing down *(6%)* d. Both a and b (*19%)* e. Both a and c *(2%)*

[a]Mod. version of ME1 at regional univ. replaced first sentence with *"An object moves in one dimension."*
[b]Mod. version of ME2 added "*IV. block moves in the neg. dir.,"* and replaced choice e with *"e. IV only"*

	Unary structural signifier	Symmetrical operational sig.	Binary op. sig.
	Dir. of a vector component	Signifies *opposite* type of charge	Potential *rel. to* a reference
E & M ITEMS	[c]***EM1:*** At a location along the x-axis, the E-field is $E_x = -10$ N/C. Consider the following statements about the "–" sign in "$E_x = -10$ N/C". Pick statement that best describes information the neg. sign conveys: a. The test charge is negative *(16%)* b. The field is being created by negative charge *(21%)* c. **The field points in the –*x*-direction (36%)** d. Both a and b *(12%)* e. Both b and c *(14%)*	***EM2:*** Valeria combs her hair and there is a transfer of charge such that $DQ_{comb}= -5$ mC. Consider the following statements about the "–" sign in "$DQ_{comb}= -5$ mC". *The neg. sign means:* I. neg. charge was added to the comb II. charge was removed from comb III. all of the charge in comb is neg. Which statements could be true? a. **I only (33%)** b. II only *(28%)* c. III only *(18%)* d. I and III only *(15%)* e. II and III only *(5%)*	[d]***EM3:*** A student uses a voltmeter to measure voltage across a battery. It reads –5V. Consider the following statements about the "–" sign in "– 5V". Pick statement that best describes information the neg. sign conveys: a. voltage is in opp. dir. as current (*32%)* b. there are 5V of neg. charge in battery *(14%)* c. voltage is in the neg. dir. *(18%)* d. **voltage at one term. is 5V less than the other (33%)** e. battery has neg. voltage *(3%)*

[c]Mod. version of EM1 at regional univ. replaced choice d with "*d. the test charge moves in the neg. dir.,"* and choice e with *"e. the electric field moves in the neg. dir."*
[d]Mod. version of EM3 replaced choice e with *"e. none of these is a valid interpretation"*

Developing Student Understanding: The Case of Proof by Contradiction

Darryl Chamberlain Jr.
Georgia State University

Draga Vidakovic
Georgia State University

Proof is central to the curriculum for undergraduate mathematics majors. Despite transition-to-proof courses designed to facilitate the transition from computation-based mathematics to proof-based mathematics, students continue to struggle with mathematical proof. In particular, research suggests that proof by contradiction is a difficult proof methods for students to construct and comprehend. The purpose of this paper is to discuss preliminary results on student comprehension of proof by contradiction within a transition-to-proof course. Grounded in APOS Theory, this paper will illustrate that students' ability to negate quantification plays an early role in student comprehension of proof by contradiction.

Key words: Proof by Contradiction, Transition-to-proof course, Teaching Experiment

Proof is central to the curriculum for undergraduate mathematics majors. Despite transition-to-proof courses designed to facilitate the transition from computation-based mathematics to proof-based mathematics, students continue to struggle with mathematical proof (Samkoff & Weber, 2015). In particular, research suggests that proof by contradiction is a difficult proof methods for students to construct and comprehend (Antonini & Mariotti, 2008; Brown, 2011; Harel & Sowder, 1998). The purpose of this paper is to discuss preliminary results on student comprehension of proof by contradiction within a transition-to-proof course. In particular, this paper will address the following question: How does a student's conception of quantification affect their comprehension of proof by contradiction? Grounded in APOS Theory, a teaching experiment was designed to assess the development of student understanding of proof by contradiction. Results from a case study consisting of three teaching sessions with one student will be presented and discussed, concluding with a discussion of how quantification negation affects student comprehension of proof by contradiction.

APOS Theory and the ACE Teaching Cycle

APOS Theory is a cognitive framework that considers mathematical concepts to be composed of mental Actions, Processes, and Objects that are organized into Schemas. An *Action* is a transformation of Objects by the individual requiring memorized or external, step-by-step instructions on how to perform the operation. As an individual reflects on an Action, he/she can think of these Actions in his/her head without the need to actually perform them based on some memorized facts or external guide; this is referred to as a *Process*. As an individual reflects on a Process, they may think of the Process as a totality and can now perform transformations on the Process; this totality is referred to as an *Object*. Finally, a *Schema* is an individual's collection of Actions, Processes, Objects, and other Schemas that are linked by some general principals to form a coherent framework in the individual's mind (Dubinsky & McDonald, 2001). Utilizing the mental constructs of Actions, Processes, Objects, and Schemas, an outline of the hypothetical constructions students may need to make in order to understand a concept can be developed, referred to as a genetic decomposition. This genetic decomposition is used as a foundation to develop instructional materials.

One such pedagogical approach aligned with APOS Theory is the ACE teaching cycle; an instructional approach that consists of three phases: Activities, Classroom discussion, and Exercises. In the *Activities* phase, students work in groups to complete tasks designed to promote reflective abstraction rather than correct answers. These tasks should assist students in making the mental constructions suggested by a genetic decomposition. In the *Classroom discussion* phase, the instructor leads a discussion about mathematical concepts that the activities focused on. Students take a prominent role in this discussion while the instructor guides the conversation and presents an overview of what the students have discussed and introduces a formal, mathematical way of presenting the concept. In the *Exercises* phase, students work on standard problems designed to reinforce the Classroom discussion and support the continued development of the mental constructions suggested by the genetic decomposition. The Exercises also provide students with the opportunity to apply what they have learned in the Activities and Classroom discussion phases to related mathematical concepts (Arnon et al., 2014).

Methodology

This paper is situated in a larger research project on how students develop an understanding of proof by contradiction within a transition-to-proof course at a public R1 university in the southeastern United States. Data for this preliminary report consists of three sessions of a teaching experiment with a single student, Chandler, during summer 2016 from *Bridge to Higher Mathematics* - the first course in which students are formally introduced to mathematical proofs and their accompanying methods of proof. Chandler's understanding is similar to 5 other participants and can be considered representative of a general participant's understanding. Unlike a typical instructional sequence of ACE teaching cycle that, in a regular classroom, usually lasts for a week, this teaching experiment consisted of 5 shorter, consecutive teaching sessions each mimicking the ACE teaching cycle. That is, each session consisted of: students working on the Activity worksheet focusing on a particular component of the genetic decomposition for proof by contradiction (A); A discussion about the concepts from the worksheet (C); and a typical series of proof comprehension questions (Exercises, E) related to the content of the worksheet. A more detailed description for each session, including the role of the interviewer during each phase, is described below. In addition, Table 1 provides an overview of the content for the first three sessions with Chandler.

- Activity – Sessions began with a presented statement and proof. The interviewee would talk out how this statement and proof can be converted to propositional logic. During this phase, the interviewer acted as another student with incomplete knowledge.
- Classroom Discussion – After the Activity, the interviewer would ask the interviewee to summarize the structure of the proof. At this point, a formal structure of the proof would be given to the student, after which the interviewee would discuss how this structure compared to the one written during the Activity. During this phase, the interviewer acted as a knowledgeable agent who guided the student to make comparisons that would develop student understanding.
- Exercise – After the Classroom Discussion phase, the interviewee answered comprehension questions on their own, after which the interviewer prompted interviewee for their answers and their thinking behind the answers provided. Note that as textbooks

do not normally provide comprehension questions on proofs, the proof comprehension assessment model by Mejia-Ramos et al. (2012) was used to develop standard proof comprehension questions for the Exercises. During this phase, the interviewer acted as a knowledgeable agent to gain insight into the interviewee's thinking.

- Student's Questions – After the Exercise phase, the interviewee was encouraged to ask questions on any topic (not just those discussed in the interview).

Table 1. Overview of content per teaching experiment session

	Activity	Classroom Discussion	Exercise	Student's Questions
Session 1	Converting statements using propositional logic.	Discussion of these conversions and quantification in general.	Comprehension questions on a proof of the statement "The set of primes is infinite"	How do you negate the statement "$(\forall x)(\forall y)\big((P(x) \wedge P(y)\big) \rightarrow x = y)$"?
Session 2	Logical structure of the statement "If every even natural number greater than 2 is the sum of two primes, then every odd natural number greater than 5 is the sum of three primes"	Discussion of procedure for proof by contradiction of implication statements.	Comprehension questions on the proof of the statement "If every even natural number greater than 2 is the sum of two primes, then every odd natural number greater than 5 is the sum of three primes"	How do you write a proof by contradiction for the statement "$P \rightarrow Q_1 \wedge Q_2$" and similar statements?
Session 3	Logical structure of the statement "There is no odd integer than can be expressed in the form $4j - 1$ and in the form $4k + 1$ for integers j and k."	Discussion of procedure for proof by contradiction of nonexistence statements.	Comprehension questions on a proof of the statement "There is no odd integer than can be expressed in the form $4j - 1$ and in the form $4k + 1$ for integers j and k."	How do you write a proof for the Triangle Inequality?

Data Analysis

All sessions were video recorded and then transcribed by the interviewer. Transcripts of the three sessions went through multiple passes of analysis. First, sections of the transcripts were grouped by Activity, Classroom Discussion, Exercises, and Student's Questions for each session. Then, grouped sections were read together and general comments were made to find themes (if any) outside of the genetic decomposition. Two themes emerged from these general comments: (1) negating quantified statements and (2) procedures for proof writing. These themes were then coded throughout all three sessions. Finally, each interview was coded for evidence of developing an understanding of proof by contradiction. Due to space constraints, the rest of this section will briefly discuss how Chandler negated quantified statements and how this affected his comprehension of proof by contradiction.

Negating a statement is the first step toward writing a proof by contradiction and thus a student's conception of quantification negation directly affects proof comprehension of proofs by contradiction. On several occasions, Chandler expressed the need for explicit rules in order to negate quantified statements, indicating an Action conception of quantification negation. For example, during Session 2 Chandler discussed having a table with instructions on how to negate statements with single and multiple quantifiers, saying "Negation… I wish there was a table on how to negate things and what they look like, I don't know. There is this [points to page in textbook with rules for negating 'for all' and 'there exists' statements] for quantifiers." The interviewer then found a table online with negations of logical operators that Chandler confirmed was what he was looking for in addition to the page in the textbook.

In addition, Chandler had difficulties negating statements without first translating the statement into propositional logic and (sometimes with prompting) using rules to negate the propositional logic, again indicating an Action conception of quantification negation. For example, in Session 2 Chandler was asked to give the negation of the statement "Every even natural number greater than 2 is the sum of two primes." An excerpt of what transpired is provided below:

> CHANDLER: Every even natural number greater than 2 is not the sum of two primes? No, all? I don't know.
> [Interviewer prompts Chandler to write the statement in propositional logic]
> INTERVIEWER: Alright. So for every n here, that's how you said it to me. So parentheses for all n, in the natural numbers, if n is greater than 2, then n is p + q. So what would be the negation of this statement?
> CHANDLER: There is a natural number…
> INTERVIEWER: There is a natural number.
> CHANDLER: n greater than 2 that is not equal to p + q.

Note that at first, Chandler was unable to state the negation of the claim. However, once the claim was written in propositional logic, Chandler was able to recognize the negation of a "for all" statement. Chandler's need to convert the statement into propositional logic can be explained by his reliance on external, specific rules for negating quantifiers.

In terms of proof by contradiction comprehension, a student with an Action conception of quantification negation would need to have the logical structure of the proof explicitly written out. If the initial logical step is omitted (as they sometimes are in textbooks), he or she would not understand the proof as a whole. Chandler expressed a difficulty with an omitted negation in Session 1 with the following claim and first line of a proof:

> *Claim:* If every even natural number greater than 2 is the sum of two primes, then every odd natural number greater than 5 is the sum of three primes.
> *Proof:* Assume that every even natural number greater than 2 is the sum or two primes and that it is not the case that every odd natural number greater than 5 is the sum of three primes.

Chandler is initially unable to recognize the hidden negation step of the above proof, stating "I'm not sure when something contradicts, if you begin with 1, step 1. The assumption, or the given, was that P and Q. If you begin with P and not Q, it's already a contradiction, isn't it? No?" Once the intermediary step, "Assume it is not true that if every even natural number greater than 2 is the sum of two primes, then every odd natural number greater than 5 is the sum of three primes" and how this statement relates to the first statement of the proof "That is, assume that every even…" was presented, Chandler indicated he understood the first statement was a rewrite of the negation of the claim. This enabled Chandler to understand the logical underpinning of the proof.

Discussion

When Chandler was prompted to convert statements to propositional logic to negate and then convert back to mathematical language, he was successful in understanding (locally and globally) how statements of the proof logically followed. Converting statements to propositional logic for negation also aided Chandler in understanding the "logical leaps" of presented proofs, such as those that begin with the negated version of a statement and not with a phrase such as "Assume the statement is not true; that is …" that would indicate a proof by contradiction. While other authors have found difficulties negating quantification to affect student construction of proofs (Antonini & Mariotti, 2008; Lin, Lee, & Wu Yu, 2003), Chandler's comprehension after logical quantification suggests that a student's ability to negate quantification plays an early role in student comprehension of proof by contradiction.

Future Plans

Data collection and analysis will continue in spring 2017. A major goal for this semester will be to refine the preliminary genetic decomposition for proof by contradiction that guides the design of this study, provided below.

Preliminary Genetic Decomposition for Proof by Contradiction

1. Students outline the propositional logic of a given proof to develop specific step-by-step instructions to construct proofs by contradiction for the following types of statements: (i) implication, (ii) single-level quantification, and (iii) property claim.
2. Students interiorize each of the Actions in Step 1 individually by examining the purpose of statements of given proofs. These Processes become general steps to writing a proof by contradiction for statements of the form (i), (ii), and (iii).
3. Students coordinate the Processes from Step 2 by comparing and contrasting the general steps to determine the necessary steps for *any* proof by contradiction. This Process becomes general steps to writing any proof by contradiction and identifying a proof as a proof by contradiction.
4. Students encapsulate the Process in Step 3 as an Object by utilizing the law of excluded middles to show proof by contradiction is a valid proof method. Students can now comprehend proofs on a holistic level.
5. When necessary, students de-encapsulate the Object in Step 5 into a Process similar to Step 3 that then coordinates with a Process conception of quantification to prove multi-level quantified statements.

Defining Functions: Choices That Affect Student Learning

Joshua Chesler
California State University, Long Beach

Textbook authors and instructors choose how to define the concept of function for students. This study examines the impact of definition choice on the mathematics work of graduate students, all of whom were mathematics majors and most of whom are in-service mathematics teachers. Data are student work on tasks requiring the application of different textbook definitions of functions. By drawing on ideas about action vs. object conceptions of function, it is hypothesized that certain linguistic features of definitions may affect students' abilities to use the definition and to build a robust concept image of function.

Key words: Definitions, Functions, Curriculum

Undergraduate mathematics programs must prepare future mathematics teachers to teach functions, a central topic in the secondary mathematics curriculum in the United States. Functions account for one of just six conceptual categories in the Common Core State Standards for Mathematics (CCSSM) for high school (Common Core Standards Initiative, 2010) and are a linchpin for much of the undergraduate mathematics curriculum. However, high school teachers often have a shaky understanding of the concept of function, exhibiting disconnected knowledge that is more procedural than conceptual (Doerr, 2004). Not surprisingly, their students are similarly challenged in their understanding of function (Kieran, 2007). This study investigates the impact of the choice definitions of functions in introductory algebra textbooks.

As shown below, different textbooks present definitions of functions that vary in their wording and are not always mathematically equivalent. These wording choices by textbook authors may have consequences in K-16 mathematics education. For example, the CCSSM's description of the standards for mathematical practice (i.e., what it means to *do* or *practice* mathematics) note that "mathematically proficient students understand and use stated assumptions, *definitions* [emphasis added], and previously established results in constructing arguments" (CCSI, 2010, p. 6). Accordingly, the big question which underlies this study is: How does the choice of definition of function impact learning and understanding? Unpacking this question, the study focuses on the questions:

1. Are some definitions more "usable" than others?
2. Does a definition respect what we know about students' knowledge development?

These questions are investigated by examining the work of in-service mathematics teachers, all of whom have undergraduate mathematics degrees, as they use different definitions of functions from high school textbooks. The preliminary results reported below indicate that, indeed, choice of definition matters.

Theoretical Framework

Understanding Functions

Much has been written about understanding of functions (for an overview see Kieran, 2007). For present purposes, the focus is to distinguish between (1) someone who sees a function as instructions to do something, and (2) one who sees a function as an object. There are several frameworks which explicate the broad idea behind this division. Sfard and Linchevski (1994), for example, described a theory of reification in which learners of mathematical concepts first hold an operational conception (process-oriented). They describe reification as "our mind's eye's ability to envision the result of processes as permanent entities [objects] in their own right" (p. 194). A learner's concept of function, through reification, progresses from operational to structural/object-oriented. APOS theory describes a similar trajectory for an individual's mental construction of a mathematical concept in terms actions, processes, and objects organized in schema (Dubinsky & McDonald, 2001). In the context of functions, an action conception may be to think of a function as a recipe (given by a mathematical expression) applied to some number. For someone with a process conception, the action is "interiorized" through repetition and reflection so that it can be thought about more abstractly (i.e., without evaluating the expression which determines the function by "plugging in" a number). Someone with an object conception can operate on functions as if they were indeed objects. Such a person may, for example, understand functions as a special type of mathematical relation, a set of ordered pairs. Thompson (1994) describes the object level as entailing "an image of functional process as defining a correspondence between two sets: a set of possible inputs to the process and a set of possible outputs from the process" (p. 27).

For the purposes of this study, the action/process vs. object distinction is sufficiently granular. In particular, for the present analysis, no distinction is necessary between action and process conceptions. The distinction between action/process and object conceptions is viewed as hierarchical with an action preceding object conceptions of function, as Thompson (1994) contended. Though, as acknowledged in APOS theory, an individual's progression through these stages may be messy and nonlinear. Furthermore, Sfard (1991) notes that "the ability of seeing a function or a number both as a process and as an object is indispensable for a deep understanding of mathematics, whatever the definition of 'understanding' is (p. 5)." In the spirit of Sfard, a definition of "understanding" is not attempted. Instead, the focus is the distinction between an action/process conception and an object conception. Paraphrasing Ponce (2007), there is a difference between a student who thinks of *a function does something* and one who sees *a function as a thing*?

