CITATION: In (Eds.) A. Weinberg, C. Rasmussen, J. Rabin, M. Wawro, and S. Brown, Proceedings of the 20th Annual Conference on Research in Undergraduate Mathematics Education, San Diego, California. (ISSN 2474-9346).

Preface

As part of its on-going activities to foster research in undergraduate mathematics education and the dissemination of such research, the Special Interest Group of the Mathematical Association of America on Research in Undergraduate Mathematics Education (SIGMAA on RUME) held its twentieth annual Conference on Research in Undergraduate Mathematics Education in San Diego, California from February 23 - 25, 2017.

The conference is organized around the following themes: results of current research, contemporary theoretical perspectives and research paradigms, and innovative methodologies and analytic approaches as they pertain to the study of undergraduate mathematics education.

The proceedings include several types of papers that represent current work in the field of undergraduate mathematics education, each of which underwent a rigorous review by two or more reviewers:

– Conference Papers are elaborations of selected RUME Conference Reports
– Contributed Research Reports describe completed research studies
– Preliminary Research Reports describe ongoing research projects in early stages of analysis
– Theoretical Research Reports describe new theoretical perspectives for research
– Posters are 1-page summaries of work that was presented in poster format

The proceedings begin with the winner of the best paper award, the paper receiving honorable mention, and the paper receiving meritorious citation; these awards are bestowed upon papers that make a substantial contribution to the field in terms of raising new questions or providing significant or unique insights into existing research programs. These papers are followed by the pre-journal award winner, which was selected based on its potential to make a substantial contribution to the field; this award is limited to authorship teams that only includes graduate students, recent PhDs (within 2 years of graduation), and/or mathematicians who are transitioning to mathematics education research.

The conference was hosted by San Diego State Univerisity and the University of California San Diego. Their faculty and students provided many hours of volunteer work that made the conference possible and pleasurable, and we greatly thank them for their support.

Many members of the RUME community volunteered to review submissions before the conference and during the review of the conference papers. We sincerely appreciate all of their hard work.

We wish to acknowledge the conference program committee for their substantial contributions to RUME and our institutions. Without their support, the conference would not exist.

Last but not least, we would like to thank Tim Fukawa-Connelly, the previous conference organizer, for his work setting up the 2017 conference and providing guidance throughout the process. His efforts over the past four years have significantly contributed to the growth of the conference and the strengthening of our community.

Leveraging Real Analysis to Foster Pedagogical Practices

Nicholas Wasserman
Teachers College, Columbia University

Keith Weber
Rutgers University

William McGuffey
Teachers College, Columbia University

Real analysis is frequently a required course for prospective secondary mathematics teachers. However, most teachers view real analysis as unnecessary and unrelated to the work of teaching secondary mathematics. The purposes of this paper are to (i) explore why real analysis, as it is conventionally taught, is not helpful to many teachers, (ii) present a new instructional model for how the course can be taught to increase its relevance, and (iii) present a case study in which our instructional model was implemented in a real analysis course and led to productive changes in teachers' actual pedagogical practice.

Key words: Real Analysis, Secondary Teacher Preparation, Advanced Mathematics, Pedagogical Practice

1. Introduction

In the United States and elsewhere, prospective teachers of secondary mathematics are required to complete extensive coursework in undergraduate mathematics. Such coursework usually includes advanced upper-level courses for mathematics majors (e.g. CBMS, 2012), with many institutions now requiring future teachers to complete the equivalent of an undergraduate degree in mathematics (Ferrini-Mundy & Findell, 2010). Consequently, prospective secondary mathematics teachers often complete more courses in advanced mathematics from a mathematics department than mathematics education courses that focus on teaching methods and secondary content. The key point is that prospective mathematics teachers' experiences in their advanced mathematics courses are a significant part of their preparation for teaching mathematics.

The requirement that prospective mathematics teachers complete advanced mathematics courses raises three important questions. First, if prospective teachers complete a course in advanced mathematics such as real analysis, are they better able to teach secondary mathematics? Second, given that experiences in advanced mathematics courses do not appear to be productive for secondary teacher preparation, is there a way to restructure advanced mathematics courses such as real analysis so that they better meet the needs of prospective teachers? Third, what evidence is there that an innovative instructional approach in an advanced mathematics course can influence teachers' actual pedagogical practice in secondary classrooms?

Our paper is centered around investigating these three questions. We answer the first research question in sections 2 and 3. In section 2, we synthesize the extant literature, which demonstrates that prospective teachers do not appear to benefit from taking advanced mathematics courses. We use existing theoretical frameworks regarding transfer (Lobato, 2012) to explain why this is the case in section 3. We address the second research question in section 4, where we present a transformative instructional model for teaching advanced mathematics to prospective mathematics teachers and describe theoretical reasons for why instruction based on this model can be beneficial to prospective teachers. We illustrate this instructional model with one example module in the beginning of Section 5. We address the third question in Section 5.3, showing that teachers who participated in this module in a real analysis course changed their pedagogical practice. At a minimum, this provides a theoretically-motivated existence proof that advanced mathematics courses can potentially benefit teachers and influence their classroom practice if taught in a productive manner.

2. Literature Review

2.1. The Influence of Advanced Mathematics Courses on Subsequent Teaching

Prospective secondary mathematics teachers are typically required to complete many courses in advanced mathematics. However, as several scholars have noted, there is little research on whether or how these courses influence prospective teachers' future pedagogical practice (e.g., Deng, 2008; Moriera & David, 2007; Ticknor, 2012), which is fundamentally important for practice-based approaches to teacher knowledge and teacher education (e.g., Ball, Thames, & Phelps, 2008). Here, we discuss two findings that suggest that completing such courses have only a modest effect on prospective teachers' pedagogical behavior. First, large-scale studies have found a weak relationship between the number of advanced mathematics courses that a teacher has completed and the achievement of that teacher's students (Darling-Hammond, 2000; Monk, 1994). For instance, Monk (1994) wrote:

> [T]he use of alternative 'cut-points' revealed that the model performed best when the distinction was drawn between having five or fewer versus more than five undergraduate mathematics courses. The addition of courses beyond the fifth course has a smaller effect. In contrast to 1.2% increase in pupil performance reported earlier, the addition of a mathematics course beginning with the 6th course is associated with a 0.2% increase (p. 130).