U.S. High School Textbooks and Definitions of Functions

Herein, the action/process vs. object distinction will be related to linguistic features of textbooks' definitions of functions and students' work using the definitions. Textbooks are conceptualized as curricular materials in accordance with Remillard's (2005) definition, "printed, often published resources designed for use by teachers and students during instruction" (p. 213). The study is framed by Remillard's description of curriculum use as a participatory relationship that is influenced by characteristics of the individual (beliefs, pedagogical content knowledge, etc.) and by features of the curriculum (voice, representation of concepts, etc.). The curricular materials of relevance to this study are three U.S. high school introductory Algebra textbooks, specifically their treatment of functions. The textbooks were selected as a convenience sample; these were readily available books on the researcher's shelf. The main goal was to capture a variety of definitions, and these textbooks provided that. The following are the textbooks' definitions of function (emphasis added):

- Definition 1. (*CME Project Algebra 1)* "A function is a *rule that* assigns each element from the set of inputs to exactly one element from the set of outputs" (Center for Mathematics Education, 2009, p. 421).
- Definition 2. *(McDougal Little Algebra 1 California)* "A function consists of:
  A set called the domain containing numbers called inputs, and a set called the range containing numbers called outputs… A *pairing of* inputs with outputs such that each input is paired with exactly one output." (Larson, Boswell, & Kanold, 2006, p. 35).

- Definition 3. *(Holt Algebra 1)* "A relation is a set of ordered pairs. The domain of a relation is the set of the first coordinates. The range of a relation is the set of second coordinates. A *relation that* assigns to each value in the domain exactly one value in the range is called a function" (Burger, 2008, pp. 206–207).

According to these definitions, a function may be thought of as a rule, pairing, or relation; that is, a function can be thought of as three different *types of objects*. Other differences are apparent as well. Definition 3 describes first and second coordinates, the other two describe inputs and outputs. Definition 2 is not equivalent to the other definitions as it defines the inputs/outputs of functions to be numbers; the others are less restrictive. Thus, without much effort, it is easy to find differences in the way high school textbooks define this essential mathematical object. This study focuses on the *type of object* that a function is defined as and how that may help learners negotiate between action/process and object levels of understanding.

Methods

Mathematics graduate students were asked *to use* each of the three definitions of functions to do two tasks:

Task 1. Show that the equation $y = x + 1$ determines y as a function of x.

Task 2. Show that sequences are functions.

The research subjects were 23 graduate students in a master's program in mathematics (option in secondary mathematics education), all of whom had undergraduate degrees in mathematics or mathematics education and were credentialed secondary mathematics teachers. All but three were either currently teaching or had previously taught middle or high school mathematics. The research subjects' statuses as current or future teachers and mathematics majors are of relevance to the study's implications; participants may be viewed dually as students and teachers of mathematics.

Operating under the hypothesis that certain features may make a definition more "usable" for students and teachers, "using a definition" was operationalized by checking if the type of object was somehow referenced in a student's response. For example, to use Definition 1 a student would need to describe how the given equation or an arbitrary sequence determines a "rule". Of particular interest was whether the student used a verb form of the object. For example, in using Definition 2 (function as a pairing), did the student say something like, "A sequence *pairs* integers with terms." Data are being coded for whether the student used the definition, how s/he used it (e.g., using a verb form of the object), and whether s/he used it correctly.

This activity was assigned prior to any treatment of functions in the course. The nature of prior instruction about or experiences with functions was not probed. Though, the participants' undergraduate mathematics degrees were assumed to be preparation for answering the questions.

Preliminary Results

There is compelling preliminary evidence that students have more success if function is defined as an object which has an accessible verb form. This is exemplified by the work of the following student (a graduate student and high school mathematics teacher). In using Definition 1, she never explicitly stated how the equation in Task 1 determines a rule and instead focuses on actions (e.g., plugging in). In using Definition 2, she used the verb form of the noun/object "pairing" to describe how inputs are "paired with" outputs and provided a more complete answer.

- Using Definition 1 (function as rule): "The equation $y = x + 1$ determines y as a function of x because for each value that you plug into x, you will produce exactly one value for y.

For example, if you plug in 2 for x, you will get 3 for y."

- Using Definition 2 (function as pairing): "For each pairing of inputs and outputs, each input value is paired with exactly one output value. For example, if the domain is {–2, 0, 5} then the range is {–1, 1, 6} and the pairing of inputs and outputs would be {(–2, –1), (0, 1), (5, 6)}. Each input is paired with exactly one output."

This student's response for Definition 1 never addressed why or how the equation determines a rule. Yet her response for Definition 2 indicates that she does, in fact, understand the conventions for using a definition. By making use of the verb form of the noun "pairing," she explicitly connected her explanation to given definition.

In using Definition 2, participants had a preference for using the verb construction "is paired with" to explaining why the equation $y = x + 1$ is "a pairing." Furthermore, the definition itself makes use of both forms, perhaps modeling flexible language use for students. Though a verb form may be available for the noun/object "relation" in the form of "to relate," only one student used it one time whereas the phrase "paired with" appears in 30 out of the 46 student responses for Tasks 1 and 2 using Definition 2. It is hypothesized below that access to a verb form may help students coordinate between action/process (verb) and object (noun) conceptions of function.

There is indication that Definition 1 (definition as rule) is particularly challenging. Only 10 students correctly used the definition to answer Task 1, and two of those answers showed some confusion. Data are still being analyzed, but will be probed too see if the lack of a readily accessible verb form of the word *rule* may have played a role – the verb *to rule* certainly wouldn't have helped.

At least three other themes have emerged in the initial analysis that will be investigated through the data. First, students did very poorly in explaining why sequences are functions regardless of the choice of definition. Second, students' use of future tense may offer further evidence of a use of an action conception of function. For example many students wrote something similar to this student's explanation: "By substituting a value of x from the domain into this equation, one will find a value of y." That is, given an input, the function performs an *action* that will result in an output. In the first example of student work in this section, the future tense was used with Definition 1 (rule) but not Definition 2 (pairing). Third, many students displayed confusion about the difference between sets and elements of a set (e.g, "A sequence is a rule with each element in the input assigns exactly one element in the output."). Other students referred to x and y as sets. Such confusion could hinder use of definitions.

Discussion

This is a preliminary report, but it offers some evidence that the definitions we choose matter. It has implications for the undergraduate preparation of mathematics students in general and future mathematics teachers in particular. Students who have action/process conceptions of functions may be challenged by definitions which do not accommodate the use of action words. The connections between an action/process conception & verb and between an object conception & noun may be more than just a linguistic novelty. For example, there is not a convenient verb form for noun "rule" as there is for the noun "pairing." This subtle difference may make a difference in a student's ability to use a definition and negotiate the transition to an object conception of function. Perhaps making sense of Definition 1 (function as rule) is more likely to require a student to have an object conception of function. Though a verb form may be available for the noun/object "relation" in the form of "to relate," only one student used it one time whereas the phrase "paired with," wording used in the definition, was commonly used. At this point in the analysis, it seems like students have more success when using action verbs.

The abstract ideas of relations, sets, and rules may pose challenge for students who do not yet have object-level conceptions. It is noteworthy that these definitions came from an *introductory* high school algebra textbook, yet presented challenges for many mathematics majors. The study raises questions about choices of definition in introductory courses at all levels. Perhaps we should heed Thompson's (1994) call for "curricula that are mathematically sound, but nevertheless are constructed from the start with an eye to building students' understandings" (p. 40). It is not enough for a definition to merely be mathematically correct – it must also accommodate beginning students' action-level mathematical conceptions.

There are, of course, many other variables at play in this investigation. For instance, especially in the case of Task 2 (about sequences), many participants' lack of mathematical knowledge or fragile concept images obfuscated the role of the definitions' wording. Also, the use of language related to sets may have played some role in participants' abilities to use the definition. Ongoing data analysis will further reveal the extent to which word choice in definitions may help or hinder the transition from action/process to object-level conceptions of functions.

Analysis and interpretation of these data and directions for future research will be guided by audience discussion prompted, in part, by the following questions:

1. Regarding the emergent themes (language about sets, use of future tense, sequences as functions), which of these are worth further investigation? How do they fit in with the main idea of thinking about definition use by students with action-level conceptions?
2. In general, these participants (as math majors) knew the conventions of using a definition. What role is that playing? How does this impact the generalizability of the results to beginning students?
3. What are the implications for secondary mathematics teacher preparation programs? For definition choice in general?

Hypothesis testing is a key concept included in many introductory statistics courses. Due to common misunderstandings of both scientists and students, the use of hypothesis testing to interpret experimental data has received criticism. This paper describes preliminary results obtained from a larger study designed to investigate introductory statistics students' understanding of one sample hypothesis testing. APOS theory is used as a guiding theoretical framework. Preliminary data analysis focused on two students' distinctions between test statistics when performing hypothesis tests on real world data. The results suggest a significant difference in these two students' understanding, one being identified having an action conception while the other had an object conception of hypothesis testing as situated in the study.

Key Words: Hypothesis Testing, Statistics, Test Statistics

Introduction

The use of statistics is crucial for numerous fields, such as business, medicine, education, and psychology. Due to its importance, statistics education has seen rapid growth over the past three decades (Vere-Jones, 1995). In the United States today, the Common Core State Standards for Mathematics calls for students to "understand statistics as a process for making inferences about population parameters based on a random sample from that population" (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010, p. 81).

One method of making inferences (formulating a conclusion) about a population is hypothesis testing, which is widely used by researchers in the social sciences and is a key concept included in many introductory statistics courses. However, the use of hypothesis testing to interpret experimental data has received criticism (Nickerson, 2000) due to the common misunderstandings of both scientists and students when using this method (Batanero, 2000; Dolor & Noll, 2015; Vallecillos, 2000). LeMire (2010) defends the use of hypothesis testing and provides a framework that can be used to revise instructional content with the goal of further developing student understanding. This is an indication that on-going research should investigate students' understanding and curriculum effectiveness in light of the critiques surrounding methods of inference.

In this preliminary research report, we focus our attention on the following research question: What are students' understandings of hypothesis testing in two distinguished real world situations?

Theoretical Framework

The guiding theoretical framework for our larger study is APOS Theory (Asiala et al., 1996). APOS Theory is a framework which models an individual's mathematical conception using Actions, Processes, Objects, and Schema. An Action is an externally driven transformation of a mathematical object (or objects). An Action can be described as an individual needing an external cue to follow, such as a step-by-step example. Once Actions are repeated and reflected on, an individual can start to interiorize them to become a Process. A Process no longer requires step-by-step external cues. An individual is now able to internally imagine the steps in a transformation, without having to actually perform them. When an individual is then able to see the Process as a totality, is aware that transformations can be applied to it, and can construct these transformations, then the Process has been encapsulated into an Object. The collection of all mental constructions of Actions, Processes, and Objects forms an individual's Schema of a particular mathematical concept.

Methodology

The focus of our study is on university students who are enrolled in an introductory statistics course based on the emporium model. The emporium model, originated at Virginia Tech, includes key components of "interactive computer software, personalized on-demand assistance, and mandatory student participation" (Twig, 2011, p. 26). For this particular institution, each week students were required to spend three academic hours in a computerized mathematics lab, as well as attend one academic hour class each week with an instructor. The time in the mathematics lab was spent actively learning using the mathematical software MyStatLab by Pearson. Students were also engaged in activities such as reading and discussing about the subject content with their peers, graduate and undergraduate lab assistants, and instructors.

Elementary Statistics Using Excel was the textbook used in the course, written through Pearson and adapted specifically for the university (Triola, 2014). The textbook describes a test statistic as "a value used in making decisions about the null hypothesis," (p. 415). While assuming the null hypothesis is true, a test statistic is found by converting a sample statistic, whether that is a sample proportion or a sample mean, to a standardized score. As students for the course are required to calculate a p-value for most hypothesis tests, the text describes the p-value as the "probability of getting a value of the test statistic that is at least as extreme as the one representing the sample data, assuming that the null hypothesis is true," (Triola, 2014, p. 416). Although we discuss test statistics as one mathematical term or value, there is a distinction needed to be noted between test statistics calculated from sample proportions versus sample means. Specifically, in our study, the distinction needs to be made between the normal distribution and the Student's t distribution.

For proportions, students always assume a normal distribution, and thus calculate test statistics which are z-scores. When calculating a test statistic for a sample representing a population mean, we are referring to a standardized value that represents the extremeness of your sample in regards to what is expected. For means, students learn about test statistics in hypothesis testing for the normal distribution (z-scores) and the Student's t distribution (t-scores). Although these distributions appear similar, the distinction occurs depending on what we know about our sample. In particular, if we know the population standard deviation, then we know how the data is spread out and can use the normal distribution (z-scores). However, if we do not know the population standard deviation, but can estimate it with the sample standard deviation, we can use the Student's t distribution to estimate how the population is spread. For this reason, t-scores are greater than or equal to z-scores for the same value of n (equal as n approaches infinity) in order to overcompensate for the lack of knowledge of the distribution (see Figure 1).

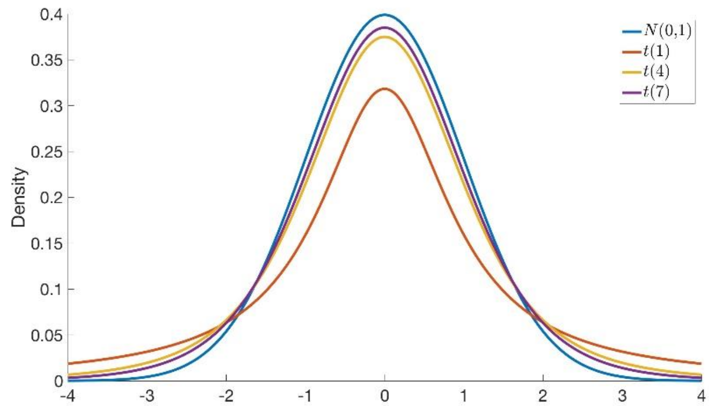

Figure 1. Graphical Representation of Normal Distribution and Student's *t* Distribution

Data was collected from these classes during the Fall 2014 and Spring 2015 semesters. Data consists of all students' work (more than 1,500 students) on hypothesis testing, including homework, quizzes, and tests. Semi-structured interviews took place with a targeted group of students of different capabilities. For this preliminary report, we will focus on two of the nine problem solving/interview sessions as the primary source of data. During the problem solving sessions, each participant worked alone on two hypothesis test questions. Following this, they participated in a semi-structured interview to further elaborate over the problems they solved. The first question asked the student to conduct and interpret a hypothesis test for a single population proportion. The second question asked the student to conduct and interpret a hypothesis test for a single population mean. The questions were as follows:

1. In a recent poll of 750 randomly selected adults, 588 said that it is morally wrong to not report all income on tax returns. Use a 0.05 significance level to test the claim that 70% of adults say that it is morally wrong to not report all income on tax returns. Use the *P*-value method. Use the normal distribution as an approximation of the binomial distribution.
2. Assume that a simple random sample has been selected from a normally distributed population and test the given claim. In a manual on how to have a number one song, it is stated that a song must be no longer than 210 seconds. A simple random sample of 40 current hit songs results in a mean length of 231.8 seconds and a standard deviation of 53.5 seconds. Use a 0.05 significance level to test the claim that the sample is from a population of songs with a mean greater than 210 seconds.

Students had seen these exact questions on their homework and quizzes when using the MyStatLab software. The only difference was that for the problem solving/interview sessions they did not have multiple choice/drop down menus as an option to answer the questions. Since there was active learning associated with these concepts in the mathematics lab and in class, students were expected to know how to conduct and interpret hypothesis tests for both questions, and in particular, they were expected to know to use the normal distribution to find the test statistic for Question 1 and the Student's *t* distribution to find the test statistic for Question 2.

Preliminary Results

Our preliminary results indicate that students are not always able to make distinctions between test statistics. Several students used the normal distribution to find the test statistic for not only Question 1, but also for Question 2. For those that did use the normal distribution when calculating the test statistic for Question 1 and the Student's t distribution for Question 2, some still could not articulate why they used two different test statistics or the relationship between the two test statistics. A common approach to finding the test statistic was to first look for key words, which suggests an Action conception of test statistic. This worked for some, however, others got confused with the language in the problems. For this preliminary report, we will describe the different approaches utilized by two students, Steve and Lana, and discuss the interpretations that helped them decide which test statistic to use.

Steve

For Question 1, Steve used the common approach of identifying key words to recognize which test statistic to use. He explained, "I immediately thought of these two formulas, and at first I wasn't sure which one to use, and then I was like, oh wait, there's no x-bar or mu or standard deviation. So that makes it pretty easy." He used a system of elimination to decide which formula not to use. Even though he correctly identified the test statistic, he went on to say that this is "just a formula that I've learned like any other" and that he "doesn't understand why we use that formula, other than we just use it". He concluded his explanation stating that Question 1 used a z-value because the problem was of proportions, what appears is likely a memorized rule applied to the problem.

For Question 2, Steve recognized that it was now a question of means, but mentioned that "it's basically the same problem" other than this discrepancy. Steve identified the distribution as normal because the question explicitly stated that "a simple random sample has been selected from a 'normally distributed' population". Based on the language in the problem, Steve associated the question with a normal distribution. He further explained that he would not know how to deal with a non-normally distributed population, that he could not recall learning anything other than a normal distribution, and that he did not know much about a Student's t distribution. Ironically, later in the interview, when asked if his answer was a z-value or t-value, he responded that it is "a t-value because you're testing means".

For Steve, it appeared as though he was basing his ideas of whether to use the test statistic associated with the normal distribution or the test statistic associated with the Student's t distribution off of key words found in the problems. When the problem for Question 2 included the phrase of "normally distributed", he used this to identify the question as a normal distribution. What could have been a result of memorized rules, led to a misconception of when to use the z-test and t-test. Steve appears to exhibit an Action conception of the test statistic as he relied on external cues, such as the key words in the problem, to identify which test statistic to use.

Lana

Lana, for Question 1, used the normal distribution to find the test statistic based on the fact that the problem was about proportions. To explain the test statistic, she initially explained how she was picturing the "big curve, the bell curve, and I'm picturing the test statistic is where the point that falls on there … so this is the mean right in the middle, and the test statistic is one side of it, saying this is how far away from what they are saying is the mean, this is what the mean of this, I guess that's what I'm thinking". Comparison of the mean and test statistic possibly indicated an

Object conception of test statistic. After her explanation, she then drew a picture to illustrate her thinking (Figure 2) of a graphical representation of the normal distribution.