Because most mathematics majors do not take advanced mathematics courses until after they have completed five courses, including a four-semester calculus sequence and a course in linear algebra, Monk's analysis suggests that prospective teachers will reap only a small benefit from completing a subsequent advanced mathematics course.

Second, when practicing secondary mathematics teachers have been asked how their experiences in advanced mathematics courses have influenced their teaching, many teachers claimed that their advanced coursework did not contribute to their development as teachers (e.g. Goulding, Hatch, & Rodd, 2000; Ticknor, 2012; Zazkis & Leikin, 2010). Few could cite specific instances of how their knowledge of advanced mathematics influenced their secondary teaching (Rhoads, 2014; Wasserman & Ham, 2013; Zazkis & Leikin, 2010). Wasserman et al. (2015) found that this occurred even when the teachers demonstrated an understanding of the advanced mathematics that they were taught.

2.2. Postulated Reasons for why Advanced Mathematics does not benefit Prospective Teachers

Researchers have proposed two reasons for why advanced mathematics courses might not benefit prospective mathematics teachers, even if the prospective teachers understood the content that they were studying. The first reason is that the representation systems used in advanced mathematics differ substantially from those used in secondary mathematics (Deng, 2008; Moreira & David, 2007). For instance, Moreira and David (2007) presented a theoretical analysis of how advanced mathematics courses framed concepts from the secondary curriculum. They noted that in advanced mathematics courses, concepts usually were introduced using a single canonical formal representation. For example, the familiar concept of fractions was defined as an equivalence class of ordered pairs in $\boldsymbol{Z} \times \boldsymbol{Z}\backslash\{0\}$ where (a, b) and (c, d) were equivalent if ad =

bc. However, Moreira and David argued that effective teaching of secondary mathematics often required the use of multiple representations, many of which were visual but not necessarily formal. For example, fractions might be represented both numerically and pictorially as pie charts.

A second reason is that the goals of teachers of advanced mathematics and mathematics educators may not align with those of prospective teachers. Ticknor (2012) argued that many prospective teachers' primary goal in their advanced mathematics courses is merely to pass the course, which is in part due to students being intimidated by the material and having a fear that they may fail (e.g., Ticknor, 2012; Pinto & Tall, 1999; Weber, 2008). Ticknor used this theoretical frame to account for her case studies of prospective teachers in an abstract algebra course learning the skills to earn passing grades on examinations but not reflecting on how the material might relate to solving equations in secondary algebra. The coping strategies that prospective teachers adapt to survive their advanced mathematics courses may bear little relationship to what they do in their classrooms.

3. Theoretical Perspective

3.1. A Trickle-Down Model

From our point of view, the anticipated benefits of having prospective teachers complete a course in advanced mathematics can be exhibited by the "trickle-down" model presented in Figure 1 (Wasserman, et al., in press), which considers the relationships between i) advanced mathematics, ii) secondary mathematics, and iii) *teaching* secondary mathematics. This model highlights that most of the material covered in an advanced mathematics course consists of advanced mathematics, where little or no attention is paid to secondary mathematics or issues of teaching. However, the hope is that the advanced mathematics provides an opportunity for the prospective teacher to better understand certain aspects of the *content* of secondary mathematics. For instance, by learning the zero divisor property about rings in abstract algebra, the prospective teacher may develop a deeper understanding for why one can solve polynomial equations by factoring polynomials. Some instructors of advanced mathematics may be explicit about such connections between advanced mathematics and the content of secondary mathematics, but in many other cases, prospective teachers are asked to make these connections themselves. Next, the expectation is that prospective teacher's better understanding of the secondary mathematics content will inform their future *teaching* of mathematics. In our experience, exactly how prospective teachers should teach differently is rarely discussed in advanced mathematics courses. Prospective teachers are expected to use their understanding of advanced and secondary mathematics to improve their teaching more or less on their own.

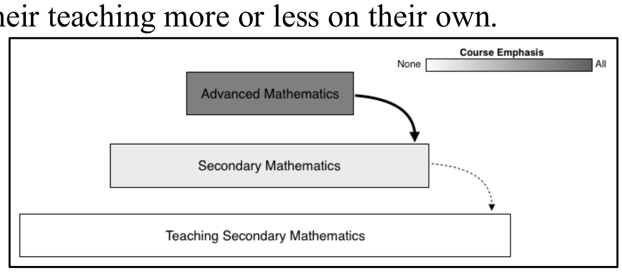

Figure 1. Trickle-down model for teaching advanced mathematics to secondary teachers.

3.2. An Issue of Transfer

As Figure 1 illustrates, the justification for having prospective teachers complete advanced mathematics courses is based on the belief that a transfer of knowledge will occur. The expectation is that prospective teachers' experience in a source domain (as students in an advanced mathematics course) will lead to improved performance in a target domain (as teachers in secondary mathematics), even though the exact nature and mechanisms of this transfer are often unspecified (Wasserman et al., in press).

Lobato (2012) has proposed two distinct lenses by which the issue of transfer can be studied: the mainstream cognitive perspective (MCP) on transfer and actor-oriented transfer (AOT). We believe both can offer insight into why the model in Figure 1 may not help prospective teachers with regard to their teaching.

According to Lobato (2012), using the MCP, transfer occurs when an individual generalizes a desired abstract piece of knowledge from a source domain, recognizes this piece of knowledge as relevant in a future target domain, and then successfully adapts this piece of knowledge to respond to a situation in the target domain. The extent to which this will occur depends on (i) the type of behavioral change that is desired and (ii) similarities between the source domain and the target domain. Wagner (2010) noted that the disposition of many researchers in MCP is to treat judgments about (i) and (ii) as independent of the participant who is doing the transferring, "as if situational structure can be directly perceived in the world" (p. 364).

For (i), transfer is more likely to occur between situations if the change in behavioral performance involves executing a previously learned procedure more quickly. Transfer is less likely to occur if the behavioral change relies on an abstract principle to change how one would approach the problem and there is no prompting that the abstract principle is relevant (Barnett & Ceci, 2002). The latter behavioral change is an instance of *far transfer*, which is widely accepted as difficult to achieve. Of course, it is exactly the type of change we are hoping to see in prospective teachers when they take an advanced mathematics course.