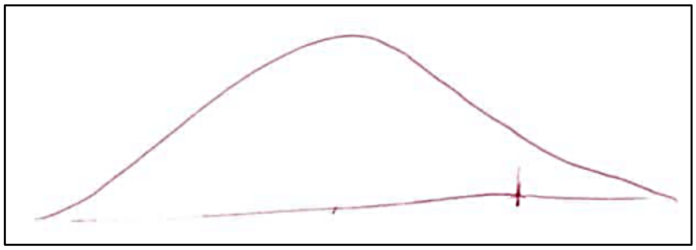

Figure 2. Lana's Graphical Representation of the Normal Distribution

For Question 2, initially, Lana in her written work used the normal distribution to find the test statistic. During the interview she became worried when asked if the question was a *z*-test. She mentioned that she remembered from high school to use a *t*-score if the sample is of 30 or less. After prompting, she realized she should have used a *t*-score, however, she also immediately recognized that her *z*-score would "probably not" be very different from the *t*-score. She knew that in the relationship between the two test statistics, "they are really close together".

Lana was able to picture in her head a graphical interpretation of the test statistic, and was also able to identify a relationship between the two test statistics, suggesting an Object conception. This was more than what most other students were capable of interpreting.

Concluding Remarks

Our data suggests that one area students have trouble with when conducting hypothesis tests on real world data is correctly identifying and interpreting which test statistic to use. Students with an Action level of understanding of hypothesis testing relied on memorizing facts and identifying key words. Without a deeper understanding, misconceptions emerged. Students who appear to base their understanding off of ideas and concepts, not memorized rules, seem to have a better grasp of the relationship between the two test statistics, and when and why to use each one. It is also suggested that not having the MyStatLab multiple choice/drop down solutions to choose from could have possibly influenced the students' responses in the analysis. The next step in analysis will be to further identify misconceptions and understanding related to hypothesis testing as a whole, not just the test statistic in particular.

Questions for the Audience

1. We have observed that the way students use certain mathematics software can influence students in developing a list of 'hints and shortcuts' for how to approach and solve certain types of problems. Does anyone in the audience have similar observations? How do we lower or eliminate this happening in our classes?
2. Does having multiple choice affect your students understanding of concepts? Do you observe your students trying to 'manipulate the system' to get correct answers instead of putting in the same amount of effort to understand the concept? How do you combat this issue?
3. Does the use of Excel versus other types of technology (calculators, statistical programs, etc) make a difference in the learning of students?

Spatial Training and Calculus Ability: Investigating Impacts on Student Performance and Cognitive Learning Style

Emily Cilli-Turner
University of Washington Tacoma

Lindsay McCunn
University of Washington Tacoma

Despite concerted efforts on the part of educational policy makers, women are still underrepresented in the STEM fields. Researchers have shown that calculus plays a major role in this gender disparity since it requires spatial skills to succeed: skills that women tend to lack compared to men. However, previous studies have shown that spatial ability is malleable and spatial skills can be improved with training. This pilot study employed spatial training in a third-term calculus course and measured the effects of this training on students' calculus ability, spatial rotation ability, and cognitive learning style. Associations between cognitive learning style and task performance were also measured. Preliminary results indicate that spatial training does not significantly impact student performance on a calculus skills assessment or a test of mental rotations, but effects on students' cognitive learning style are present.

Key words: spatial training, calculus skills, cognitive learning style

Introduction & Literature Review

While the call for more graduates in Science, Technology, Engineering and Mathematics (STEM) continues (Executive Office of the President, PCAST, 2012; Stieff & Uttal, 2015), women remain consistently underrepresented in these fields (Schlenker, 2015). The major cause of this gender gap may concern a sequence of courses in calculus. Calculus is universally required for STEM majors and, therefore, often acts as a gatekeeper to student success and continuation into STEM careers (Bressoud et al., 2015). However, women are 1.5 times more likely to change to a non-STEM career pathway after a calculus course than men (Ellis et al., 2016). Women may struggle with concepts in calculus because they rely heavily on visual representations: females to have been shown to have less developed spatial abilities (Ferrini-Mundy, 1987) and to underperform on spatial tasks compared to males, starting as young as four years of age (Levine et al., 1999; Voyer, Voyer, & Bryden, 1995). Other studies indicate that individuals with higher scores on spatial tests are more likely to enjoy STEM subjects and to choose careers in STEM (Wai, Lubinski, & Benbow, 2009).

While the body of literature seems to suggest that women may have a disadvantage in the STEM fields, encouraging evidence exists that practice with spatial concepts can improve spatial ability (Uttal, 2009; Stieff & Uttal, 2015) and that spatial training can decrease the gender gap in spatial thinking (Newcombe, 2010). We refer to this idea in the paper as *spatial training,* which we define as explicit instruction and practice on spatial skills such as rotation, planar views or unfolding of an object. At this time, knowledge about the benefits of spatial training is not conclusive concerning whether an increase in spatial ability has direct effects on performance in the STEM fields. A study conducted with engineering students found an association between spatial training and academic performance, as well as a closing of the gender gap (Sorby et al., 2013). However, very few studies exist that investigate the link between spatial training and mathematical skills. One study by Ferrini-Mundy (1987) required undergraduate students to complete spatial training exercises during a calculus course but did not find significant increases in calculus performance (although female students were better able to visualize solids of revolution than male students). Other research has found that while spatial training does reduce the gender gap in performance on spatial tasks, it fails to eliminate it (Uttal, 2009). Thus, a call has been made in the spatial cognition literature to extend this line of enquiry into the potential for spatial training to close the gender gap in the STEM fields by investigating new mediating variables and extending periods of spatial training (Casey, 2013).

One factor that may be associated with spatial and mathematical ability is the psychological construct of cognitive learning style. A cognitive learning style represents a coherence of a person's manner of cognitive function (i.e., information acquisition and processing) (Harvard Mental Imagery and Human-Computer Interaction Lab, 2013). Because the human visual system distinctly processes properties about objects (color, shape) and space (location and spatial relations), Kozhevnikov, Kosslyn, and Shephard (2005) have used neuropsychological evidence to propose the Object-Spatial-Verbal theoretical model of cognitive style. This model outlines three independent dimensions (object imagery, spatial imagery, and verbalization) to explain that object visualizers prefer to construct vivid, concrete, and detailed images of individual objects, spatial imagers schematically represent spatial relations of objects and spatial transformations, and verbalizers prefer to process and represent information verbally and rely on non-visual strategies (Kozhevnikov, Kosslyn, & Shephard, 2005).

It seems that preference for one of the three strategies has been shown to directly relate to one's performance on either mathematical, object imagery ability, or spatial ability tests (MM Virtual Design, 2016). Thus, cognitive learning styles may assist math educators to tailor material, assignments, and visualization media to students' individual differences in cognitive learning style and decision-making based on visual stimuli. Learning and performance based on visual information presented in a manner congruent to one's cognitive learning style may help close the gender gap in STEM. Indeed, Peters et al. (1995) found that women report using verbal strategies to solve mental rotation tasks more often than men and Casey (2013) points out that one reason why large gender differences are found for mental rotation tasks is because verbal strategies are often less effective than holistic mental rotation approaches used more often by men. Thus, measuring cognitive learning style in association with spatial ability and an understanding of calculus may afford information about whether those with predominant verbal cognitive learning styles are women, as well as whether their performance in calculus improves with spatial training.

This study targets the lack of literature investigating effects of spatial training on mathematical skills and seeks to answer the following research questions: (1) What are the impacts of spatial training on undergraduate students' performance in calculus? (2) Are differences present in the effects of spatial training between male and female students? And (3) What are the impacts of spatial training on students' cognitive learning style?

Methods

Context

The study took place at a mid-sized state-funded university in the northwestern United States in a summer 2016 quarter. All student participants were enrolled in a third-quarter calculus course covering the calculus of sequences and series, vectors equations, and multi-variable functions. The course was taught using an inquiry-based learning pedagogy; spatial training was incorporated during class time.

Spatial training was conducted for, on average, 10 minutes during every class meeting (twice per week for 10 weeks). Students completed exercises from a spatial training workbook developed by Sorby et al. (2013; and used with permission). Exercises in the workbook ranged from assessments of what a given shape would look like when rotated around a given axis, to asking students to draw an object from different angles using different cross-sections, to showing 2-D views of an object and asking students to draw the 3-D object. During the spatial training portion of class, students were asked to discuss the exercises in small groups and come to a consensus on the correct answer before answers were discussed with the whole class.

Participants

Participants had already completed two quarters of undergraduate calculus and spent an average of 12 hours a week (SD = 3.70) studying course material. Seventeen students (8 males, 9 females) attended class for both rounds of data collection and all but one took part in the study (n = 16; 8 males, 8 females, mean age = 21 years). Five (31%) participants reported enrollment in another math course during the quarter while 11 participants (69%) reported that they were not receiving other forms of math training at the time of the study.

Data Collection

Participants were given three separate instruments in a pre-post data collection model that measured spatial ability, calculus ability, and preferred cognitive learning style. The measurement of spatial ability was obtained using a 15-item version of the Purdue Spatial Visualization Test: Rotations (PSVT:R) (Guay, 1977). This multiple-choice instrument gives an example of an object and a rotation of the same shape and asks participants to choose (from 5 possibilities) the result of the same rotation on a new object. The PSVT:R was used to obtain a baseline measure of spatial ability and to quantify improvements from the spatial training. The Calculus Concept Inventory (CCI) was administered to measure calculus ability. This instrument, designed by Epstein (2013), measures students' understanding of the basic concepts of differential calculus. The CCI contains 22 questions about limits and derivatives, many of which require interpretation of a graph or visual aid. The Object-Spatial Imagery and Verbal Questionnaire (OSIVQ) developed by Blazhenkova and Kozhevnikov (2009) was used to measure students' predominant cognitive learning style. The OSIVQ consists of 45 questions to assess object imagers, spatial imagers, and verbalizers and takes approximately 10 minutes to complete. Each item asked students to rate their agreement on a 5-item Likert scale ranging from "totally disagree" (1) to "totally agree" (5) with statements of preference or ease of performing various tasks.

Additionally, basic demographic questions, such as age, gender, and the number of courses related to mathematics taken at the post-secondary level were asked. To gain an understanding of students' concurrent exposure to mathematical and spatial concepts outside of the training, and the course in general, students were asked to report whether they were receiving (or intended to receive) alternative instruction or tutoring during the term (e.g., enrollment in a different math course or spending time at the learning and teaching center), as well as the number of hours of this additional instruction per week.

All instruments were administered to participants during class time and no significant time pressure was placed on the students. Tasks were administered to participants in the following order: consent form; OSIVQ; Visualization and Rotation Purdue Spatial Visualization Test; Calculus Concept Inventory. Thus, the tasks were not completed simultaneously: only when a task was completed was the next task offered to a participant by one of the authors. No calculators or other electronic devices were used during task completion.

Results

The CCI and PSVT:R were scored by assigning 1 point for a correct answer and 0 points for an incorrect answer. Descriptive statistics for each inventory separated by gender are given in Table 1. To answer our first research question, students' pre- and post-test scores were computed and a paired-samples *t*-test was performed to determine significant improvements in calculus ability. No significant improvement was revealed over the term ($p > .05$). While male participants' average scores were higher on the CCI than women at the start of term ($M = 9.63$, $SD = 4.47$ and $M = 7.75$, $SD = 7.75$, respectively), they were not significantly higher ($p > .05$). This result was also borne out at the end of term whereby male students' average scores on the CCI were insignificantly higher than female students' scores ($M = 10.25$, $SD = 2.09$ and $M = 8.25$, $SD = 1.40$, respectively).

Table 1:
Descriptive Statistics for Test Variables Per Gender Type

Variable	Gender	Mean *Round 1*	Standard Deviation *Round 1*
CCI (scored out of 22)	Male	9.63	4.47
	Female	7.75	3.45
PSVT:R (scored out of 15)	Male	9.88	4.29
	Female	9.75	2.05
OSIVQ: Spatial (scored out of 75)	Male	49.75	2.74
	Female	46.13	3.44
OSIVQ: Object (scored out of 75)	Male	47.00	2.67
	Female	50.13	2.26
OSIVQ: Verbal (scored out of 75)	Male	42.75	1.40
	Female	39.50	1.58
		Round 2	*Round 2*
CCI (scored out of 22)	Male	10.25	2.09
	Female	8.25	1.40
PSVT:R (scored out of 15)	Male	10.5	1.45
	Female	9.25	1.24
OSIVQ: Spatial (scored out of 75)	Male	54.00	2.19
	Female	47.50	3.70
OSIVQ: Object (scored out of 75)	Male	52.38	3.42
	Female	49.25	2.04
OSIVQ: Verbal (scored out of 75)	Male	45.38	0.80
	Female	40.13	1.42

To determine an association between students' spatial ability and mathematical ability, a correlation coefficient for a student's final grade in Calculus III and their final PSVT:R score was calculated. This correlation ($r = 0.4283$) was not significant ($p > .05$). Additionally, a paired-samples *t*-test did not determine a significant improvement in students' rotational ability during the term ($p > .05$). Consistent with previous studies (Levine et al., 1999; Voyer, Voyer, & Bryden, 1995), male participants' average scores were higher on the PSVT:R than women at the start of term ($M = 9.87$, $SD = 4.29$ and $M = 9.75$, $SD = 2.05$, respectively), and at the end of the term ($M = 10.5$, $SD = 1.45$ and $M = 9.25$, $SD = 1.24$, respectively). However, these differences were not significant ($p > .05$).

On average, more students at the start of the term self-identified as object learners ($M = 48.56$, $SD = 7.00$) than they did as spatial learners ($M = 47.94$, $SD = 8.69$) or verbal learners (M

= 41.13, SD = 4.41). Indeed, scores on the spatial sub-scale were significantly higher than on the verbal sub-scale, $t(15) = 3.97$, $p = .001$. In addition, scores on the spatial sub-scale were significantly higher than those on the object learner sub-scale, $t(15) = -2.98$, $p < .01$.

After 10 weeks, the object cognitive learning style remained the predominant style for the class as a whole (M = 50.81, SD = 7.87) and, similar to the start of term, the second-most common learning style among the class was spatial (M = 50.75, SD = 8.96), followed by verbal (M = 42.75, SD = 4.16). However, unlike at the start of the term, these differences were significant: students sscored significantly higher on the object learning style sub-scale compared to the verbal learning style sub-scale, $t(15) = -3.57$, $p < .01$. They also self-scored significantly higher on the spatial sub-scale compared to the verbal sub-scale, $t(15) = -3.55$, $p < .01$.

Although mean scores on each of the three sub-scales increased over the term, paired-samples t-tests revealed only one significant difference between sub-scale scores over time. Students did not self-score significantly better or worse on the object or verbal subscales over time (all ps > .05). They did self-score significantly higher on the spatial sub-scale at the end of the term after receiving spatial training, $t(15) = -2.59$, $p < .05$.

At the start of the term, the men in the sample identified most, on average, as spatial learners (M = 49.75, SD = 2.74) and least as verbal learners (M = 42.75, SD = 1.40). This was also the case at the end of the term (see Table 1). In contrast, the highest average score among the three cognitive learning styles for women was on the object sub-scale (M = 50.13, SD = 2.26) while the lowest was on the verbal subscale (M = 39.50, SD = 1.58) and remained so at the end of term.

While participants' general perceptions of dominant learning styles remained stable over 10 weeks, each gender's scores increased on each sub-scale -- except that women's scores on the object learning style sub-scale decreased slightly (but insignificantly, $p > .05$) over time.

After the first round of data collection, independent samples t-tests revealed no significant differences between male and female participants' scores on the three OSIVQ sub-scales (all ps > .05). However, at the end of the term, a significant difference between men and women's scores on the verbal sub-scale of the OSIVQ was revealed, $t(14) = 3.22$, $p < .01$.

Finally, scores on the spatial sub-scale of the OSIVQ did not correlate significantly with high scores on the PSVT:R at the start of the term ($p > .05$) but did so at the end of term ($r = .62$, p =.01). No other significant correlations were revealed between scores on the PSVT:R and other sub-scales of the OSIVQ, nor were there any significant associations between scores on the OSIVQ sub-scales and the CCI at the start or end of the term.

Discussion & Future Work

This pilot study revealed that students who self-identified more as object or spatial learners than verbal learners did so significantly more strongly after spatial training. In particular, a strong identification as a spatial learner linearly associated with mental rotation ability after spatial training. However, spatial training alone did not significantly impact the calculus or mental rotation abilities of undergraduate students. The results of this research will inform an adjustment to the methods before a second study is undertaken with a second-term calculus course. Since the present study was done during a summer term, only a total of 18 classes occurred, with approximately 15 minutes of spatial training done per class. This may not be sufficient for students to be influenced by the training: indeed, less than half of the items in the workbook were completed during the term. Thus, the next iteration of this research will require students to complete some training modules independently to allow more time for an effect.

Applying Variation Theory to Study Modeling Competencies

Jennifer A. Czocher
Texas State University

This paper presents preliminary results of using variation theory to design modeling tasks in order to explore ways of strengthening undergraduate engineering students' modeling skills. The responses of two undergraduate engineering students enrolled in differential equations to a set of three versions of the same task are reported.

Key words: mathematical modeling, qualitative methods, differential equations, variation theory

Mathematical modeling has been identified as a critical component of students' mathematics education at all levels, but in particular for preparing them for successful STEM careers (Cai et al., 2014; PCAST, 2010). Mathematical modeling can be seen as defining a mathematical problem from a nonmathematical situation, a process Freudenthal referred to as *horizontal mathematizing* (Freudenthal, 1991). STEM students struggle to define mathematical problems because there can be an overwhelming number of real-world considerations that they might not be able to handle mathematically. The goal of this study was to explore how purposeful variations in the real world conditions explicitly given in modeling tasks might aid students in strengthening their abilities to connect real world conditions and constraints to mathematical properties, parameters, structures, and representations.

Theoretical Background

Mathematical Modeling

A mathematical model is a real-world system, a mathematical system, and a relationship between the two that maps the objects, properties and relationships from one system to the objects, properties, and relationships of the other system. Mathematical modeling is a nonlinear, iterative process that renders a real world situation as a mathematical problem that can be analyzed mathematically (e.g., Blum & Leiß, 2007). The results of mathematical analysis are then interpreted and validated against constraints from the real world situation. Two competencies have a reputation of being the most difficult: *simplifying/structuring* and *mathematizing* (Galbraith & Stillman, 2006; Stillman, Brown, & Galbraith, 2013). Simplifying/structuring consists of identifying conditions and assumptions of the real-world situation then selecting variables or constraints deemed to be important. Mathematizing introduces conventional representational systems (equations, graphs, tables) to present mathematical "properties and parameters that correspond to the situational conditions and assumptions that have been specified" (Zbiek & Conner, 2006, p. 99). Previous research has found that students' real-world reasoning is important to students' ability to define a mathematical problem (Stillman, 2000) and that the modeler's initial interpretation of a problem situation evolves in tandem with their construction of the mathematical model (Lesh, Doerr, Carmona, & Hjalmarson, 2003). Thus it is important to find ways to help students connect their real-world knowledge to their mathematical knowledge.

Variation Theory

In task design, variation theory focuses on what varies and what remains invariant in a sequence of tasks such that "desirable regularities might emerge from the learners' engagement with the task" (Watson & Mason, 2006, p. 93). Dimensions of variation occur across tasks (they operate like variables) and ranges of change are values those variables can take on. For the modeling tasks presented below, the dimensions of variation are the real world constraints for which assumptions are given explicitly. When the real world constraints are given explicitly as assumptions in the task statement, they can be immediately mathematized. For example, consider a liquid contaminated with 4 grams of chemical agent per liter entering a tank at a rate of 5 liters per minute. The amount of contaminant remaining after one minute is 20 grams. In contrast, not stating information about the liquid entering the tank could lead to the more general model $c_i(t)r_i(t)t$ of the amount of contaminant in the tank at time t, where c_i represents the concentration of contaminant entering and r_i represents the rate at which the liquid enters. The second mathematization requires the assumption that concentration and rate can vary in time.

One use of variation theory is to guide successive versions of tasks across design cycles. Here, I present students' responses to the first iteration of a set of tasks designed to direct students' attention to similarities and differences in real-world situations drawn from the same context – reflected by the information stated in the task. The students then reflected on the similarities and differences in mathematical structures and representations used to model them.

Methods

Participants and Interviews

Mance and Orys were sophomore male engineering undergraduates participating in a larger research study of undergraduate STEM majors' mathematical thinking during mathematical modeling (Czocher, 2016). Each was enrolled in a first course on differential equations. Mance's instructor focused on solution techniques. In contrast, Orys's instructor focused on applications and modeling with differential equations. I focus on the work of Mance and Orys here because they successfully engaged with all three versions of Tropical Fish Tank task (presented below). As part of the larger study, Mance and Orys participated in a series of one-on-one task-based interviews (Clement, 2000; Goldin, 2000). I refrained from teaching or correcting the students' work in order to minimize influence on their reasoning. My questions focused on making students' implicit assumptions explicit and on understanding how the participants were selecting mathematical representations and structure. The interviews were audio/video recorded and transcribed. Analysis examined the students' implicit and explicit assumptions and the ways they connected their real world knowledge to their mathematical knowledge.

The Task and Its Variations

The real-world situation presented in the Tropical Fish Tank task can be modeled with a first-order, inhomogeneous, differential equation. Three versions were used for this study:

Version 1. To regulate the pH balance in a 300L tropical fish tank, a buffering agent is dissolved in water and the solution is pumped into the tank. The strength of the buffering solution varies according to $1 - e^{-\frac{t}{60}}$ grams per liter. The buffering solution enters the tank at a rate of 5 liters per minute. How much buffering agent is in the tank at any point in time?

Version 2. To regulate the nutrients in a 300L tropical fish tank, a buffering agent is dissolved in water and the solution is pumped into the tank. Because the fish are more active during the night than during the day, the strength of the solution entering the tank varies. A book on pet care suggested that the strength might vary according to $\sin\left(\frac{t}{45}\right)$. The buffering solution enters the tank at a rate of $.25$* liters per minute. One morning, you notice that the pump removing soiled water is unreliable. How much of the nutrient is currently in the tank? [*Mance received a value of 5 liters per minute]. (Note: depending on the value of t, the function may take on negative values – this would violate real world constraints).

Version 3. To regulate the pH balance in a tropical fish tank, a buffering agent is dissolved in water and the solution is pumped into the tank. Another pump takes well-mixed solution from the tank. How much buffering agent is in the tank at any point in time?

Three dimensions varied for this set of tasks are real world constraints: the volume of liquid in the tank and the rates at which liquid flowed in and out of the tank (see *Table 1*). Because different information is given across the three versions, the students had to make assumptions (implicitly or explicitly) that would satisfy the constraints in each. The intention was that as a set the tasks would aid the students in realizing that the variations did not affect the mathematical structure used to model the Tropical Fish Tank.

Table 1 Dimensions of variation and range of permissible change for the Fish Tank Problem

Dimension of Variation	Possible Values	Reason Varied	Anticipated Student Responses
Rate in and rate out	5 (or .25) (Versions 1 & 2), Not Given	Draw attention to similarities among the models even if the concentrations were different; develop a more general model	Set rate out to be constant, give a specific value (e.g., 0); Set rate out to be constant, give a parameter; Set rate out so $\frac{dV}{dt} = 0$; Set rates to vary with time
Concentration	Exponential decay (Version 1), Sinusoidal (Version 2), Not Given (Versions 2 & 3)	Draw attention to similarities among the models even if the concentrations were different; develop a more general model	Consider real-world implications of the given concentrations; Assume concentration = 0; Set concentration to vary with time
Volume of the Tank	Given (Versions 1 & 2), Not Given (Version 3)	Dependent upon rates in and out	Assume constant, give a specific value; Assume constant, give a parameter; Assume varies with time

Borrowing Orys's notation, let $Q(t)$ represent the quantity of agent in the tank at time t, let $c(t)$ represent the concentration of the solution entering the tank, let V be the volume of the tank, and let $r_i(t), r_o(t)$ represent the rates at which the liquid flows in and out of the tank. In Version 1, $c, V,$ and r_i are given. The rate r_o must be assumed to be constant, left as a parameter, or left as an unknown function of time. In Version 2, c, V, r_i, are given while r_o must be inferred to be zero (note that depending on the situation imagined, this might force V to be a function of time). In Version 3, none of c, V, r_i, or r_o are given. They must be inferred as parameters or as functions of time. The differential equation that models the situation in Version 3 can be written as

$$\frac{dQ(t)}{dt} = r_i(t)c(t) - \frac{Q(t)}{V} r_o(t).$$

Results & Analysis

On all three versions, both students successfully obtained a differential equation to model the given situation, shown in *Table 2*. Both responded to the changed conditions in each version. For example, Orys observed that Version 3 seemed "to be missing a lot of stuff," "the usual things just aren't even mentioned like rates or volume of the tank…" He stated that he could make some assumptions but that he didn't know if it would be right. Orys's comments indicate his unease in engaging in *simplifying/structuring*.

Both students successfully handled the lack of information given about the rates in/out in Version 3. They also acknowledged that rate in/rate out need not be equal in any of the versions. Mance showed that $V(t)$ could be determined by integrating $\frac{dV}{dt} = r_i(t) - r_o(t)$. He indicated he was confident he could *mathematize* a nonconstant volume into the differential equation for the quantity of buffering agent in the tank, but that he was not sure if the differential equation with a non-constant coefficient of $Q(t)$ would "follow all the things we learned before." That is, though the model made sense to him, he was cautious in applying mathematics he knew to a novel mathematical context. In all 3 versions, both students eventually assumed that $\frac{dV}{dt} = 0$. Orys found an explicit expression for volume as a function of time (see *Table 2*), but did not solve the resulting differential equation. Mance's work illustrates a successful arc through *simplifying/structuring* and *mathematizing* regarding this constraint. He appropriately converted an assumption (volume of liquid does not change) to a mathematical property (rate of change of volume is zero) to a mathematical representation ($\frac{dV}{dt} = 0$), successfully *mathematizing* the assumption. He then explained the consequences of assuming that $\frac{dV}{dt} = 0$ and why it was reasonable to do so. Ultimately, both simplified the problem by assuming that the volume of liquid in the tank constant so that the tank wouldn't empty or overflow.

In Version 2, Mance did not notice that the function describing the concentration of the entering solution could turn negative. This is an example of how implicit assumptions which don't capture the real world situation be mathematized. On Version 2, Orys noted that the concentration should not be negative and decided to use $1 + \sin\left(\frac{t}{45}\right)$ to describe its oscillation around a unitized amount instead. Below are their differential equations for Version 3.

Table 2 The students' differential equations derived for Version 3

Mance: (in the notation from above)	Orys:
$\frac{dQ}{dt} = \big(r_i(t)c_i(t) - r_o(t)c_o(t)\big)V(t)$	$\frac{dQ}{dt}(t) + \frac{r_0(t)}{V(t)}Q(t) = r_i(t)c(t)$, with $V(t) = V_0 + r_i(t)t - r_o(t)t$ and V_0 as the initial volume of liquid in the tank

Mance stated that his equation on Version 3 was "the most general expression [he] could come up with." In this equation, the change in quantity of the agent does not depend on the amount of agent currently in the tank. This led the interviewer to probe Mance about the condition that the solution was *well-mixed* and why it was necessary, Mance indicated that if a solution was not well-mixed, the concentration of the tank would vary over space as well as over time. Indeed, without the assumption in place, the concentration of the solution leaving the tank would depend on where the overflow pump was placed. Thus Mance's model mathematizes one consequence of the well-mixed condition (concentration of agent in the tank is uniform) and not another (rate of change of quantity depends on current concentration).

Mance and Orys both reasoned using dimensional analysis. For example, on Version 2, Mance narrated his work to determine the rate at which agent entered the tank, "Your rate in ends up being like a number, it's 5 liters per minute and then you multiply that times your strength and you get some grams or whatever, your pH, per minute." On Version 3, Orys used dimensional analysis to set up a difference equation for the change of quantity of agent in the tank and let the limit $\Delta t \rightarrow 0$ in order to obtain a differential equation.

Discussion & Conclusions

Varying the assumptions and conditions relevant to the real world situation revealed that the students were reflecting on how the mathematics they knew could apply to the situations as they *simplified/structured* and *mathematized*. Mance commented that ideally, he would like to see worked examples with numbers given and more generalized representations of situations in order to increase his skill at deriving and solving equations. Constructing ever more general models may have helped these students explore the limitations of what the mathematical structure (or analytic technique) may be. Indeed, written and follow-up questions which varied parameters, changed assumptions, or otherwise focused on *simplifying/structuring* showed potential in helping Orys and Mance identify invariant mathematical properties and relationships that could be attached to real-world conditions and assumptions. This finding is consistent with research at the middle and high school level (Czocher & Maldonado, 2015).

Further, the preliminary results here seem to suggest that at least for these advanced engineering students in differential equations, the development of modeling skills was facilitated by familiarizing the student with certain mathematical conventions that effectively *mathematize horizontally* (Freudenthal, 1991). Two examples of such a convention are: *concentration is positive* or *time increases from zero*. The latter convention would have been well-assimilated by the time the students arrived in differential equations. Other examples of assumptions that became conventions were: *solutions are well-mixed* or *rate of change of a quantity can be expressed as a linear combination of base rates*. Other elements of the students' models were made up of more basic building blocks that could be assembled through the four basic operations and dimensional analysis. Using variance and invariance of real world conditions and drawing students' attention to how those variations impacted the mathematical properties, parameters, structures, and analytic techniques appropriate to successfully model the real world situation could aid students in seeing how mathematical choices connect to and depend on real world conditions. Such task sequences therefore seem to be a promising path for developing modeling skills, but of course require further study. With regard to the research setting, varying real world conditions provided multiple opportunities for the interviewer to explore and probe how the students were envisioning the real world situation (their situation models, Blum & Leiß, 2007) and how they chose to represent those conditions mathematically.

Questions for the Audience

1. When conceptualizing modeling competencies as learning objectives, how can task effectiveness be measured? 2. Would follow up questions, e.g., *what-if* scenarios posed by the interviewer, also qualify as variations in task dimensions? 3. In the context of modeling, it is important to nurture the skill of generating one's own assumptions. How can variations which target identifying real world assumptions and constraints and matching them with mathematical properties and parameters be implemented without overriding the dimensions the student spontaneously attends to?

Do Students Really Know What a Function is?: Applying APOS Analysis to Student Small Group Presentations

Tara C. Davis, Georgianna L. Martin
Hawai'i Pacific University

One of the fundamental concepts in mathematics is that of a function. This concept also appears to be a difficult concept to grasp for a large percentage of students. In order to assess the overall understanding of the concept of a function, we conducted an experiment with math majors at our university. In an upper division math problem solving course, the students were asked specific questions about the nature of functions. Students presented their understandings of function in groups of 2-3, which were recorded and then transcribed. Based on the IBL teaching methodology and the small group and classroom discussion data collected we have applied a sociocultural framework. The innovation we add is applying APOS, an individually oriented theory, to the collective level. Analyzing the video transcripts, we will discuss the overall trends in understanding as well as some of the common misconceptions that we have identified.

Keywords: Function, Problem Solving, Pre-service Secondary Teachers, APOS Theory

Purpose of the Study

The major goal of this study is to answer the question: Do students really know what a function is? This project was motivated by our experiences teaching upper and lower division math and science courses. We noticed an inability in a significant amount of students to apply the function concept to math and science problems. This in turn created an obstacle to success in a variety of undergraduate courses.

For example, the students in classes ranging from precalculus to linear algebra exhibited difficulty in evaluating functions of single or multiple variables. While learning to estimate areas under a curve with finite sums, students in calculus were unable to relate the height of a rectangle to the y-value of a given function. In introductory physics, students had difficulty applying formulas where certain letters represent constants and other represent variables (e.g. simple harmonic motion), as well as translating between representations of these functions in the graph form, and in the equation form.

Students appear to "get by" based on rote memorization and we wondered how much they actually understand. Without a comprehensive understanding and the ability to apply the function concept, we were concerned that higher order mathematical and scientific concepts would not be available to otherwise capable students. In addition to comprehension, the application of this knowledge can be found throughout a math or science degree. For example, the physical sciences require a basic understanding of the composition of functions. Differential and integral calculus requires deep understanding of how changes in the domain, even over an interval, affect the range of a function. Further, students with a degree in pure mathematics or math education require application of functions in a more abstract setting, specifically with regards to groups, vector spaces, Euclidean spaces, and more.

Theoretical Framework and Literature Review

One of the most pervasive big ideas (Schifter & Fosnot, 1993) in all of mathematics is the concept of a function. Michael Oehrtman and colleagues (Oehrtman, Carlson & Thompson, 2008) give an overview of the concepts necessary to understand the idea of function. Extensive studies that have been done on functions (Breidenbach, Dubinsky, Hawks & Nichols, 1992; Carlson, 1998; Dubinsky & Harel, 1992; Thompson, 1994; Oehrtman et al., 2008) substantiate our experience that there is a lack of comprehensive understanding at the undergraduate level.

Our framework will be an integration of the APOS and sociocultural theories – where we take the unusual perspective of using the normally individual oriented APOS theory at the collective level.

In (Breidenbach et al., 1992), the following explanations of the terms action and process are given: "An action is a repeatable mental or physical manipulation of objects. Such a conception of function would involve, for example, the ability to plug numbers into an algebraic expression and calculate. It is a static conception in that the subject will tend to think about it one step at a time (e.g., one evaluation of an expression)…A process conception of function involves a dynamic transformation of objects according to some repeatable means that, given the same original object, will always produce the same transformed object. The subject is able to think about the transformation as a complete activity beginning with objects of some kind, doing something to these objects, and obtaining new objects as a result of what was done." Building upon the work done in (Breidenbach et al., 1992) the faculty in (Cottrill et al., 1996) improve upon the theory adding, the concepts of:

…an object is defined as the result of "when the individual becomes aware of the totality of the process, realizes that transformations can act on it, and is able to construct such transformations."

…a schema "as a coherent collection of actions, processes, objects, and other schemas that are linked in some way and brought to bear on a problem situation."

This rounds out the theory defining APOS as Action Process Object Schema. They further argue that the process view or "dynamic conception" must be preceded by the action or static view.

Although APOS is usually used to analyze individual conceptions it does tell us what to look for in how students talk about functions. That is, we categorize the group responses without saying that they capture any or all of the individual student conceptions. To be clear, we have identified our unit of analysis as the group of students not the individual students.

The sociocultural theory was initially introduced in (Vygotsky & Cole, 1981) and (Vygotsky, 1979). The sociocultural perspective explains the study design in terms of the class being taught with small group inquiry-based instruction, and synthesis of information occurring via whole class discussion, as well as the data collection of whole class video, and discourse analysis. The mathematical knowledge is constructed and transmitted via social interactions. In addition to this classroom culture, we keep in mind that that our students are pre-service teachers addressing mathematics through the lens of what they believe students should know. More specifically we can unpack the framework into the following three pieces:

Cultural	Social	APOS
Class culture IBL teaching method Type of students (pre-service teachers)	Group dynamics Classroom dynamics Data collection – video transcription	Analysis of the action vs. process understanding of functions

We apply the sociocultural perspective mainly to our study design, and the APOS theory to the data analysis. However, when analyzing the video transcript and seeing certain mathematical ideas arise, we interpret them in terms of the group dynamics that brought them to the surface. These theories fit together in a complementary way because we structure the instruction and data collection around a sociocultural perspective, and apply the APOS theory to the small group level to answer our question about whether students know what a function is, and more specifically whether the small groups collectively possess an action a process view.

Methods

This study took place during Spring 2013 and Spring 2014 semesters in a course designed to prepare future secondary educators with problem solving skills. There were 11 and 9 students enrolled in the courses, respectively. The students were geographically and ethnically diverse, as is common at our institution. The first author was responsible for teaching the course both semesters. This course is required for math education majors, and is a terminal math course, focused on problem solving and teaching. No new math content is introduced; rather students apply known concepts relating to high school math to solve novel problems at the college level.

Activity

One unit of the course is on the theme of Functions and Covariation (Carlson, Jacobs, Coe, Larsen & Hsu, 2002). The two authors taught one course period devoted to a "Teaching Functions" activity prior to the unit being taught. During the "Teaching Functions" activity, students were broken up into small groups of 2-3 people, for a total of 7 groups. They were given the following prompts and asked to produce a mini-lesson in response:

- What is a function?
- What is an example of a function?
- What is the role of the variable in a function?
- What are the characteristics of a function?
- What are the typical misconceptions about functions? (From the perspective of a high school student or person learning functions for the first time.)

Students had 30 minutes to plan the lesson. The written lesson plans were then collected. Each group gave a 5-10 minute presentation, which was followed with brief question and answer time. The presentations were video recorded and we transcribed the audio portion of the presentations for our analysis. We did a detailed analysis of the results of this activity and video. Similar research has been published recently with a video analysis of students investigating the Cartesian Connection (Moon, Brenner, Jacob & Okamoto, 2013). These authors argue that cognitive obstacles arise as a result of misunderstanding fundamental and pervasive big ideas in mathematics.

Analysis

The analysis was done with the help of RQDA software. This is a R-based Qualitative Data Analysis software package. RQDA serves as a way to highlight and sort different ideas within multiple files allowing for the compilation of information related to each specific idea. All of the code creation and text categorization was done collaboratively, and following best practices

(Dewar & Bennett, 2015), (Taylor-Powell & Renner, 2003). We used a thematic analysis on the transcription of each group's presentation.