For (ii), Barnett and Ceci (2002) described six ways in which the target situation may differ from the source situation: (a) knowledge domain, (b) physical context, (c) temporal context, (d) functional context (academic vs. play), (e) social context (individual vs. large group), and (f) modality (lecture vs. writing). For each aspect that Barnett and Ceci highlighted, there are substantial differences between the context in which prospective teachers learn advanced mathematics and the contexts in which they will be teaching. We elaborate each point: (a) prospective teachers learn about advanced mathematics as it is expressed with formal symbolic notation but when they teach secondary mathematics, they often use multiple informal representations (Moreira & David, 2007); (b) prospective teachers learn in university classrooms but teach in high schools; (c) the time gap between completing a real analysis course and teaching can be several semesters; (d) the goal of advanced mathematics involves establishing claims via proof while the goal of a secondary mathematics teacher involves enhancing student understanding; (e) the prospective teacher goes from being a student usually working individually (directed by the course instructor) to being a teacher (and leader) of many students; and (f) the teacher switches from writing homework solutions to lecturing, preparing lessons, and leading other instructional activities. Again, these descriptions indicate the goal of improving prospective teachers' pedagogy by teaching them advanced mathematics is an instance of far transfer. Given the distance between the source and target domains, we would expect the influence of advanced mathematics on the teaching of secondary mathematics to be minimal.

Lobato (2012) offered an alternative approach to the MCP that she labeled Actor Oriented Transfer (AOT). In AOT, the researcher seeks to account not by the similarities and differences that the researcher observes between source and target domains, but rather the similarities and differences that the individual doing the transferring finds relevant and salient. In this perspective, the researcher is not so much interested in predicting or measuring whether normative transfer occurred, but rather aims to document any transfer that occurred (i.e., specify all the ways that an individual's experience in a target domain affected subsequent performance in a source domain, including ways that the researcher might find unproductive) and account for this by the individual's perceptions of the source and target domains. AOT offers an additional insight into why prospective teachers might not benefit from completing a course in advanced mathematics. Wasserman et al. (2015) interviewed 14 prospective and in-service teachers about their experiences in real analysis. Many participants found real analysis irrelevant for their teaching because the participants expected to use the proofs that were presented as explanations that they could provide to students in their secondary mathematics courses. Because the real analysis proofs were lengthy and used technical terminology (the concept of limit, epsilons and deltas), the participants found them useless for their teaching. Hence, when studying real analysis, these participants were not focusing on the relationships between concepts (as researchers often do) but what was salient to them was the literal proofs and explanations that were presented and whether or not they could be transported "as is" to their own classrooms.

4. An Alternative Model for Teaching Advanced Mathematics to Secondary Teachers

We present an alternative instructional model for how advanced mathematics can be taught to prospective teachers in Figure 2. In essence, we are "book-ending" the study of advanced mathematics by beginning and ending our lessons with a discussion of teaching secondary mathematics.

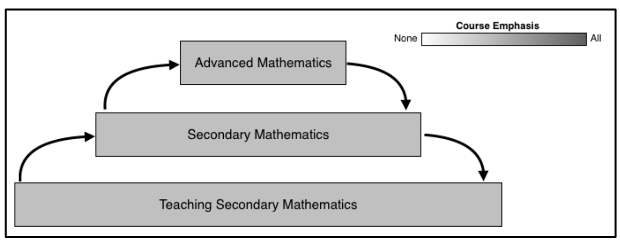

Figure 2. Alternative model for teaching advanced mathematics to secondary teachers.

The left side of the figure consists of *building up from (teaching) practice.* In this phase, we begin an instructional unit with a secondary teaching situation – oftentimes in the form of a comic strip using LessonSketch Software[1] (Herbst et al., 2011). Teachers are asked to evaluate a teachers' pedagogical action or to provide a pedagogical response to that situation (or both). These situations were chosen so that prospective teachers had to engage in the high-leverage teaching practices (HLPs) that Ball and her colleagues documented as central to the work of teaching (TeachingWorks, 2013). Such HLPs include explaining and modeling content, establishing productive classroom norms, eliciting and interpreting student thinking, and providing feedback to students. The right side of the figure is *stepping down to (teaching) practice*. After engaging with the advanced mathematics, such as studying definitions, theorems, and proofs, prospective teachers are asked to reconsider the secondary mathematics and pedagogical situations that they had previously discussed in light of the advanced content. Their homework consists of them doing traditional advanced mathematics exercises (i.e., writing proofs), answering questions about secondary mathematics, and providing responses to other pedagogical situations.

[1] This software is available at Patricio Herbt's Lesson Sketch webpage: https://www.lessonsketch.org/

Our model (Wasserman, et al., in press) in Figure 2 has several theoretical benefits over the "trickle-down" model presented in Figure 1 that undergirds the way advanced mathematics is typically taught to prospective teachers. First, our learning goals include specific pedagogical behaviors that we would like prospective teachers to exhibit as a result of completing our module, goals that we are able to convey to our students and that we assess. As Barnett and Ceci (2002) argued, it is easier for individuals to transfer specific behavioral actions to a new domain than it is to transfer abstract principles. Second, in accord with our practice-based view of secondary mathematics teacher education, our lessons are situated within the context of teaching secondary mathematics. Hence, our modules are closer to the context of secondary teaching than is typical of a real analysis course. Prospective teachers are asked to act as the teacher when responding to pedagogical situations, including providing oral explanations to a hypothetical class of students, interpreting hypothetical students' mathematical justifications, and providing oral and written feedback to student work, all of which should be accessible to a secondary student. Of course, there are differences between responding to our pedagogical situations and the actual craft of teaching (e.g., in our situations, teachers do not need to worry about time management or classroom management) and there are contextual differences between the two that cannot be addressed (e.g., there still is a time lapse and a change in physical location). Nonetheless, compared to the traditional model, the gap between learning real analysis and teaching secondary mathematics has been closed considerably, which Barnett and Ceci (2002) contended will increase the likelihood of successful transfer.

Perhaps most importantly, our model will help prospective teachers notice the aspects of real analysis that we think are important for teaching. Previous research has demonstrated that teachers do not find advanced mathematics helpful for their teaching because they used unproductive coping strategies (e.g., rote memorization) to survive their courses with a passing grade (Ticknor, 2012) or that they take advanced mathematics courses with an eye toward learning proofs that they could share with their future students (Wasserman et al., 2015). Under our alternate instructional model, prospective teachers' grades depend in part on their responses to pedagogical situations, which means they cannot simply ignore the pedagogical implications of the real analysis course. As successfully responding to pedagogical situations goes beyond reciting a proof that was learned in real analysis, prospective teachers are asked to broaden their views on how real analysis can be beneficial to them in their future professional work.