Preliminary Results and Analysis

In order to summarize our initial findings, we will discuss the analysis as it pertains to the assigned questions. The first question the students were asked to address was based on the definition of a function. With regards to the definition of a function, we found that the students' responses could be summarized by four overall themes listed in order from inaccurate to accurate: 1) A function must have an equality or inequality with at least one unknown; 2) A function must be an equation with one variable; 3) For every x, there exists a unique y mapped to by x and the more sophisticated but less accurate definition: 4) A relationship between two quantities with a specific input/output role.

When asked to provide examples we note that most groups gave the linear and quadratic examples. This is perhaps not surprising, as these are some of the simplest examples of functions. We wonder whether our instructions to teach the lesson at the high school level influenced the types of examples that the students provided. We observed some other examples, such as the tangent, absolute value or other piecewise defined functions, as part of the later discussion that arose, for instance about one-to-one or onto functions or during a conversation about the vertical and horizontal line tests. The more sophisticated examples appear to result from classroom discussions evident of learning taking place through classroom dynamics.

The impetus for asking the students to identify the role of the variable came from our experience in the classroom. We had noticed many students making the same mistakes involving evaluating functions at expressions, such as believing that $f(x+h)=f(x)+h$, including errors forming composition of functions, as well as mistakes involving setting all functional expressions to 0 and trying to solve for x even when it is inappropriate to do so. We conjectured that these mistakes may be occurring due to a basic lack of understanding of the role of a variable. The responses from the students can be summarized in the following three concepts: 1) The relationship between unknowns; 2) A placeholder for a value; and 3) The concept of the independent variable as input vs. output. Although many groups did focus on plugging values into the variable, their responses overall appeared flexible enough that they might be less likely to fall into the mistakes we mentioned earlier.

Related to our earlier question about the role of a variable, we were also interested in how the students would relate the various characteristics of a function. One group specifically reflected on their experience working with functions in their upper division numerical methods course, and how in this course the characteristic of the graph allowed them to solidify the initial ideas presented in their precalculus courses. This addresses a question we had about students making connections between courses and synthesizing and applying the concept and characteristics of a function. We were also interested to note that one group said, "what they're going to learn in high school is to work with numbers but this could be vectors, or anything, it could be all kinds of numerical objects, all kinds of restrictions that you put in there and you get all things out." This shows that some students believe the domain could be a set other than the real numbers.

An analysis of the student presentations identified seven main themes in response to the characteristics question. They are 1) It has a 'number' of variables; 2) Has to have an equals sign; 3) Functions can be represented in a graph; 4) One-to-one, onto or Inverse; 5) Vertical line test; 6) Domain & Range; and 7) F(x) vs F(y). This last theme refers to the importance of identifying the independent variable; e.g. that it is possible for a single expression to define a function of x but not of y or vice-versa.

The final question concerning misconceptions was very rich. The students addressed common misconceptions, but also had a few of their own. The common misconceptions that they identified their potential students having were as follows: 1) All functions are one-to-one; 2) All functions have domain all real numbers; 3) The function is only dependent on the expression x or that y=f(x); 4) x as a function of y vs. y as a function of x; 5) Not necessarily a connection between the graph and equation; and 6) Not necessarily a connection between the notation and evaluation of expression. We found the variety of misconceptions identified by the students interesting. From the breadth of misconceptions we infer a high level of intuitive understanding of functions. Students appear to have reflected on and learned from their own mistakes as well as their experiences tutoring and observing others actual mistakes.

It should be noted that the two authors actively chose not to correct or comment upon the content of the students' presentations during the course of the exercise. Whilst we did not correct mistakes, we noticed that over the course of the conversation they as a group they came to consensus on the correct answer. The self-correction was seen in both years. For example, it was surprising to note that one group believed that an inequality is an example of a function. This error spawned a discussion within the class about whether an inequality is a function. Another student attempted to rationalize the example trying to help their colleagues. The group finally conceded that the inequality does not meet the definition of a function on real numbers. We asked ourselves what was the sociocultural dynamic in the group or classroom that resulted in this idea. Upon further viewings of the presentation it seemed that one member of the pair was more dominant. The less dominant student who began the presentation provided correct information inconsistent with the later incorrect ideas. We also noted that several groups were triples and perhaps this pairing of the dominant student with a wrong idea did not lend itself to be corrected in the small group.

While the APOS theory is typically used to analyze the individual, here we apply the theory to the groups, thereby defining the small groups as our unit of analysis. We identified three groups as possessing only an *Action View*. Predominantly these students described a function as something that you plug a number into and get another number out of. For example, one group described plugging numbers into functions to evaluate them and to create t-charts. They claim that the relationship between the variables is just a plug-in process. We categorized three groups as possessing a *Process View*. The group that went the furthest into process interestingly did not present the plug-in model. They presented two different instances of a process understanding. This group explained, "…and when we're introducing the function concept what's going to be more effective probably is that we're not talking about a letter with a hidden value. We're talking about a relation between some value that we don't know and another value that we don't know, but we can still say a relation between them." They do not view a function as an equation that needs to be solved, but instead describe a dynamic relationship. The second instance demonstrated an understanding of the relationship between input and output and their reversal as defining an inverse function, rather than algebraic procedures such as switching x and y and solving. The remaining group did not have their transcript coded as either "action" or "process."

Teachers' Beliefs & Knowledge of the Everyday Value of High School Algebra & Geometry: Is One More Useful than the Other?

Jennifer Dunham
University of Maine

Despite recent emphases on teaching that mathematics is useful, little is known about teachers' beliefs about the value of the topics they teach. While teachers have been found to believe mathematics overall is worthwhile, it may be that this belief varies among subjects. This study examines the beliefs and knowledge of students enrolled in teacher preparatory courses by employing a survey and algebra and geometry tasks related to each subject's usefulness and connection to real-world applications. Preliminary results show they value algebra above geometry in terms of future use by their students. However, while their confidence was equal in their abilities to produce real-world applications, they were more successful producing those related to geometry than algebra. Further survey and clinical interview data collection is planned with additional pre-service and in-service teachers to examine beliefs and knowledge expert (in-service) teachers bring to teaching to inform the preparation of secondary school teachers.

Key words: pre-service teacher education, algebra, geometry, teacher beliefs, pedagogical content knowledge, mathematical content knowledge

Introduction

The Common Core State Standards for Mathematics, as well as the Next Generation Science Standards, and the National Council for Teachers in Mathematics, have each expressed the need for students to value mathematics and to see it as a useful pursuit. The Common Core's Standards for Mathematical Practice includes in its description of mathematical proficiency, a "productive disposition (habitual inclination to see mathematics as sensible*, useful, and worthwhile*, [emphasis added] coupled with a belief in diligence and one's own efficacy)" (National Governors Association Center for Best Practices and the Council of Chief State School Officers, 2010, p. 6).

Research has shown that teachers see mathematics, as an entire discipline, as valuable. Yet little is known of mathematics teachers' beliefs regarding the usefulness and value of the individual subjects they teach, or whether their beliefs are aligned with their practice. This study was designed to examine whether pre-service teachers' beliefs towards algebra and geometry might differ, as well as their abilities to demonstrate the relevance and usefulness of the mathematics by producing real-world examples or stories.

Research on Teachers' Beliefs and Knowledge

Research into teacher beliefs has been popular for decades. Despite this, little has been done that narrows in on an area of mathematics, particularly in regards to its nature or value. Peterson et al. (1989) conducted a study of teachers' pedagogical content beliefs regarding addition and subtraction with first grade teachers. They write, "Unfortunately, research on teachers' beliefs has not been concerned with subject-matter content…Thus, these studies are limited because they report findings on teachers' beliefs across a wide range of curriculum areas and grade levels" (Peterson, Fennema, Carpenter, & Loef, 1989, p. 3). In other words, it is one thing for a teacher to believe that mathematics is a valuable and useful pursuit, and another thing to believe that algebra or geometry is a valuable and useful pursuit. Furthermore, believing in the importance of all topics within mathematics for all of students is yet another thing entirely. Hence, there is a lot yet unknown related to teachers' beliefs about the value of the subjects that they teach. This is despite the accepted view that teachers' beliefs shape instructional practices and student learning opportunities (see, e.g., Leder, Pehkonen, & Torner, 2002; Philipp, 2007).

On the other hand, research into teacher knowledge often focuses on a specific topic in order to categorize the knowledge they bring to bear, not only in solving mathematical problems, but teaching them as well. Work such as Ma's (1999) pinpoints topics within mathematics to examine teachers' mathematical knowledge in that small area. However, Ma's research was with elementary teachers. At the secondary level, less has been done to examine teachers' mathematical knowledge related to topics they teach within the wide field of mathematics. Therefore, less is known about variations in teachers' levels of expertise from topic to topic, beyond the elementary level. Hogan, Rabinowitz, and Craven (2003), stated that "Because the scope of the school curriculum in a given subject is sufficiently broad to preclude expertise in all topics within the curriculum, a teacher may feel more knowledgeable and confident within one specific content area" (p. 239). Therefore, it would appear necessary to examine teachers' knowledge on a variety of mathematics curriculum topics in order to gain a complete picture of secondary mathematics teachers' knowledge and abilities to apply that knowledge in practice.

While the U.S. lags behind a number of nations in mathematics, its weakest subject is certainly geometry. Results from the Third International Mathematics and Science Study (TIMSS) have repeatedly shown that of all the mathematical domains tested, the U.S. does best in algebra and worst in geometry (Clements, 2003; Provasnik et al., 2012). In fact, U.S. secondary students have been found to score near or at the bottom on every geometry item on the TIMSS (Clements, 2003). Thus, the focus of this study is teachers' beliefs and knowledge of algebra and geometry, as relevant to the learning standards for grades 8-12 and with the goal of providing insights into teachers' knowledge and beliefs that can inform the design of pre- and in-service professional development.

Research Design

Research Questions

In order to add to the existing work on teacher knowledge and beliefs, the specific research questions addressed in this study are,

1. How do pre-service and in-service teachers perceive the importance of learning algebra and geometry?
2. What kind of real-world algebra and geometry problems or models are pre-service and in-service teachers able to produce?

These questions were designed to explore both mathematics teachers' knowledge and beliefs at two different stages, during preparation and in practice. Studies have shown that teachers gain certain knowledge "on the job" that they may not have opportunities to acquire through teacher preparation programs, e.g., knowledge of common student difficulties, knowledge beyond understanding mathematics for oneself but for teaching mathematics, etc. (Borko & Livingston, 1989; Livingston & Borko, 1989, 1990; Ma, 1999). Whether that pertains to knowledge of and beliefs about the value and usefulness of the mathematics they teach is the subject of this study.

Theoretical Perspective

This study is being conducted with cognitive, expert-novice educational psychology theoretical framework. That is, it assumes that experts are characterized as having the ability to organize their knowledge in ways that reflect deep conceptual understanding of the area of study (Bransford, Brown, & Cocking, 1999). This organized knowledge allows them to observe meaning and patterns that would go unnoticed by novices. This also allows experts to contextualize their knowledge, making it flexible to retrieve and to apply. Novices, on the other hand, struggle to make connections between what they see as unrelated rules and facts, which prevents them from developing conceptual understanding.

While the research defining expert and novice knowledge is well-established and accepted, there is less research on characterizing expert beliefs. Wieman (2007) described experts in his work on science education as believing science has a coherent conceptual structure. Novices, on the other hand, see science as isolated pieces of information that are transmitted by authority. Since they believe science to be unorganized, they rely on memorization rather than deep conceptual learning. Their knowledge remains fragmented, lacking the structure they also believe the subject to be lacking.

In this study I am applying this theory to beliefs about mathematics and examining the extent to which mathematics teachers demonstrate expert beliefs about the nature of mathematics by conceiving of it as a coherent conceptual structure, interconnected and organized. In this framework, novice beliefs about mathematics would be characterized by assumptions that mathematics is made up of disparate facts and algorithms, meant to be transmitted from teachers, the authority, to their students. Their students then "learn" this material by repetition and rote memorization.

Methods

A two-part survey was administered to 35 pre-service teachers enrolled in an algebra course for elementary education majors near the end of the spring 2016 semester at a northeastern land-grant university. The first part of this survey, focused on beliefs, was modeled after the "Usefulness" portion of the Fennema-Sherman attitude survey for students of mathematics (Fennema & Sherman, 1976). The 12 Fennema-Sherman items were reduced to five, eliminating redundancies to increase participation and limit fatigue (e.g., see Figure 1 below).

1. I believe knowing algebra will help my students earn a living.

1	2	3	4	5
Strongly Disagree	Disagree	Undecided	Agree	Strongly Agree

Figure 1: Sample Beliefs Survey Item (modeled after Fennema-Sherman)

In addition, three items were created to gather data on teachers' attitudes towards the use of real-world problems in their teaching (e.g., see Figure 2 below). All eight items were written both in terms of algebra and geometry.

6. I believe it is important to show my students real-world applications of geometry.

1	2	3	4	5
Strongly Disagree	Disagree	Undecided	Agree	Strongly Agree

Figure 2: Sample Beliefs Survey Item (author-generated)

The second part of the survey consisted of two two-part tasks modeled after Ma's (1999) interviews with U.S. and Chinese teachers on the division of fractions, one each related to algebra and geometry. Teachers were asked to work through a problem and then to generate a scenario that could be modeled by the computations they just completed (see Figure 3 below).

People often adopt different approaches when solving a problem. How would you solve the following problem? Show your solution below.

1. Solve for x. $\frac{16}{1} = \frac{240}{x}$

Now imagine you are teaching an algebra course. To make this topic more meaningful to your students, you want to create real-world scenarios to show them the relevance of algebra in their daily lives. What would be a good story or model to demonstrate the application of this problem?

Figure 3: Sample Algebra Task

Three different tasks were designed for each subject to allow survey participants to have varied problems from their neighbors. Methods of analysis are discussed in conjunction with results presented below.

Preliminary Results

The beliefs survey items were scored using a Likert scale from one to five, one being "strongly disagree" and five being "strongly agree" with three being "undecided." Scores were then inversed for statements that were phrased negatively, so that a five became a one, a four became a two, etc. In this way, a score above a three meant a positive belief towards the subject, and scores below three meant a negative belief. This also allowed for measuring differences in beliefs by subtracting one from the other, between disciplines. Therefore, a positive difference when subtracting geometry from algebra meant the participant valued algebra more than geometry, no difference meant a belief in equal value, and a negative difference meant they valued algebra less than geometry.

For all but one of the beliefs survey questions, participants believed algebra to be equally as valuable or more valuable than geometry for their students' lives. Most felt real-word examples were important for both subjects (n=34 vs. n=33) but would be somewhat more often used in class for algebra (n=18 vs. n=14). However, despite the majority believing in the importance of real-world examples, the number who were actually confident in their ability to produce these examples was fewer (n=23 for both). In addition, about half of participants ranked the importance higher than their confidence (approximately 56% for algebra and 53% for geometry). The numbers here are close due to the small sample size however, they suggest a trend of pre-service teachers believing algebra to be more useful than geometry and, despite feeling that real-world examples are important in both subjects, having little confidence in their ability to demonstrate these for their students.

In the second half of the survey, participants were asked to solve a problem and then generate real-world scenarios that could be described by the solution they just produced. The first part (solving the problem) was scored "correct," "partially correct," or "incorrect." If a participant left the question blank, this was also scored as "incorrect." The second part was scored using a 0-3 point rubric. A detailed complete example that correctly reflected the problem given was scored a 3. A related example lacking detail was scored a 2. An unrelated or so incomplete as to be unclear example was scored a 1. If a participant left the question blank then this was scored a 0. Using these scoring guides on this small sample, it appears there is no visible relationship between correctness and ability to produce real-world examples (see Table 1 below). Despite nearly half of the participants answering the algebra task problem correctly, slightly more were unable or unwilling to produce a related real-world example. In fact, only 5 participants scored a 3. On the other hand, one-fifth of participants answered the geometry task problem correctly and again, only 5 participants wrote real-world examples that were scored a 3. Thus, even though participants had a higher success rate solving the algebra tasks than the geometry tasks, they had an equal success rate producing geometry-related real-world examples.

Algebra					Geometry				
	0	1	2	3		0	1	2	3
Incorrect	7	2	0	0	Incorrect	8	6	0	0
Partially Correct	5	2	1	2	Partially Correct	6	2	4	2
Correct	6	5	2	3	Correct	2	2	0	3

Table 1: Algebra and Geometry Task Scores

Conclusions and Implications

The goal of this study is to add to the body of knowledge available to instructors of pre-service teachers. Preliminary findings suggest that pre-service teachers generally believe algebra and geometry to be useful to their students' futures but they lack confidence in their ability to produce real-world applications and, in fact, are often unable to, given common mathematical tasks. A typical pre-service teacher in this study believes algebra to be somewhat more useful than geometry but is unable to generate rich real-world examples for either, despite a belief in the importance of doing so. This suggests that pre-service teacher preparatory coursework needs to include more instruction on the applications of the mathematics they will teach, particularly everyday use and career applications of geometry. This would both serve to better prepare them to teach mathematics as useful and also to see it as useful themselves. The Common Core Standards has identified the need for students to see the value of mathematics, therefore it is vital that our teachers going into the classroom be able to see the value of their subjects, and be able to present it clearly and purposefully to their students, including via real-world examples.

This survey will be administered to pre-service teachers enrolled in college mathematics courses again in the fall of 2016. From this, participants will be identified for clinical interviews to gain further insight into pre-service teachers' knowledge, beliefs and abilities to generate real-world examples. Additionally, clinical interviews will be conducted with in-service high school mathematics teachers from the surrounding area. This will allow for a deeper picture of what pre- and in-service teachers believe and both the pedagogical content knowledge and mathematical content knowledge they possess and how they differ with their level of teaching experience. Coupled with findings from pre-service teachers, findings about in-service teachers can then inform the design of instruction to enhance pre-service teachers' capacities to provide rich learning opportunities for their students.

Second Semester Calculus Students and the Contrapositive of the Nth Term Test

David Earls
University of New Hampshire

Little is known about the difficulties second semester calculus students have determining series convergence, and why students have such difficulty. This report seeks to add to the existing literature on series by analyzing second semester calculus student responses to a multiple choice item that involves the use of the contrapositive of the nth term test. We frame our discussion in terms of what these answer choices might say in terms of student concept images of series and sequences. We also analyze what prerequisite knowledge might help students be more successful in answering questions about series and sequences typically seen in a second semester calculus course.