5. An Illustration of our Model

The goal of this section is threefold. First, we illustrate how we used our instructional model to design real analysis modules for prospective teachers. Second, we portray how this was implemented in a real analysis classroom and how prospective teachers interacted with one module. Third, we describe the results of a study in which we followed six teachers into their secondary classrooms and illustrate how their pedagogy changed as a result of completing our modules. This provides an existence proof that real analysis can be relevant for the teaching of secondary mathematics as well as an illustration that instruction based on our module has the potential to foster these changes.

5.1. Overall Module Design

To generate our modules, we engaged in the following process. Our research team examined the first six chapters of Fitzpatrick's (2006) real analysis textbook, identifying any overlap between the concepts covered in Fitzpatrick and the Common Core State Standards in

Mathematics (CCSS-M, 2010). Once these topics were identified, we tried to generate pedagogical situations with the following attributes: (i) the pedagogical situations were authentic, (ii) the prospective teachers were asked to engage in a High Leverage Practice (TeachingWorks, 2013) that is central for teaching, and (iii) successfully engaging in these High Leverage Practices required mathematical knowledge that could be informed by real analysis. We developed 12 modules based on this approach.

5.2. One Module: Considering Derivative Proofs as "Attending to Scope"

5.2.1. Research context and data collection. The data presented in this section is part of a larger corpus of data. We are currently in the second year of a three-year project using design research. We are engaged an iterative process in which we teach a real analysis course using the 12 modules that we generated. The data presented here are from the first iteration of the course that was taught by the first author. The course had 31 prospective and in-service teachers who agreed to participate. In this paper we focus on the "Attending to Scope" module, which took place across two 100-minute sessions. All classes were videotaped and all teacher conversations were audio-taped, and all homework assignments and reflective journal entries were collected.

5.2.2. Building up from (teaching) practice. In their professional work, teachers must explain content, practices, and strategies (e.g., TeachingWorks, 2013); for this particular module, we focus on a mathematical practice that mathematics teachers should engage in – attending to the scope to which an explanation, idea, or justification applies. For example, in trying to help elementary students understand subtraction, some teachers might state: "you cannot subtract a larger number from a smaller one." This explanation has a limited scope – it is only accurate when one is considering positive numbers. Acknowledging the limitation of scope in explanations is an important component of teaching. As Leinhardt, Zaslavky, and Stein (1990) noted, "a primary feature of explanations is the use of well-constructed examples, examples that make the point but limit the generalization, examples that are balanced by non- or counter-cases" (p. 6). Real analysis, with its careful attention to stating explicitly the conditions for when a statement applies, is a domain that is well-suited for helping prospective teachers recognize the importance of being careful with their language, particularly as it relates to considering the mathematical scope to which statements or theorems apply.

We began the module by presenting teachers with the cartoon in Figure 3, asking the teachers to evaluate the pedagogical quality of two of Mr. Ryan's explanations – the *exponent statement* and the *power rule statement*. (Mr. Ryan was a fictitious comic teacher who appeared in many of our modules.) In addition to a variety of other pedagogical issues that might be of concern, both explanations that Mr. Ryan gave were limited in scope. During the module, all groups of teachers highlighted limitations of the explanations, but only two groups highlighted the limitation in scope of both explanations (e.g., the power rule statement doesn't when you need the "chain rule"). Rather than the "*mathematics* of the explanation," most teachers' comments instead dealt with the "*explanation* of the mathematics" – for example, that students might misinterpret what Mr. Ryan had said (e.g., 'repeated multiplication' might mean "2x3x5x7") or that Mr. Ryan's explanations were too procedural. The next part of the module focused on the secondary mathematics, asking teachers to state the number sets (or objects) for which Mr. Ryan's explanations would be valid. Therefore, this task prompted the groups that did not attend to scope previously to consider this facet of his explanations; all groups identified the limited scope to which these statements would apply during this portion of the module.

Classroom Scenario: Mr. Ryan teaches everything from Pre-Algebra to Calculus. The following scenes are snapshots from his classes at different times during the year.

Figure 3. A classroom scenario.

5.2.3. Real analysis. During the real analysis portion, we first presented a standard proof of the power rule for derivatives using the binomial theorem that appears in many secondary calculus textbooks. Teachers were asked to which number set each step in the proof applies (***N***, ***Z***, ***Q***, or ***R***). All groups of teachers eventually recognized that the proof using the binomial theorem was only correct for the natural numbers, with many expressing surprise because they had always assumed that the proof that they read applied to all real numbers (as they knew that the power rule is valid for all real numbers). Afterwards, the instructor presented a sequence of proofs, each of which expanded the scope (***Z***, ***Q***, ***R***) to which the power rule for derivatives applied, which, along the way, involved proving other derivative rules like the product, quotient, chain, and inverse function rules. These derivative proofs are nearly ubiquitous in real analysis courses. What is critical is that the product, quotient, chain and inverse function rules were presented as lemmas for the goal of proving the general power rule.

5.2.4. Stepping down to (teaching) practice. After the proofs were presented, we stepped back down to practice by asking the teachers to discuss, "When, if ever, would the statements made by the teacher be appropriate? Describe the specific context." For their consideration, they were also given specific classroom contexts for each statement (graphing exponential functions for the *exponent statement*, and an end-of-year review for the *power rule statement*). During this time, all groups of teachers further examined the mathematical limitations of each statement, identifying more exact constraints around which each was true. In addition, the groups discussed various contextual factors. For example, one group mentioned "this only makes sense for little kids" (with regard to the *exponent statement*), and another group noted "they're reviewing" as a reason that someone might make somewhat informal statements (with regard to the *power rule statement*). Some groups also discussed that the *power rule statement* would not ever be pedagogically appropriate unless the teacher was only intending to teach a procedure; other groups suggested "fixes" to the statements to make them more mathematically precise. What is important is that the teachers had meaningful discussions around the use of statements with limited scope in mathematics education; indeed, one student claimed, "I feel like I just discovered gold, math gold," which we took to indicate that she found the discussion of the limitations of statements to be very valuable.