Key words: Calculus, Nth Term Test, Series, Sequences, Contrapositive

Researchers have called for more research in the area of infinite series (González-Martín, Nardi, & Biza, 2011). Some of the existing literature on series includes the role infinity plays on students' understanding of series(Sierpińska, 1987), student understanding of definitions (Roh, 2008; Martínez-Planell, R., Gonzalez, A., DiCristina, G., & Acevedo, V., 2012), student's beliefs about their role as a learner and the relationship between these beliefs and approaches to solving convergence problems (Alcock & Simpson, 2004; Alcock & Simpson, 2005), how series are introduced to students (González-Martín, Nardi, & Biza, 2011), the difficulties students have accepting that comparison tests can be inconclusive (Nardi and Iannone, 2001), and the development of a framework used to analyze student errors determining the convergence of series (Earls & Demeke, 2016).

This preliminary report seeks to add to the existing literature on series convergence by analyzing second semester calculus student solutions to a problem that could be solved using the contrapositive of the nth term test. The report is part of a larger dissertation study that seeks to determine the difficulties students have finding the convergence of sequences and series in second semester calculus, and in what ways these difficulties are related to prerequisite knowledge students' instructors mightexpect their students to have from precalculus and first semester calculus prior to entering the course.

Conceptual Framework

Tall and Vinner (1981) use the term "…*concept image* to describe the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes" (p. 152). A student's concept image of a particular concept usually results from working with examples and non-examples (Vinner & Dreyfus, 1989). The concept image for concepts that do not have graphical components or have weak graphical components will include symbols, formulas, and associated properties (Vinner & Dreyfus, 1989).

Tall and Vinner (1981) define *concept definition* as "…a form of words used to specify that concept" (p. 152). They also differentiate between a student's *formal* concept definition and a *personal* concept definition. A formal concept definition is the definition of a concept that is agreed upon by the mathematical community. A personal concept definition, however, might be constructed by the student and could change over time.

Although distinct, concept images and concept definitions are intricately related. Tall and Vinner (1981) describe this relationship by saying, "for each individual a concept definition generates its *own* concept image" (p. 153). In other words, the words used to describe a particular concept generate a mental image associated with the concept. As an example of this relationship, consider the function concept. The formal concept definition of function can be described as a relation between two sets where each element of the first set is assigned exactly one element of the second set. However, a student studying functions might not remember this definition, and the concept image for the student might include the idea that a function must be given by a rule or formula.

In the discussion that follows, this paper describes what one multiple choice question might say about students' concept images of sequences and series in general and the nth term test in particular.

Research Methodology

The targeted population for this study is second semester calculus students enrolled at a large research university in the northeastern United States. One hundred seventy-nine students responded to an anonymous six question multiple choice survey on sequences and series with a cover sheet. The cover sheet asked students to list their previous three mathematical courses, whether or not they had experience with sequences and series prior to entering the course, age, year, gender, race, and expected grade in course.

The main research aims of the full dissertation study are to (1) determine what misconceptions of sequences and series are revealed when students solve problems on sequences and series typically seen in a second semester calculus course, (2) determine what ways, if at all, these misconceptions relate to the prerequisite knowledge students are expected to have prior to starting a second semester calculus course, and (3) determine what additional knowledge or conceptualization of sequences and series students might need to be successful in second semester calculus courses.

This preliminary report focuses on one problem on the multiple choice test, a problem that focused on students' understanding of the nth term test and its contrapositive. This question was chosen for this report because more students answered this problem incorrectly than any of the others:

Instructions: Please Circle The Letter of The Best Response.

Suppose that you know that

$$\sum_{n=1}^{\infty} b_n = 3$$

What can you say about $\lim_{n\to\infty} b_n$?

A. $\lim_{n\to\infty} b_n = \infty$
B. $\lim_{n\to\infty} b_n = 0$
C. $\lim_{n\to\infty} b_n = 3$
D. We can't say anything about $\lim_{n\to\infty} b_n$

Recall that the nth term test states that, if $\lim_{n\to\infty} a_n \neq 0$, then $\sum_{n=1}^{\infty} a_n$ diverges. Consequently, the contrapositive of this statement tells us that if the series converges, then the limit of the sequence must go to 0. Therefore, choice B is the correct answer.

This question was recommended by a mathematics professor with many years of experience as a second semester calculus instructor. Distractors were chosen based on responses given to this question during interviews in a pilot study. This choice was made based on Kehoe's (1995) recommendation that any multiple choice assessment should have three to four well written answer choices. All of the questions on the multiple choice test were reviewed for appropriateness (as in, typical problems that a second semester calculus student should be able to solve) and correctness by a mathematics graduate student, a mathematics education graduate student, and an experienced mathematics professor.

Data was analyzed using first exploratory data analysis (EDA) followed by confirmatory data analysis (CDA). Exploratory analysis involves looking at variables individually, then two at a time, and then multiple variables at a time. Behrens (1997) recommends starting with EDA before moving to CDA because EDA allows researchers, "…to find patterns in the data that allow researchers to build rich mental models of the phenomenon being examined" (p. 154).

During EDA, some hypotheses developed. For example, it appeared as though students that had experience with sequences and series coming into the course performed better on this question than those that lacked experience. The purpose of CDA is to test this and other hypotheses using statistical significance tests such as a chi-squared test, or Fisher's 2-tail test.These two statistical tests were chosen based on recommendations from the Institute for Digital Research and Education website (IDRE, n.d.). All statistical tests were performed using the JMP software.

Preliminary Results

Only 48 of the 179 students, or just over 26 percent, chose answer choice B, the correct answer to this question. Ninety-two students, which is over 50 percent, chose answer choice C, with seven students, under four percent, choosing answer choice A and 32,about 18 percent, choosing answer choice D.

Students that said they had experience with sequences and series in a previous course performed better on this question than those who said they had no experience. Sixty-eight students said they had experience with sequences and series prior to their second semester calculus course, and 111 said they had no experience. Unfortunately, the sample sizes were too small to determine if there was statistical significance within each answer choice. Consequently, I instead considered whether or not the students answered the question correctly.

Of the 68 students with prior experience, 25 students, or just over 36 percent, answered the question correctly. Of the 111 students with no prior experience, only 23, or just over 20 percent, answered the question correctly.

Fisher's two-tail test revealed a p-value of .0238, indicating that this difference is statistically significant. Likelihood ratio and Pearson chi squared tests were also performed and revealed p-values of .0198 and .0187, further indicating the likelihood that the difference in performance between students with prior experience and those without prior experience is statistically significant.

The full contingency table from JMP is shown below to give a visual representation and more detail on what was presented above. The no/yes on the left side of the table indicates whether or not students had experience with sequences and series prior to entering the course. The no/yes on the top of the table indicates whether or not students answered the question correctly:

Figure 1: Contingency Table – Question six correct by experience

Experience? Question 6 Correct?

Count Total % Col % Row %	no	yes	Total
no	88 49.16 67.18 79.28	23 12.85 47.92 20.72	111 62.01
yes	43 24.02 32.82 63.24	25 13.97 52.08 36.76	68 37.99
Total	131 73.18	48 26.82	179

Tests

N	DF	-LogLike	RSquare (U)
179	1	2.7146923	0.0261

Test	ChiSquare	Prob>ChiSq
Likelihood Ratio	5.429	0.0198*
Pearson	5.531	0.0187*

Fisher's Exact Test	Prob	Alternative Hypothesis
Left	0.9939	Prob(Question 6 Correct?=yes) is greater for Experience?=no than yes
Right	0.0153*	Prob(Question 6 Correct?=yes) is greater for Experience?=yes than no
2-Tail	0.0238*	Prob(Question 6 Correct?=yes) is different across Experience?

Discussion

There are several plausible explanations for answer choice C, which over 50 percent of the population thought was the correct answer. Note that the value for the sequence convergence in answer choice C is the same as the value of the series convergence. It is possible that students are having difficulty understanding the difference between sequence notation and series notation. In other words, their concept image of sequences and series may include the fact that the symbols are interchangeable. A review of existing literature on semiotics confirms that students have a difficult time reading and understanding symbols in mathematics (Marjoram, 1974; Chirume, 2012; Earle, 1977). However, more research is needed to understand the role of symbols on student concept images of sequences and series.

Another possible reason for answer choice C is that students don't see the difference between sequences and series because of their use in everyday conversation. That is to say, in the English language, the words “sequence” and “series” are interchangeable. As an example, consider the sentence, “A long sequence of events has led me to a career in mathematics education.” Replacing the word ‘sequence’ with the word ‘series’ leaves the meaning of this sentence unchanged. However, sequences and series are very different in mathematics. Perhaps further research can explore the effect of the English language on student concept images of sequences and series.

The results above indicate that students that had some prior experience with sequences and series performed significantly better than students whose first experience with sequences and series came in this particular second semester calculus course. This prior experience, however, varied greatly. Some students noted on the cover sheet that they had seen sequences and series in BC calculus in high school. Others said that they were familiar with finite series from high school precalculus courses. Still others noted that they recognized series from the definition of the integral in a first semester calculus course. Regardless of the level and depth of experience, some exposure to sequences and series prior to entering the course seemed to have helped. It is worth noting, however, that even among the students with prior experience, most students, about 64 percent, still answered the question incorrectly.

It is difficult to know exactly how the concept images of those who answered this question correctly differ from those that did not answer the question correctly. It does appear, however, that the concept images of those that answered the question correctly may include a proper understanding of the nth term test and its contrapositive. Those that did not answer the question correctly appear to have an incomplete concept image of the nth term test. In particular, it appears as though they do not recognize the contrapositive of the nth term test. The difficulties that students had in this problem with the contrapositive of the nth term test are consistent with existing literature describing student and teacher difficulties understanding the logical equivalence of a statement and its contrapositive (Gregg, 1997).

Questions

I plan to continue the statistical analysis of the other problems on the multiple choice assessment. As this is part of a larger dissertation study, I also intend to analyze the transcripts of students that solved this problem during interviews. To help with further analysis, I would like my presentation to receive feedback on the following questions:

(1) What other correlations do you think I should look for as I analyze the other multiple choice items?
(2) What other methods can I use to further analyze student concept images of the nth term test aside from the transcript analysis?
(3) Are there any other methodological suggestions you have that might help enhance this study and future research projects on student concept images of sequences and series?

Implications

Moving forward, further research can be done to examine the effect of semiotics and word meanings in the English language on student concept images of sequences and series. Future research can also examine the understandings of sequences and series that students have in an undergraduate real analysis course, and this can be compared to the misconceptions of second semester calculus students. Results from studies such as the larger dissertation study have potential implications for the development of curriculum materials and teaching strategies that can be used to strengthen student concept images.

Let's Talk About Teaching: Investigating Instructors' Social Networks

[1]Kathleen Quardokus Fisher, [2]Naneh Apkarian, & [3]Emily M. Walter
[1]Florida International University; [2]San Diego State University; [3]California State University, Fresno

Researchers who evaluate efforts to improve STEM undergraduate education have recently begun to explore the importance of instructors' informal teaching discussion networks. These informal networks allow for the flow of knowledge between instructors that can include information about how to implement research-based instructional practices and creative perspectives that lead to innovative solutions to address localized classroom challenges. In this report, we reanalyze the network data from three pioneering studies in this area to explore the features of mathematics department networks as compared to other STEM department networks at multiple institutions. We plan to discuss implications of these features on the design and implementation of change efforts.

Key words: Social Network Analysis, Instructional Change, Academic Departments

Numerous STEM-focused calls for enhancement of undergraduate education have been focused on improving instruction. These calls have resulted in the creation of evidence-based instructional practices that have been shown to improve student learning outcomes. However, many instructors remain unaware of these practices or face challenges in adopting these techniques to their unique classroom environments and student population. Change efforts have recognized these challenges and the importance of the networks of instructors that provide expertise and creative ideas to successfully implement and coordinate instructional practices. For example, Kezar (2014) specifically identifies the need for social network analysis to harness the power of these networks to inform instructional change.

Social Network Analysis (SNA) is an investigation of social phenomena via the techniques of graph theory. In SNA, the vertices of a graph are individuals, the edges are relationships between two individuals, and the graph is called a sociogram. In this study, the individuals are STEM instructors and the relationships that connect the individuals are discussions about teaching. Each graph consists of all of the instructors in an academic department and the discussions among them. Figure 1 provides a sample discussion network in a STEM department.[1]

We use this preliminary report to begin to analyze datasets of networks from multiple departments. In particular, we are interested in investigating if mathematics departments have unique features when compared to other STEM networks. For example, mathematics departments often have comparatively large numbers of non-major students who take many lower and upper division courses. This results in large numbers of students per mathematics course and requires more instructors to support multiple sections. In other STEM departments, such as engineering, students are often majors and class sizes are smaller. Furthermore, mathematics departments are part of a larger disciplinary culture that influences how instructors are trained in graduate school and encultured into the discipline. We suspect that these disciplinary differences might manifest in varying department social network structures. Finally,

[1] All images and analysis were completed using UCINET 6 and NetDraw software (Borgatti, 2002; Borgatti, Everett, & Freeman, 2002).

as many academic departments do have similar policies and purposes, we may uncover similar social network features that reproduce themselves despite institutional and disciplinary differences. This finding in itself would be insightful and imply that change efforts in any STEM department would have similar network-based advantages and challenges. Our final report on this study will discuss these implications.

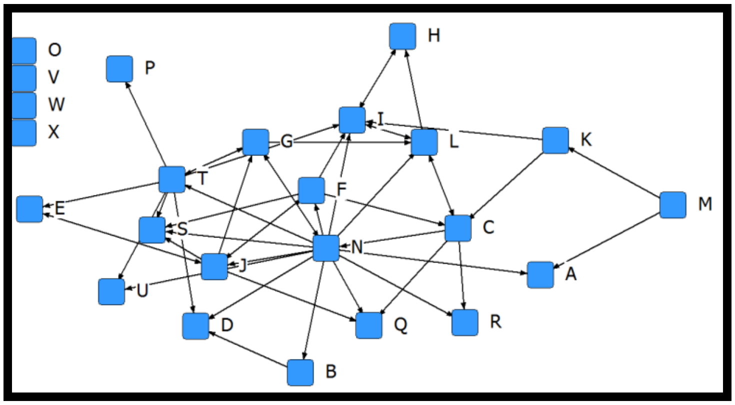

Figure 1: Discussion network sociogram where vertices are individuals and edges are discussions about teaching.

Theoretical Perspective

The goal of instructional change efforts is to improve the practice of instructors in the classroom. Changing an individual's practice requires addressing not only the individual's knowledge and abilities but also the contextual environment within which the individual works. Thus, the development of curriculum and practices by external experts that are meant to be adopted directly by instructors are not likely to be successful. This process does not provide flexibility or insight into the specific context of the individual. Networks may be especially important in remedying this challenge by allowing for adaption and adoption of evidence-based instructional practice. First, network members will be familiar with the challenges of the context and provide opportunities for collective sensemaking to articulate the purpose and features of the practice (Kezar & Eckel, 2000). Second, network structures that have infrequent but trustworthy relationships connecting subgroups of individuals promote innovation because of the ability for an individual to hear and create novel ideas (Levin & Cross, 2015). Finally, changing behavior at the department level can create supports and pressure for even more individuals to change their practice, which in turn will increase the impact of the change efforts (DeHaan, 2005).

Three Studies on Discussion Networks in Departments

This preliminary report represents the cooperative efforts of multiple investigators to reanalyze datasets in order to identify trends across multiple departments and institutions. The datasets represent three different studies, with different methods and different purposes. In our reanalysis, we are challenged to reconcile as many differences as possible across the datasets and to acknowledge those that could not be remedied in both the methods and results. In this section, we discuss the similarities and differences in the methods of the three studies.

The first study investigated social networks of mathematics departments across multiple institutions. In this study, members of mathematics departments at six different institutions were given an online survey to report discussion networks. This study included graduate students as members of the department. The survey listed all of the members of the department and asked respondents to mark each person "with whom they discussed instructional activities" during the last term in which they taught courses. Other items of the survey measured advice networks, friendship networks, and collective trust measures.

The second and third study shared similar survey designs. In both of these studies, respondents were given the opportunity to list up to seven individuals within the department with whom they "discussed teaching-related issues at least once a month." The members of the departments were provided in dropdown lists and the respondent also included the frequency with which the discussions occurred: nearly every day, weekly, monthly, and less than once a month. If the discussion occurred less than once a month, then no relationship was recorded between the two individuals. The second study included 15 STEM departments at a single institution. The third study was of six STEM departments at a single institution and included advice networks and data were collected twice (two years apart).

Reanalysis of Social Network Data

In order to analyze the data of the three studies, we made the following adjustments and choices. First, we added professional rank as an attribute for each individual. This allows us to remove graduate students from the sample, if necessary. Next, we chose to measure discussion relationships only if they occurred during a term in the first study, and at least once a month in the second and third study. We were unable to reconcile the difference in the nomination methods. In the first study, respondents could list ties with all individuals within the department. In the second and third study, this list was limited to seven people. We will need to discuss these differences when we are using measures that are likely to be greatly influenced by nomination approach, such as density of the network. Finally, we investigated if sample bias was influencing our results by comparing descriptive statistics of study one, study two, and study three before beginning our comparison of department-level network measures.

Preliminary Results and Lessons Learned

We begin by reporting descriptive statistics of each of the study's networks. We are interested in determining if institutional and/or study-based characteristics influence metrics, and if so, which metrics. Table 1 displays the average values and standard deviation for network degree centralization, average degree, density, average distance, and diameter. [2] Because of the limited number of departments, we do not make statistical claims.

From this table, we can see that the studies have the most impact on the degree centralization of the network, and relatively smaller impact on the other metrics. Because study one also was only mathematics departments, we may consider if this difference in degree centralization was partially due to the disciplinary culture. However, recall that study one had nomination methods that did not limit respondents to seven entries. This may also be the cause of the difference. In the future we hope to investigate this finding with even more mathematics departments' metrics and values. Future work will theorize what impact these metrics are likely to have on change efforts through sensemaking, creativity, and social norms.

Table 1: Average values and standard deviation for common network metrics of each study

	Degree Centralization	**Average degree**	**Density**	**Average Distance**	**Diameter**
Study 1 Average (Standard Deviation)	40.1 (9.7)	4.3 (0.9)	0.13 (.05)	2.2 (0.4)	4.5 (0.8)
Study 2 Average (Standard Deviation)	25.4 (7.3)	3.3 (0.8)	0.14 (0.06)	2.6 (0.3)	5.3 (0.9)
Study 3 Average (Standard Deviation)	20.4 (5.5)	3.6 (1.1)	0.13 (0.06)	2.4 (0.5)	4.9 (1.1)

These preliminary results give us confidence in pursuing our initial research questions regarding the differences or similarities among networks of various departments. We also stress the importance of coordinating research efforts in order to make large-scale impact on instructional change efforts. If each researcher has different survey designs and measurements with no standardization, then finding implications with broad application will be difficult. We therefore, call for a standard practice among network researchers in this area to produce studies that can build on the findings of one another and support the development of this area of research.