5.2.5. Teacher performance on homework tasks. In addition to asking students to prove several real analysis theorems, teachers were presented with two statements: "The perimeter is just the sum of all side lengths" (*perimeter statement*) and "Remember, to multiply a number by ten, just add a 0 to the end" (*add zero statement*). The teachers were asked to, "Determine for what set(s) of objects the statement is true. If there are any, provide an example of a set(s) of objects for which the statement is not true. Discuss in what mathematical contexts might the statement by the teacher be appropriate, if ever? When might it be in appropriate, if ever?" For both tasks, all 31 teachers identified at least one valid counterexample that revealed the limitations in scope. For instance, 29 of the 31 teachers noted that the statement about the perimeter would not apply to a curved figure and 29 of the 31 participants cited a rational number as an instance in which you cannot multiply by 10 by adding a zero at the end.

The teachers were also asked to submit a reflective journal entry in which they described what, if anything, they learned from this week's class. Of the 27 teachers who completed this assignment, 26 mentioned the importance of language and 17 cited the importance of attending to the scope of an explanation and letting students know if there were sets of objects to which the statement would not apply. For instance, the following response was representative:

> *We tend to make general statements for the sake of time without even realizing we are doing it. This past week in class I learned that as teachers, we must think about the statements we make and the limitations we place on students learning moving forward… This statement made by the teacher does not hold for all cases, therefore this is not a mathematically precise statement.*

In summary, the teachers' homework assignment provided some suggestive evidence that our module went well. The prospective teachers' journal entries indicated that the majority of the prospective teachers indicated an increased appreciation for attending to the scope of the explanations that they provide, and, the prospective teachers could recognize the limitations of scope in mathematical explanations if they were prompted to do so. However, our primary concern was not teachers' performance on these written assignments but whether completing this module would influence their actual pedagogical practice.

5.3. Influence on Teachers' Practice

5.3.1. Data collection. The first iteration of our experimental real analysis course was in Spring 2016. For the 2016-2017 school year, six teachers volunteered to participate in a follow-up study. Of the volunteers, five were in-service teachers with under seven years experience, and one was a pre-service teacher who obtained her first job (Ms. J, discussed below). Five participants taught in public schools and one taught in a private school; all schools were around a large urban metroplex. For the courses we observed of these teachers, two teachers taught geometry, two taught calculus, one taught Algebra II, and one taught pre-calculus.

For each teacher, the first and third authors of the paper visited their classroom up to six days during the academic year. For each visit, we observed a one-period lesson that was 45 minutes or 90 minutes in length. Lessons were audiotaped (from a microphone on the teacher) and the researcher kept field notes for each lesson, including transcribing all inscriptions on the whiteboard or projector. We videotaped the lessons as well when it was possible to do so (but school district regulations sometimes did not allow this). After each classroom visit, the teachers participated in a post-interview in which the interviewer recalled common occurrences or key events in their class and asked them to describe why they engaged in those specific behaviors during the lesson. We then asked them whether any of their classroom actions were influenced by their experience in our experimental real analysis course.

We say a teaching unit displayed "attention to scope" when the following three conditions occurred: (i) during the lesson, the teacher paid explicit attention to the scope of a teacher or student-generated claim in their lesson; (ii) in the post-interview, they highlighted this excerpt as an instance where their experience in real analysis influenced their teaching; and (iii) in the post-interview, they explicitly mentioned how the real analysis course led them to be more mindful of the language that they used and/or the limitations in the claims that they made.

5.3.2. Results. Across the six teachers, we made 31 observations. (Due to scheduling constraints by the school districts, we still have to make 4 observations for 3 of the teachers). In these 31 observations, the observed teaching unit displayed “attention to scope” on 17 occasions. That is, in the majority of our observations, we observed the teachers attending to scope in their explanations *and* citing their experiences in real analysis as a reason that they did so. We use two lessons to illustrate.

In our first example, Ms. J, a first-year teacher, was teaching a pre-calculus course about polynomials. During her lesson, she covered the Remainder Theorem, the Factor Theorem (i.e., for a polynomial *f(x)*, *f(c)* = 0 if and only if the factor *(x-c)* divides *f(x)*), synthetic division, and the Rational Zero Theorem. Throughout the lesson, Ms. J emphasized the limitations to the scope of statements that she gave. We illustrate two excerpts from the lesson in Figures 4 and 5.

Mathematics	Explanations and class dialogue (emphasis added)
Remainder Theorem: If a polynomial $f(x)$ is divided by $x-k$, then the remainder is $r=f(k)$. (Example. Find the remainder of $f(x)=2x^2-x+12$ when divided by $x+3$.) Proof. What’s the “r” of $f(x)$ when $f(x)$ is divided by $(x-k)$? $f(x)=(x-k)q(x)+r$ $f(k)=(k-k)q(k)+r$ $f(k)=0\cdot q(k)+r$ $f(k)=r$	Ms. J: So let’s think about that. I have some polynomial and I’m dividing by $x-k$. Instead, I can take this k and evaluate my function at that value and that will be my reminder when I divide by it .. Do you want to see why this works? It’s pretty quick. And I think it's worth seeing so we have some understanding of how this ends up working…It cancels out because I have $(k-k)$, so that’s zero times some polynomial. So then I get $f(k)=r$. Kind of cool to actually see why that works. And then it feels a little less arbitrary. It’s just I plug it in and I know why because Ms. J told me to. (pause) **Again, this only works when it’s $(\mathbf{x}-\mathbf{k})$ of degree one divisor, so keep that in mind. If it’s $(\mathbf{x}^2-\mathbf{5})$, we can’t do this.** Kind of like synthetic division, remember synthetic division only worked when we had terms, divisors of “*x* plus or minus a number.”

Figure 4. Ms. J’s classroom instruction around the Remainder Theorem.

Mathematics	Explanations and class dialogue (emphasis added)
Example. $f(x)=3x^3-2x^2+x-5$ divided by $x-1$. $\begin{array}{c\|cccc} 1 & 3 & -2 & 1 & -5 \\ & \downarrow & 3 & 1 & 2 \\ \hline & 3 & 1 & 2 & -3 \end{array}$ So, $3x^2+1x+2+\frac{-3}{x-1}$.	Ms. J: We’re saying $f(x)=3x^3-2x^2+x-5$ divided by $x-1$. **Synthetic division is a tool we can use to divide polynomials when our divisor is a degree one polynomial, right? “*x* plus or minus a number.” That’s the only time we can use synthetic division. I can’t say that enough.** … Student A: For both divisions, it’s only if it’s to the degree one? Ms. J: For both divisions, meaning what? Student A: (Long) Division and synthetic division Ms. J: Long division… Synthetic division is an algorithm that mathematicians figured out, when **if it’s a specific case, it saves you time from long division**. So that’s why it looks different because it’s an algorithm for a specific type of situation, type of division problem. **The long division works for everything.**

Figure 5. Ms. J's classroom instruction about synthetic division.