Audience Discussion Questions

The audience can help further this study be providing discussion around the following questions.

- Do audience members have anecdotal experience of large-scale differences of mathematics departments from other STEM disciplines?
- Do audience members believe that the data adjustments necessary for comparing networks are likely to challenge the validity of the study?

[2] The degree centralization is a measure of the degree to which ties are concentrated among a few key individuals. Average degree is average number of edges each individual has. Average distance is the average number of edges that span the distance between any two individuals in the network. The diameter of the network is the shortest distance between the two most distant individuals. For calculations of these metrics see Wasserman and Faust (1994).

- What other features of networks do audience members expect to be important for improving instructional practices?

Instrumental Genesis and Generalization in Multivariable Calculus

Brian Fisher
Lubbock Christian University

Jason Samuels
City University of New York – BMCC

Aaron Wangberg
Winona State University

Raising Calculus to the Surface is a multi-year project designed to introduce important topics from multivariable calculus through the use of physical manipulatives. This report focuses on data collected through a series of task-based interviews with multivariable calculus students enrolled in a course featuring these manipulatives. To explain the students' activity, a two-dimensional framework was designed based upon characterizations of their interaction with the instruments and the generality of their mathematical activity. The report concludes by discussing the contributions to the field and possible future uses of the framework.

Key words: Multivariable Calculus, Instrumental Genesis

Literature Review

Multivariable calculus is a course that is important for the introduction of ideas that are complex and essential for STEM students (PCAST, 2012). Some research has been done on student conceptions in multivariable calculus of function (e.g. Martinez-Planell & Trigueros-Gaisman, 2012), derivative (Martinez-Planell, Trigueros-Gaisman & McGee, 2014), and integral (Jones & Dorko, 2015), yet the overall body of work remains thin. Further, little is understood about the impact of non-traditional instructional approaches on student learning of these key ideas.

Raising Calculus to the Surface is a multi-year project with an innovative curriculum designed to introduce important topics from multivariable calculus through student exploration with physical manipulatives. Students use, as representations of two-variable functions, surfaces which are molded from clear plastic and have a dry erase surface. Accompanying tools include an inclinometer (used to measure the slope at a point on the surface in a given direction), domain mats (dry erase sheets with coordinate lines or contour lines), and squares (made of clear dry erase plastic and used to simulate a tangent plane). Students in small groups complete activity sheets in-class, which emphasize collaborative learning, student inquiry, and measurement with quantitative reasoning (for further details see Wangberg & Johnson (2013)).

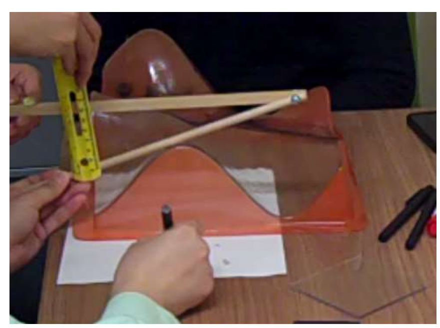

Figure 1

For students who use tools to complete tasks and answer questions in their activities on multivariable calculus, little is understood about how they enhance their understanding of calculus, or what role the tools play in that process.

Research Question

At the nexus of these issues lies the following research question:

What is the interplay between instrumental genesis and generalization as students develop conceptions of multivariable calculus during exploration involving the use of a physical manipulative?

Theoretical Perspective

Verillon & Rabardel (1995) presented Rabardel's theory of instrumental genesis to explain the complex process by which a person engaged in achieving a goal adopts the use of some assisting object. The material object when first introduced is an artifact. For it to be a productive tool, the user must attach to the artifact a role in solving the present task. Actions and behaviors cognitively organized by the user for a set of situations comprise a utilization scheme. Schemes can be constructed personally by the user, or received in a social context. The result of instrumental genesis is to have an instrument, an artifact endowed with a set of utilization schemes for tasks, a combination of material object and cognitive structures. During instrumental genesis, the artifact shapes the user through interactions which enhance the user's understanding of the subject matter, a process known as instrumentation. Additionally, the user shapes the artifact by developing schemes for interacting with the artifact, a process known as instrumentalization. Thus, as user and instrument develop their partnership, each one causes a transformation in the other. Subsequent to the development of the theory, instrumental genesis was applied in mathematics education to understand student use of graphing calculators, computer algebra systems (Artigue, 2002), and dynamic geometry software (Leung & Chan & Lopez-Real, 2006).

The curriculum used by students in this project has as its general pedagogical pattern exploration of a concrete scenario followed by mathematizing the observations into a rigorous formula. Thus the students' inductive reasoning is a natural target of inquiry. This form of reasoning is both one of the most important higher-level cognitive functions, and one of the most complex (Zhong et al., 2009). For this analysis, we use the lens of generalization as described by Tall (1991). Generalization is “an extension of familiar processes” in order to “operate on a broader range of examples” (Tall, 1991, p11-12).

Methodology

The data for this preliminary report were obtained from semi-structured task-based interviews with ten multivariable calculus students enrolled in a class using the Raising Calculus to the Surface materials. All students completed an activity sheet in class meant to introduce the concept of linear approximation for functions of two variables. In the interviews, which all took place within three days of that activity, students reflected on their experiences and responded to prompts further probing their ideas of linearization and differentiation in multivariable calculus. The data was analyzed using grounded theory (Strauss & Corbin, 1990). After an initial viewing of the data, categories naturally arose, and the data was reviewed and coded to confirm those categories.

Results

Analysis of the interviews revealed that students’ interactions with the artifacts depended both upon whether the student engaged in instrumentalization or instrumentation in regards to the artifact and whether the engagement occurred while the student was addressing a specific or general case of the mathematical phenomena. Therefore, we created a framework which classifies student interactions with the artifacts using those two dimensions (as illustrated in Table 1.)

Table 1

		Level of Generality	
		Specific	*General*
Relationship to instrument	*Instrumentalization*	Instrumentalization-Specific	Instrumentalization-General
	Instrumentation	Instrumentation-Specific	Instrumentation-General

Instrumentalization - Specific

Interactions were identified as instrumentalization-specific when the student brought prior conceptualizations of a specific case of a mathematical phenomenon to bear upon an artifact and as a result created schemes for utilizing the artifact meaningfully in this specific context.

Instrumentalization-Specific Example. During a previous conversation about the meaning of the term "partial derivative," R described the concept as a ratio of the change of the height of a function with respect to a change in either the x or y directions. The student was asked to determine the partial derivative at a specific point on the surface and given an inclinometer and a ruler as artifacts to use along with the surface. An inclinometer is a device that consists of two wooden rods connected at a hinge (see Figure 1). On one of the rods is a level which allows the user to confirm that one of the arms is horizontal while manipulating the other arm to represent the slope of the surface. Once introduced to the artifacts, R began experimenting with holding the inclinometer at different orientations until he determined which of those orientations best represented his understanding of partial derivatives.

> R: And this one [references the horizontal arm] we try to do it in such a way that this little ball is in the middle [references the bubble used for leveling the arm]. Then we will have something like this [holds the inclinometer such that it has a horizontal arm and the other arm reflects the slope of the surface] … Then you measure how high it is [holds a ruler vertically to the device]. So it will be just like a triangle.

The student then proceeded to explain how to use the ruler to measure the change in height and change in distance as indicated by the inclinometer in order to calculate the partial derivative as the ratio of these two measured quantities.

The student used his prior understanding of the partial derivative as a ratio of change in height over change in distance in order to create schemes for interacting with the surface and the inclinometer, therefore this was classified as instrumentalization-specific.

Instrumentalization - General

Interactions were identified as instrumentalization-general when the student brought prior conceptualizations of a general case of a mathematical phenomenon to bear upon an artifact and as a result created schemes for engaging with the artifact.

Instrumentalization-General Example. A group of three students were asked to determine whether the partial derivative of a two variable function at a point should be equal to the partial derivative of the tangent plane to that surface at that point. One student, J, began to argue that the two partial derivatives should be equal by relating back to his experiences in single variable calculus. He picked up a plastic square and used it along with the surface to reason about this relationship.

> J: If we take this and put it here. [Student picks up the plastic square and places it on the surface as a tangent plane.] … So you just cut it right here, [student makes a downward chopping motion with his hand across the plane and the surface] and you view it sideways. You would see a function with a line at that point.

The student proceeded to articulate that this representation should be viewed as similar to the single variable calculus relationship between a function and its tangent line.

It is important to note that this was the student's first experience encountering the plastic square. Once it was introduced, the student developed a scheme of placing the plastic square on the surface to represent a tangent plane along with a "cutting" scheme for viewing a cross-section of the surface. This development of new schemes for interacting with the surface led us to classify this action as instrumentalization. Additionally, the student was engaged in a conversation about the relationship between the tangent plane and the surface at any point in the domain, so the student's actions were not about a specific instance of this relationship, but rather about all such relationships across the surface, leading us to classify the activity as instrumentalization within a generalized context.

Instrumentation - Specific

Interactions were identified as instrumentation-specific when the student's interactions with the artifact led the student to develop new conceptions of a specific case of a mathematical phenomenon.

Instrumentation-Specific Example. A group of three students were asked to determine whether the partial derivative of a two variable function at a point should be equal to the partial derivative of the tangent plane to that surface at that point. The group first considered a single point, marked in blue on the surface, to determine whether they are the same at that point. During this conversation, one student, M, picked up the inclinometer and used a previously developed scheme to measure the partial derivative on both the surface and on the plastic square placed tangent to that surface.

> M: [while measuring the partial derivatives with the inclinometer] I guess it's the same. For either the plane or the surface, because this plane is tangent to the blue dot…

In this activity we see M used previously developed schemes, namely the scheme for measuring a partial derivative and the scheme for representing a tangent plane, to convince himself that in this case both calculations would yield the same result and thus the partial derivatives of the surface and of the tangent plane at that one point must be equal. Therefore this was classified as instrumentation-specific.

Instrumentation - General

Interactions were identified as instrumentation-general when the student's interactions with the artifact led the student to develop new conceptions of a general case of a mathematical phenomenon.

Instrumentation-General Example. A group of two students were challenged to use only the value of a multivariable function and its partial derivatives at a point to approximate a nearby value of the multivariable function. The students used the surface and the plastic square along with schemes for interacting with these artifacts developed during the classroom activity to reason about how to approximate the nearby value and why that value is an approximation and not the exact value of the multivariable function.

> [Student places the plastic square on the surface as a tangent plane and uses the dry-erase marker to draw lines parallel to the x and y-axes. The student then labels the nearby point in question on both the surface and the tangent plane.]
> P: We can get the value of this point on the plane, but we cannot get the value on the surface. It's an approximation, because the slope will change. In the x and y direction the slope will change at any point. On the plane it's not going to change.

In this activity the student evoked previously developed schemes for using the instruments to reason about linear approximation. It was through the use of those schemes that the student identified the reason why the value should not be exact: that the surface had a changing slope while the tangent plane had a constant slope. Earlier in the interview, the students were unable to explain why this result should not be exact. Because the students used their prior utilization schemes for the instruments about partial derivatives and tangent planes to develop this new understanding about approximation which holds at every point on the surface, we classified the activity as instrumentation within a generalized context.

Discussion

In this report, we have aimed to extend the knowledge of the field related to the crucial area of student understanding in multivariable calculus. Due to the complexity of the material, individual examples may be easier for students to grasp initially, and it can be a challenge to extend these to general principles. Further, an additional challenge is presented by the 3-dimensional nature of the mathematical objects. Students can use 3-dimensional tools to aid their study, but their use can be a complex process.

We have designed a framework to better understand student activity while using the Raising Calculus to the Surface materials. The research presented in this report extends the perspective of instrumental genesis in two important ways. First, it incorporates into the perspective a measure of the level of generality, allowing for analysis based both upon activity with the instrument and the type of mathematical activity in which the student is engaged. Second, the perspective of instrumental genesis has been primarily used to describe engagement with technological instruments; our research extends this framework to apply to the use of physical models and measurement tools.

When the categories described in this framework are coordinated temporally, they can create rich descriptions of student instrument use. Using this framework to describe mathematical activity, not only by categorization, but by moves between the different states of instrumental genesis and level of generality, may be a fruitful area of future study.

A Continued Exploration of Self – Inquiry in the Context of Proof and Problem Solving

Todd A. Grundmeier and Dylan Q. Retsek
Cal Poly, San Luis Obispo

Self-inquiry is the process of posing questions to oneself while solving a problem. The authors' previous work has explored the self-inquiry of undergraduate mathematics majors and a mathematics professor. Student self-inquiry was explored via structured interviews requiring the solution of both mathematical and non-mathematical problems. The professor's self-inquiry was explored through self-reporting of questions asked in an advanced problem-solving context. Using transcripts of the student interviews, a coding scheme for questions posed was developed and extended after coding the professor's self-inquiry. Previous results will again be highlighted here but will be followed by a discussion of self-inquiry in the context of an introduction to mathematical proof course. Data from the introduction to proof course is being collected and will be analyzed using the already developed coding scheme. This analysis will be compared and contrasted to previous self-inquiry results and we will present questions about possible future directions for exploring self-inquiry.

Key words: Problem Solving, Proof, Self-Inquiry, Logic, Questioning

Many teachers refuse to simply answer a student's question; instead, these teachers insist on responding to the student's misconceptions with other related questions that the student can answer, slowly scaffolding the student's responses until the student has answered (knowingly or unknowingly) their own question. This method, when done correctly, allows the student to recollect related knowledge, receive a confidence boost in their own knowledge of the subject, and receive a lesson in problem-solving strategies that could be utilized to solve future problems. This method of answering questions with other questions seems to work extremely well for student ownership of material, but the question remains as to why students don't ask themselves some or all of these leading questions. Since the student is capable of answering the posed questions that lead them to the solution, what is stopping the student from posing these questions themselves? Is effective self-inquiry a mark of a "good" student? What types of questions do these "good" students ask themselves while problem solving? More importantly, how can we foster pedagogical knowledge from these "good" students' questions so that teachers can guide all students toward productive self-inquiry?

We would expect that experts in mathematics do things differently than the masses. It therefore makes sense to also rigorously study exactly what characterizes expert mathematical thought, ultimately aiming to transfer this understanding to better educate undergraduates in mathematics. Indeed, much recent work in undergraduate mathematics education has explored this very idea. From how experts read proofs (Inglis & Alcock, 2012) and vet the work of their peers (Inglis, Mejia-Ramos, Weber & Alcock, 2013) to how they make conjectures (Belnap & Parrott, 2013) and use metaphors/perceptuo-motor activity (Soto-Johnson, H., Oehrtman, M., Noblet, K., Roberson, L., & Rozner, S., 2012), a clearer picture of expert mathematical practices is beginning to emerge. Adding expert self-inquiry to this developing picture of mathematical practices and comparing and contrasting it to undergraduate self-inquiry may shed further light on teaching practices that foster productive self-inquiry.

This preliminary report will summarize the authors' previous forays into self-inquiry, and motivate and describe the most recent data collection efforts in an introduction to mathematical proofs course. Finally we will pose questions and lead a discussion with the audience about data analysis, relevance of self-inquiry in RUME and possible future directions.

The Initial Exploration Into Self-Inquiry

A detailed initial exploration motivated by the questions posed above (Grundmeier, Retsek & Stepanek, 2013) suggests marked differences between the questioning profiles of "strong", "average" and "weak" students. This work led to a classification of the questions being posed by undergraduates. The following question tree was developed to exhaust the coding of all questions posed. The question tree will be explained in greater detail during the presentation, but essentially serves to group questions during problem solving into three main categories (and many subsequent subcategories) ranging from "static" to "dynamic" on a spectrum of action taken in the course of problem solving. See Figure 1.

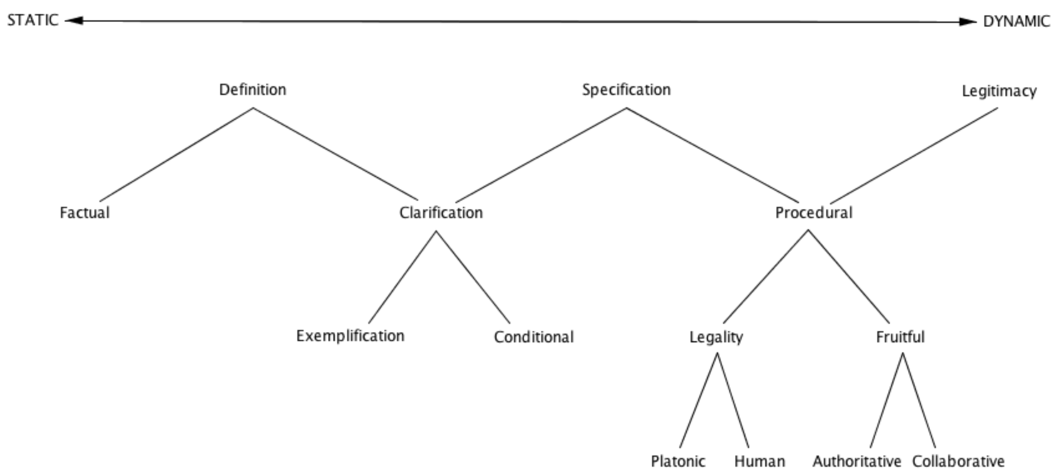

Figure 1: The question tree

In order to explore the self-inquiry of "good" students the authors defined the statistic RSQ (Relative Success Quotient) and calculated an RSQ for all students. To calculate the RSQ the authors focused on the 11 upper division courses that had been taken by at least 7 of the participants. For each course the average GPA and standard deviation of grades were calculated for the last 5 years of course offerings. A participant's RSQ is then calculated as the average number of standard deviations their grades are away from the mean for the courses they had completed from the 11 chosen. Participants clearly fell into three RSQ categories, deemed high, middle and low, and data has been organized accordingly. The table below highlights data from the mathematical task.

	Low	**Middle**	**High**
RSQ	*-0.167*	*0.479*	*.879*
Average # of Q's	13.75	16	9.2
Definition Q's	29.09%	18.75%	28.26%
Specification Q's	29.09%	46.875%	26.09%
Legitimacy Q's	41.82%	34.38%	45.65%

It is interesting to note that the students with a high RSQ were more efficient problem solvers who asked fewer questions. More interesting, though, is that these fewer questions focused on legitimizing their problem solving efforts and a smaller percentage of questions that served the purpose of specifying the problem-solving situation or related to definitions.

Comparison to an Experts Self – Inquiry

In order to shed further light on these questions, the authors designed and undertook a similar data collection process wherein a single "expert" recorded his own self-inquiry over an extended period of study on an advanced mathematical topic. The overarching goal of this study was to compare and contrast these expert questions to those of undergraduate students (Grundmeier, Retsek & Stepanek, 2013). Following an identical coding scheme, analysis of expert questions posed during the problem solving process shed further light on what makes for "good" self-inquiry and tested the adequacy and completeness of earlier question coding schemes.

As the main activity in a quarter long sabbatical the participant worked through the majority of the first two chapters of the text *Real Analysis: Modern Techniques and Their Applications* (Folland, 1984). This text was chosen because it is frequently used in graduate course work and would allow for a faculty mentor just in case mathematical questions needed to be referred to a colleague.

The participant's typical plan for working on the material was to carefully read each section of the text while noting questions that arose. He then attempted the problems that had been assigned in a recent Real Analysis course. While attempting to solve each problem the participant would document all questions that arose as well as the time between each question. Many problems required multiple attempts before a solution or proof was reached and questions during each attempt were recorded separately. For example, in organizing the data many headings such as "Section 2.3, Problem #22 attempt #2" appear. The choice to record these questions separately was made for a number of reasons. First there was often a significant amount of time between attempts, as the participant might have tried another problem in between or needed to sleep on the strategy he was using. Second, the participant assumed there would be overlap between the questions asked which might be important to analyze and discuss. Finally, it may be interesting to determine if the types of questions asked were different after some time subconsciously considering the problem. Working through this process for the first two chapters of the text led to the collection of 404 questions. A broad comparison of self-inquiry is presented in the table below.

	Low	**Middle**	**High**	**Expert**
RSQ	*-0.167*	*0.479*	*.879*	*NA*
Average # of Q's	13.75	16	9.2	10.54
Definition Q's	29.09%	18.75%	28.26%	25.7
Specification Q's	29.09%	46.875%	26.09%	42.9
Legitimacy Q's	41.82%	34.38%	45.65%	31.4

This initial analysis was followed by a more detailed analysis by question type that is presented in the tables below. All data represent percentage of questions within question type.

Definition Questions				
	Low	Middle	High	Expert
Factual - Definition	0	8.3	7.7	35.2
Clarification - Definition	81.3	75	53.8	44.4
Exemplification - Clarification - Definition	12.5	8.3	30.8	11.1
Conditional - Clarification - Definition	6.2	8.4	7.7	9.3

Specification Questions				
	Low	Middle	High	Expert
Clarification - Specification	56.2	33.3	41.6	21.1
Conditional - Clarification - Specification	18.8	33.3	16.7	22.2
Procedural - Specification	18.8	23.4	25	45.6
Human - Legality - Procedural - Specification	6.2	10	16.7	0
Exemplification - Clarification - Specification	0	0	0	11.1

Legitimizing Questions				
	Low	Middle	High	Expert
Procedural - Legitimacy	21.7	0	4.7	19.7
Platonic - Legality - Procedural - Legitimacy	60.9	77.3	76.2	10.6
Human - Legality - Procedural - Legitimacy	8.7	18.2	14.3	1.5
Collaborative - Fruitful - Procedural - Legitimacy	8.7	0	0	47.0
Authoritative - Fruitful - Procedural - Legitimacy	0	4.5	4.8	21.2

This analysis suggests the following points that will be discussed during this report.

- Expert may be more satisfied than undergraduates with precise and working senses of definitions with less need for exemplification.
- Undergraduates focus information gathering on clarification while the expert focuses information gathering on execution of procedures.
- Expert uses exemplification in the context of specification while undergraduates don't.
- Undergraduates focus legitimization on checking their work while the expert generates ideas for progress.

Further Data Collection and Analysis

With the goal of continued refinement of the question tree and to continue our foray into self-inquiry the authors will collect further data in an introduction to proof course during the fall 2016 quarter. While we have explored self-inquiry during the problem solving process we have decided that a potentially fruitful further direction is a focused exploration of students' self-inquiry at the beginning of the problem solving / proving process. During the proof course students will be required to state the first question that comes to mind after their initial consideration of the problem statement. This inquiry requirement will be pervasive throughout the course and be an expectation on all assignments. With approximately 50 students in two sections of the course and the requirement of student's to submit a portfolio with all problem solutions / proofs from the course the author's have the potential to collect at least 5000 questions and problem solutions to code.

Once data collection is complete the authors will code students' self-inquiry using the question tree as well as score their problem solutions with the goal of addressing the following questions.

1. Are there similarities and/or differences between self-inquiry in the context of mathematical proof and self-inquiry in the previous contexts explored?
2. Does the initial self-inquiry of "good" students in the context of this course differ from other students?
3. Is their any correlation between type of initial question and quality of the problem solution / proof?

Questions for the Audience

While related research has been conducted in secondary education and reading comprehension (Kramarski & Dudai, 2009; King, 1989) and in general mathematical thinking (Schoenfeld, 1992), it seems that the self-inquiry of undergraduates and experts has not been explored. Therefore another goal of this project is to continue this line of inquiry and add to the current mathematics education research related to problem solving and mathematical proof. The following questions for the audience may help shape our future research direction:

1. Is self-inquiry a relevant enough topic to the RUME community to deserve more attention and exploration?
2. Are there other potentially fruitful ways to analyze this data set and/or make comparisons of self-inquiry?
3. What other data collection tools or research design options would help explore self-inquiry?
4. Should we attempt further data collection of expert self-inquiry? If so, how might we do this is some authentic way.
5. How do we extend our work beyond the first question asked in the context of mathematical proof?

Undergraduates' Reasoning about Integration of Complex Functions within Three Worlds of Mathematics

Brent Hancock
University of Northern Colorado

Recent research illustrates the importance of studying students' nuanced mathematical argumentation, as well as students' tendency to invoke attributes of real numbers that no longer apply to situations in complex analysis. This preliminary report explicates a study exploring undergraduate student pairs' reasoning about integration of complex functions. I am particularly interested in students' attention to the idiosyncratic hypotheses of powerful integration theorems as they evaluate integrals. Here reasoning is treated as contributing to collective argumentation within one or more of Tall's (2013) three worlds of mathematics. Data were collected via task-based, semistructured interviews with pairs of undergraduates to elicit such reasoning, and classroom observations of the six class sessions devoted to integration prior to the interviews. All interviews have been transcribed and current analysis consists of conducting a Toulmin (2003) analysis, augmented by a three-world classification. Potential implications of this work and connections to the associated literature are also discussed.

Key words: collective argumentation, complex variables, integration, reasoning

Introduction and Literature Review

According to Tall (2013), "Mathematics is often considered to be a logical and coherent subject, but the successive developments in mathematical thinking may involve a particular manner of working that is supportive in one context but becomes problematic in another" (p. xv). The mathematics education literature on the teaching and learning of complex numbers reveals that such difficulties can arise when learning complex analysis. For instance, Danenhower (2000) identified a theme of "thinking real, doing complex" (p. 101) wherein individuals demonstrated a proclivity towards invoking attributes of real numbers that do not necessarily apply in the complex setting. Troup (2015) found further evidence of this phenomenon when undergraduates reasoned about derivatives of complex functions.

It is possible, then, that undergraduates might be tempted to initially reason about integration of complex functions as area under a curve, as this is one common interpretation in the setting of certain real-valued functions. This could be especially prevalent given that even within the context of real-valued functions, the literature reveals numerous examples of students' difficulties with integration (Grundmeier, Hansen, & Sousa, 2006; Judson & Nishimori, 2005; Mahir, 2009; Orton, 1983; Palmiter, 1991; Rasslan & Tall, 2002). However, many of these studies documented the *product* of students' deficiencies and misconceptions rather than the *process* of students' reasoning. As such, while students might end up with faulty conclusions about integration, their process of reasoning might actually be teeming with healthy connections to intuition or past experiences. Indeed, if nurtured properly, such connections between experientially-based intuition and formal mathematics could benefit students' reasoning in courses such as complex variables or analysis (Soto-Johnson, Hancock, & Oehrtman, 2016).

Moreover, by carefully documenting students' successful reasoning about undergraduate mathematics topics, we are able to gain insight into "what deep understanding and complex justifications are possible for students as they engage in mathematics" (Wawro, 2015, p. 355).

Students' reasoning within the subject of complex variables could particularly benefit from such an investigation, as the mathematical activity within this course is often situated somewhere between formal proof and symbolic calculation. In particular, students that integrate complex functions often invoke powerful theorems, which rely on idiosyncratic hypotheses and draw on ideas from topology and real analysis. While formal proof is typically not the focus of undergraduate courses in complex variables (Committee on the Undergraduate Program in Mathematics, 2015), application of such theorems requires that students at least recognize when these hypotheses apply. Hence it is possible that students might draw upon a combination of intuition, visualization, symbolic manipulation, and formal deduction when integrating complex functions. Accordingly, integration of complex functions serves as an appropriate topic to elicit the complex justifications that Wawro advocated for. Integration of complex functions is also an important topic for undergraduates with respect to practical applications. For instance, it is extensively used in physics and engineering to analyze and compute flux and potential. Moreover, one can apply techniques using integration of complex functions in order to drastically simplify or enable evaluation of certain real-valued integrals.

Despite the practical and theoretical assets inherent to integration of complex functions, there exists no educational research regarding undergraduates' reasoning in this mathematical domain. In particular, it is unclear as of yet how undergraduate students reason algebraically, geometrically, and formally with the notion of integration of complex functions. This study serves to ameliorate this gap in the literature and to inform the teaching and learning of complex variables by investigating undergraduates' multifaceted argumentation about integration of complex functions. Using Tall's (2013) Three Worlds of Mathematics framework, my ongoing research seeks to answer the following guiding questions:

1. How do pairs of undergraduate students attend to the idiosyncratic assumptions present in integration theorems, when evaluating specific integrals?
2. How do pairs of undergraduate students invoke the embodied, symbolic, and formal worlds during collective argumentation regarding integration of complex functions?

Clearly, this requires a careful consideration about what constitutes mathematical reasoning. According to the National Council of Teachers of Mathematics (NCTM), reasoning is characterized as "the process of drawing conclusions on the basis of evidence or stated assumptions" (NCTM, 2009; p. 4). Hence, because reasoning is not directly observable as a mental process, researchers can use individuals' argumentation, including the components mentioned by the NCTM, as a window into the mind. A common model used to document individuals' argumentation was formulated by Toulmin (2003) and consists of six components: data, warrant, backing, qualifier, rebuttal, and claim. According to Toulmin, any argument is based upon the arguer attempting to convince his or her audience of some *claim* (C), or asserted conclusion. This claim is necessarily grounded in foundational evidence, or *data* (D), on which the claim is based. The arguer can then supply a *warrant* (W) justifying the link between the given data and the purported claim. A *modal qualifier* (Q) is often necessary to explicitly reference "the degree of force which our data confer on our claim in virtue of our warrant" (p. 93). Depending on the warrant provided, there might also be circumstances in which the intended claim does not hold; in this case, conditions of *rebuttal* (R) are needed to indicate when the "general authority of the warrant would have to be set aside" (p. 94).

In the mathematics education literature, participants' mathematical argumentation has been analyzed with the aid of Toulmin's model in several different contexts. In the in-class setting, some researchers (Krummheuer, 1995; Krummheuer, 2007; Rasmussen et al., 2004; Stephan &

Rasmussen, 2002) felt that a reduced Toulmin model where the qualifier and rebuttal are omitted was appropriate, and rarely found evidence of explicit backing. Moreover, Krummheuer (2007) illuminated warrants invoked by the participants that did not even relate to the mathematical content directly, such as an appeal to the teacher's perceived authority. However, when more formal arguments such as proofs are concerned, researchers (Alcock & Weber, 2005; Inglis, Mejia-Ramos, & Simpson, 2007; Simpson, 2015) argued for the use of the full Toulmin model. They also mentioned that simply reading the finished product of a purported proof is inherently difficult because some components of the Toulmin model, such as backing and sometimes even the warrants, are implicit and cannot be elicited through real-time discourse with the proof author. Thus it would appear that an investigation into undergraduates' nuanced argumentation about integration of complex functions should adopt the full Toulmin model and incorporate opportunities for clarification, as in an interview setting.

Theoretical Perspective

In this study, I adopted Tall's (2013) Three Worlds of Mathematics as a way to theoretically orient my inquiry into undergraduates' reasoning pertaining to integration of complex functions. This perspective traces all mathematical knowledge back to three distinct but interrelated forms of thought: *conceptual-embodied*, *operational-symbolic,* and *axiomatic-formal.* According to Tall, conceptual embodiment begins with the study of objects and their properties, progressing towards mental visualization and eventually description through increasingly subtle language. The second world of operational symbolism grows out of actions on objects and is symbolized in potentially flexible ways via *procepts*, or symbols operating dually as process and concept (Tall, 2008). Tall's (2013) third world is that of *axiomatic formalism*, wherein individuals build "formal knowledge in axiomatic systems specified by set-theoretic definition, whose properties are deduced by mathematical proof" (p. 17). These three worlds can also combine to form, for example, *embodied symbolic* or *symbolic formal* reasoning.

As mentioned previously, Tall (2013) argued that our previous experiences with mathematics can either support or create conflict with new and abstracted mathematical notions. He referred to the knowledge structures predicated on these prior experiences as *met-befores*. Tall also argued that mathematical growth can be traced back to three innate *set-befores* of recognition, repetition, and language. These set-befores foster three forms of compression: categorization, encapsulation, and definition. Through this compression, individuals build so-called *crystalline* structures, which incorporate many equivalent formulations of a mathematical object and can be unpacked in various worlds.

These worlds can also lend additional specificity to a mathematical argument, in that "each world develops its own 'warrants for truth'" (Tall, 2004, p. 287). For instance, in the embodied world, truth is initially established based on what is *seen* to be true by the learner visually. In contrast, within the symbolic world, truth is established in arithmetic based on calculation. Finally, in the formal world, a statement is true either by assumption as an axiom, or because it can be proved formally from the axioms. Hence Tall's three-world perspective can complement the Toulmin analysis of a mathematical argument by adding specificity with regard to the types of backing and warrants used. As such, I classify participants' Toulmin components as embodied, symbolic, formal, or various mixtures of these, as viewed through Tall's three-world lens. Therefore, in the context of this study I define *reasoning* as mathematical argumentation within one or more of the three worlds.

Additional specificity with regard to backing exists due to Simpson (2015), who examined how earlier papers (e.g. Evens & Houssart, 2004; Inglis et al., 2007; Stephan & Rasmussen, 2002) reported its use. Simpson found that there were three distinct roles for backing of warrants within an argument. The first, *backing for the warrant's validity*, was invoked to explain why the warrant applies to a given argument. A second type of backing served to "highlight the logical field in which the warrants are acceptable," which Simpson characterized as *backing for the warrant's field* (p. 12). Finally, a third type, *backing for the warrant's correctness*, illustrated that a given warrant is actually correct.

Given that my study considers how pairs of students reason about integration tasks, it is additionally important that I consider how each individual contributes to an argument. According to Krummheuer (1995), *collective argumentation* takes place when multiple participants construct arguments through emergent social interaction. As part of this interaction, an individual invokes one of four speaker roles. As *author*, a speaker is both syntactically and semantically responsible for his or her statement. On the other hand, a speaker might claim responsibility for neither the semantic nor syntactic aspects of an utterance, in which case he or she acts as *relayer*. Alternatively, a speaker "uses the words of someone else to mean *something different* from the meaning ascribed to the utterance of the original speaker" (Krummheuer, 2007, p. 67, italics in original) as a *ghostee*. Finally, when a speaker revoices a previously mentioned idea using his or her own language, he or she is acting as *spokesman*.

Methods

In order to rigorously address my research questions, I enlisted the help of two pairs of undergraduate students to partake in a videotaped, semistructured (Merriam, 2009), task-based interview comprised of two 90-minute portions. Participants were selected from undergraduate students at a military academy in the United States, enrolled in the complex variables course during the spring 2015 semester. My first pair of participants consisted of Sean and Riley. Sean was a fourth-year physics and mathematics major and Riley was a second-year applied mathematics major with a cyberwarfare concentration. The second pair consisted of Dan, a third-year mathematics major, and Frank, a second-year applied mathematics major with an aero concentration. Table 1 summarizes my methods of analysis for the interview data; note that step one is now complete.

To obtain a rich understanding of the context in which these participants learned about integration of complex functions, I also observed and videotaped six class sessions at participants' undergraduate institution. These observations and ensuing field notes allowed me to document what mathematical content was introduced and emphasized during the integration unit in the complex variables course. They also allowed me to discern the nature of mathematical argumentation that was deemed appropriate for the complex variables course.

Discussion

Recently, Soto-Johnson et al. (2016) found that mathematicians drew upon a wealth of personal embodied experiences when discussing their conceptions of continuity of complex functions. Although their study pertained to the population of mathematicians, Soto-Johnson et al. hypothesized that meaningfully connecting experientially-based intuition and formal mathematics could also benefit students' reasoning in courses such as complex variables. In part, my research serves to reveal how undergraduates reconcile their met-befores with the formal idiosyncrasies present in integration theorems. Hence, my hope is that my inquiry into students' reasoning about integration might illuminate ways in which instructors can cultivate healthy connections between students' embodied intuition and rigorous, formal mathematics.

Additionally, I anticipate that my study will complement and extend the mathematics education literature regarding students' mathematical argumentation. Wawro (2015) found that her participant's argumentative successes were primarily due to the fact that he was "flexible in his use of symbolic representations, proficient in navigating the various interpretations of matrix equations, and explicit in referencing concept definitions within his justifications" (p. 336). Accordingly, this suggests a potentially strong connection between representational fluency and effective mathematical argumentation. I anticipate that the results of my study will serve to corroborate this finding by exploring how students' embodiment, symbolism, and formalism collectively inform their argumentation about integration.

Table 1
Interview Analysis Summary

Step	Description
1. Transcription	Document participants' exact verbiage; provide rich description of gesture and written inscriptions
2. Code Toulmin components	Classify participants' arguments for each task according to data, warrant, backing, rebuttal, qualifier, and claim as in Toulmin's (2003) model
3. Code for speaker roles	Categorize participants' speaking roles as that of author, relayer, ghostee, or spokesman (Levinson, 1988, as cited in Krummheuer, 2007)
4. Code for three worlds	Further classify participants' arguments from step 2 according to Tall's (2013) three worlds framework
5. Code for backing types	Refine coded arguments from step 3 by categorizing backing according to the types identified by Simpson (2015)
6. Thematic analysis	Reflect on the coded data from steps 1-5 to identify common themes within and across interviews

Potential Questions for the Audience

(1) How might I connect each of the analysis pieces to address my research questions? (2) How might one develop a teaching experiment where instructors draw students' attention to any implicit assumptions used when evaluating integrals in complex analysis?