In Figures 4 and 5, Ms. J explicitly noted a limitation in the scope of both the Remainder Theorem and synthetic division – namely, that the divisor must be a linear factor of degree one, of the form $x - k$. At times, these were her explanations, and in other cases they were prompted by student questions – but in both situations, she was very explicit about the limitations in scope. Further, at a different point, one student asked her about other linear factors, such as $2x - 2$. The guiding notion in her response was that synthetic division works for factors of the form, $x - k$, and this explicit attention to scope helped her resolve how to respond to the student. In the post-interview, Ms. J discussed why she insisted on clarifying the scope of many of her statements.

Ms. J: I think that there are common mistakes made as a student if you hear a rule. Like great, a rule, I can do synthetic division, especially if it looks like *x* plus or minus something. But they might think x^2 plus or minus something, or just like it's a trick, I'll plug the last number in for the example of synthetic division. So *knowing the common mistakes and trying to prevent them is one reason I think it's important to say that* […] *I think that this reminds me of like the exponents lesson, where I make these vast like generalizations, like exponents, just like repeated multiplication. And it's like, well, that's true if, you know, it's a positive integer and things like that.* But the thing is if you don't say them, it could get confusing later, I think for them. So like that one would have caused them to make mistakes, but it's just explaining I'm simplifying this and here's the restriction that I need to say to make this so.

We wish to highlight two things in this excerpt. In the first italicized section, Ms. J shows how she was able to apply the theme of attending to scope flexibly in coordination with her other pedagogical knowledge – in this case, her knowledge of common student mistakes. She hoped that by highlighting limitations in scope, it would reduce the chance of student mistakes in the future. In the second italicized section, Ms. J references the exponents lesson (i.e., the module described previously) as part of the rationale for her justification of why teachers should avoid vast generalizations that could confuse students at a later time. Later in the post-interview, Ms. J again emphasized the importance of her experiences in the real analysis course.

Ms. J: *I attribute that probably one of the biggest things, like one of the biggest take-aways I had from the analysis course because the exponents one really threw me off.* Like I remember we had to do a problem—I think I even talked about this before, but I just really remember it. We had to do a problem for homework or something where it was, you know, what's two squared? What's two to the one-half? And then it was like, the last one was what's like pi to pi? And I was like I have no idea how to be thinking about this right now. *So it just made—it really stuck out to me how it's important to (pause) really limit your – it's trying to present a smaller view of the topic, but just set the situation so that when you're presenting a smaller view, it's an accurate view still. So very much so to analysis.*

The highlighted excerpts again illustrate how the exponents lesson (i.e., the module described previously) emphasized to Ms. J that she should be careful in her language and even when presenting a "smaller" view on a topic, she should still be mathematically accurate.

In our second illustration, we highlight Ms. T, a teacher with six years experience, teaching an AP Calculus BC course. In this lesson, she covered the Extreme Value Theorem, Fermat's Theorem, Rolle's Theorem, and the Mean Value Theorem. When presenting the theorems, Ms. T attended to the scope of the theorems in an interesting way. She first asked individual students to draw a graph of a function that satisfied the conditions of the theorem. When commenting on the graph, she explicitly checked and then emphasized that each condition was satisfied. We illustrate this in Figure 6.

Mathematics	Explanations and class dialogue (emphasis added)
Rolle's Theorem: Let $f: [a, b] \to R$ be a function that is continuous on the closed interval $[a, b]$, differentiable on the open interval (a, b), and satisfies $f(a) = f(b)$. Then, there exists at least one $c \in (a, b)$ such that $f'(c) = 0$. [Student-drawn example of graph that satisfies Rolle's Theorem] 	Ms. T: We want an example. So, we want a sketch of a function that can be used to help interpret Rolle's Theorem and the Mean Value Theorem. So, it might be easier to sketch something that you can easily see Rolle's Theorem with. So, can I have a volunteer? Your what goes up must come down. … Ms. T: So, let's think about it. *Is she continuous on a closed interval? Is she differentiable on the open? Does $f(a) = f(b)$ somewhere? Is the derivative zero somewhere? So, did she satisfy Rolle's? Okay.*
… Mean Value Theorem: Let $f: [a, b] \to R$ be a function that is continuous on the closed interval $[a, b]$ and differentiable on the open interval (a, b). Then, there exists at least one $c \in (a, b)$ such that $f'(c) = \frac{f(b)-f(a)}{b-a}$. [Student-drawn example of graph that satisfies Mean Value Theorem] 	… Ms. T: I need a volunteer. And the volunteer just has to sketch a function where the Mean Value Theorem will work. You're thinking of our two conditions. Continuous on the closed. Differentiable on the open. … So, the Mean Value Theorem has to work. You need continuity and differentiability. … Ms. T: *Good. Is that continuous? It's continuous. She gave us a closed interval. I'm just gonna highlight it. Is it differentiable? Yeah.*

Figure 6. Ms. T's classroom instruction about Rolle's Theorem and the Mean Value Theorem.

In each italicized excerpt, Ms. T explicitly highlighted how each condition of the relevant theorems was satisfied. In other instances, Ms. T would use student-generated examples not only to illustrate the necessity of the conditions of a theorem, but also to explore the ways in which examples that did not fulfill the conditions resulted in the implication being invalid. Ms. T was able to apply the themes of the real analysis class on attending to scope in a flexible manner, in this case one that involved making students active in the construction of examples in her course. Later in the post-interview, Ms. T affirmed that she attended to scope because of her experience in the real analysis course.

Interviewer: Every time you brought up a theorem, you like specifically referenced the conditions for the theorem.

Ms. T: Yeah.

Interviewer: So, what was your rationale for that?

Ms. T: Yeah. *So, that's still from the course, the Real Analysis course, because the specificity of language* … so it was really being clear like when these things actually will occur, and *that also inspired like, you know, draw a graph where it failed to meet a condition so you can see that it's actually not always going to work out*.

Interviewer: Okay. And so, would you say that—is that something that you normally do? Like would you normally mention it every single time you reference it on your own?

Ms. T: No. I think, now it's just – my own better understanding is why I keep repeating it so that it's kind of more ingrained to them under what conditions things can happen.

In this section, we have documented that in the majority of the instances that we observed, the teachers attended to the scope of mathematical statements and verified in their post-interview that they did so because of their experience in the real analysis course. The excerpts that we presented showed how teachers were able to adapt this theme to their own style of teaching.

6. Discussion and Conclusion

The aim of our paper was to address three research questions. We synthesize our answers to these questions. First, we argue that advanced mathematics courses usually do not benefit prospective mathematics teachers due to the difficulty of the far transfer that we expect to occur and also because what is salient to the students in these classes may differ from what is important to the course instructor or mathematics education researchers. Second, we describe an alternative model for how students can be taught real analysis – one in which the lessons are situated in classroom practice. We first build up from classroom practice in order to motivate studying the real analysis content. We then step back down to classroom practice so students can practice applying the mathematics they have learned to the pedagogical situations. Third, we document that teachers who completed a module on attending to the scope of explanations in real analysis attended to scope in their subsequent instruction and attributed this pedagogical practice to what they learned in real analysis.

To our knowledge, this paper is innovative in several respects. First, although several researchers have documented the limited impact that advanced mathematics courses have on teachers' pedagogical practice (e.g., Goulding, Hatch, & Rodd, 2000; Moreira & David, 2007; Ticknor, 2012; Wasserman et al., 2015; Zazkis & Leikin, 2010), there have been few research-based attempts to ameliorate the situation. In general, attempts to make the study of advanced mathematics courses relevant to secondary teachers have involved making connections to the *content* of school mathematics; in this study, we have attempted to be more explicit about connections to the *teaching* of school mathematics. Second, when attempts have been made to highlight the connections between advanced mathematical content and secondary teaching, they have occurred primarily in "capstone" or "connections" courses (e.g., Murray & Star, 2013) or in professional development programs. Our innovative instructional model, instead, alters the structure of an advanced mathematical course such as real analysis to specifically meet the needs of secondary teachers. Third, the standard by which we evaluated the efficacy of our course did not only rely on how prospective teachers did on our in-course assessments but also on the changes that were reported in their actual teaching practice. This is, of course, the ultimate measure of teacher development, but one that is not often used in evaluating the efficacy of advanced mathematics courses in secondary teacher education.

For the reasons above, we believe our model offers a potentially valuable alternative to the typical model in which advanced mathematics is taught with limited regard for changing prospective teachers' pedagogical practice. By design, the real analysis content in our modules was both tightly connected to and framed by this pedagogical practice. To substantiate the value of our model, however, merits further research. In particular, what we have offered here is a proof of concept. Our model *can* be used to develop real analysis instruction that can improve teachers' secondary teaching. However, we certainly do not have the data to generalize beyond that. For instance, we only explored one specific module in this paper. In the module discussed in this paper, for example, although one does not have to learn real analysis to be able to attend to the scope of secondary mathematics explanations, since a real analysis course already inherently models this idea in both the precision of statements and progression of proofs, it seems sensible to exploit this connection for teachers. We would want to know, at a minimum, the effectiveness of the other 11 modules – some of which paid more attention to specific theorems or proofs in real analysis, others of which had different kinds of connections to teaching. We are currently in the process of evaluating and refining these modules. Further work studying how best to mathematically prepare secondary teachers is needed, including the degree to which this particular model is productive and/or needs refinement, and could help guide improved design and implementation of advanced mathematics courses for secondary teachers.

Students' Epistemological Frames and Their Interpretation of Lectures in Advanced Mathematics

Victoria Krupnik	Keith Weber	Timothy Fukawa-Connelly
Rutgers University	Rutgers University	Temple University

In this paper, we present a comparative case study of two students with different epistemological frames watching the same real analysis lectures. We show that students with different epistemological frames can interpret the same lecture in different ways. These results illustrate how a student's interpretation of a lecture is not inherently tied to the lecture, but rather depend on the student and her perspective on mathematics. Thus, improving student learning may depend on more than improving the quality of the lectures, but also changing student's beliefs and orientations about mathematics and mathematics learning.

Key words: epistemological frames, real analysis, student understanding of lecture

1. Introduction

In recent years, several researchers have explored the relationship between students' epistemological beliefs and their learning of advanced mathematics. In particular, some scholars have claimed that some students struggle to learn mathematics because they lack the epistemological beliefs to support this learning (e.g., Alcock & Simpson, 2004; Bressoud, 2016; Dawkins & Weber, in press; Lew et al., 2016; Solomon, 2006). The primary aim of this paper is to extend this research. In particular, we adapt the notion of epistemological frames (e-frames), a construct from physics education (e.g., Redish, 2004), and illustrate how students who hold different e-frames can interpret the same advanced mathematical lecture in different ways. In particular, we first give an account of two students' e-frames in an advanced mathematical setting; we then use these e-frames to give a fine-grained account for these students' different interpretations of the same utterances by a lecturer.

2. Theoretical perspective and related literature

2. 1. Epistemic frames

Goffman (1997) introduced the notion of *frame* to describe how individuals develop expectations to help them make sense of the complex social spaces that they inhabit. For instance, most adults in the Western world have a "restaurant frame" consisting of expectations that are activated when they enter a restaurant. When frequenting a restaurant, an individual likely would expect that the restaurant employees will prepare food for the individual, the individual will be obligated to pay for this food, and so on (Schank, 1990). Such restaurant frames are usually helpful; these frames allow individuals to act sensibly in restaurants that they have never visited before. However, frames can occasionally be counterproductive if two individuals frame the same situation in different ways. For instance, a European diner may offend a waiter in the United States if she was not aware of the United States custom to leave at least a 15% gratuity.

Physics educators have introduced the notion of an individual's *epistemic frame*, or e-frame, as consisting of their epistemological expectations about a pedagogical situation. These consist of an individual's responses to questions such as "what do I expect to learn?" and "what counts as knowledge or an intellectual contribution in this environment?" (Redish, 2004). If a teacher and her students approach the same pedagogical activity with different e-frames, the students likely will not learn what their teacher intends. For instance, Redish (2004) described a physics tutorial in which students were asked to form a hypothesis. The teacher's aim of this activity was for students make qualitative predictions using their conceptual understanding of physics principles. Redish found that a student who viewed intellectual contributions in physics as consisting of numeric answers derived from textbook formulas responded to such tasks by engaging in computations, thereby avoiding the conceptual considerations the activity was designed to elicit.

We are not aware of any mathematics education research that has specifically used the notions of e-frames to account for students' behaviors. However scholars have explored the relationship between students' epistemological beliefs and their concomitant mathematical cognition. In many of these cases, the claims of these scholars can be expressed using the construct of e-frames. For instance, Thompson (2013) presented a situation in which a teacher provided many conceptual explanations to her high school algebra class but these explanations were ignored by some students in the class who had a procedural orientation. We might interpret Thompson's claim with e-frames as follows. In the students' e-frames, an intellectual contribution in an algebra class consisted of using a procedure to solve a problem symbolically. The teacher viewed part of the intellectual contribution of her presentation as explaining the meaning of the procedure that she was implemented. Since students did not recognize this as a legitimate intellectual contribution in a mathematics, they simply ignored the conceptual explanations.

We can use similar reasoning to characterize other mathematical constructs. For instance, the didactical contract (Brousseau et al., 2014) includes expectations about what mathematical contributions the teacher is required to make, establishing sociomathematical norms (Yackel & Cobb, 1996) involves the negotiation of what an acceptable mathematical contribution is, and institutional meanings of proof (Recio & Godino, 2001) are expectations about what constraints a justification must satisfy in different contexts. In summary, while we are introducing the notion of e-frames to mathematics community, this work builds upon a rich tradition of scholarship examining the links between students' epistemology and cognition. Our contribution is offering a more fine-grained account of how specific e-frames influence students' interpretations of specific mathematical utterances in advanced mathematics.

2. 2. Logical versus psychological understandings in advanced mathematics

In this paper, we distinguish between two ways of knowing a mathematical concept. An individual knows a concept *psychologically* if she believes the statement is true and feels that they understand why the statement is true. An individual knows a concept *logically* if she can provide a deductive justification demonstrating the statement is true from previous statements (usually definitions and axioms) that are assumed to be true.

We make three observations about this distinction. First, in many mathematical settings, psychological and logical knowing are inextricably intertwined. Mathematicians often believe a statement is true exactly when they see how it can be logically deduced from other things that are known or assumed to be true (e.g., Harel & Sowder, 2007). Second, psychological knowing and logical knowing are nonetheless distinct. Some mathematicians hold rational certainty in the veracity of unproven conjectures (e.g., Goldbach's conjecture) and others retain some doubt in claims that have been proven (on the grounds that they cannot be certain that their proofs are correct) (c.f., Weber, Inglis, & Mejia-Ramos, 2014). This reflects the view that the acceptability of a proof is dependent upon a reference theory specifying what facts are allowed to be assumed (Mariotti, 2006). Third, in some cases, the purpose of proof is not to enhance one's psychological knowing, but to provide logical justification (c.f., Dawkins & Weber, in press). Mamona-Downs (2010) expressed this clearly when she wrote that "the point [of proof] is not so much about conviction, but how we can clarify the bases of the reasoning employed" (p. 2338). Arzarello (2007) expressed a similar sentiment, arguing that the purpose of proof is to give meaning to a statement by placing the statement into a network of mathematical knowledge in the form of logical consequence.

2. 3. Systematization

In this paper, we focus on a particular type of activity that deVilliers (1990) has coined *systematization*. In this activity, mathematicians transform an existing theory—i.e., a constellation of concepts and related statements that are accepted as true—into a unified whole. Mathematicians do so by creating a system of axioms and definitions and then demonstrating that commonly accepted statements within the existing theory are deductive consequences from this system of axioms and definitions. As deVilliers (1990) noted, with systematization, "the main objective is clearly not *to check whether statements are really true*" (p. 21, emphasis was the author's). In our interpretation, the purpose of systematization is not to enhance one's *psychological knowledge*; the statements being justified are already accepted as true. Rather, the purpose is to create a system of axioms and definitions that lets us provide logical justifications for things that are accepted as true.

In this paper, we explore two students interpretation of the same real analysis lectures. In these lectures, the instructor is using the integers to define the systems of rational numbers and real numbers. He then derives some well-known consequences of these number systems. For instance, the professor defined the rational numbers as equivalence classes of pairs of integers, and addition on rational numbers as an operation on these equivalence class of ordered pairs. The professor then sketched a proof that addition on the rational numbers is a well-defined operation. We can thus say that the rational numbers are being *re-presented* to the students as we can assume that mathematics majors in a real analysis course have had extensive prior experience with rational numbers. In our view, the mathematical contribution being made is many facts that students already knew *psychologically* about rational numbers can now be seen as *logical* consequences of how the rational numbers were defined. In this paper, we analyze two different student views on what the purpose of this re-presentation is.

2. 4. Students' understanding of lectures in proof-oriented math courses

Most proof-oriented courses in advanced mathematics are taught via lectures (e.g., Fukawa-Connelly, Johnson, & Keller, 2016). Although there have been several studies on how these lectures are given (e.g., Gabel & Dreyfus, in press; Lew et al., 2016), there have been few studies on how students perceive these lectures. We describe one such study, and how e-frames can account for the results of this study below.

Lew et al. (2016) described a real analysis professor, Dr. A, who presented a proof to illustrate a heuristic that would be useful in proving other theorems. However, when Lew et al showed a videotape of this lecture to six students in the class, none of them recognized this heuristic as Dr. A's reason for presenting this proof. In his commentary on Lew et al., Bressoud (2016) conjectured that students "understood the instructor's intention as one of communicating that this is a valid result worthy of being noted and remembered" (paragraph 6) whereas the professor was trying to showcase a new approach that could be used to prove a new class of propositions. We can interpret Bressoud's commentary in terms of e-frames as follows: The professor in Lew et al's study believed the intellectual contribution of his proof presentation was describing an important proving heuristic. In the students' e-frame, the intellectual contribution of a lecture proof was communicating a valid result that was worthy of being remembered. Hence, the main points that the professor was trying to convey were thought of as tangential by the students.

3. Methods

3. 1. Rationale

The goal of this study was to understand how a student's e-frames can shape how that student interprets a real analysis lecture. To accomplish this, we interviewed two students as they watched a publicly available video-recording of a pair of real analysis lectures. This methodology had the advantage that students could act as if they were attending an actual lecture, yet the interviewer or student could pause the video to discuss their in-the-moment impressions of what was being discussed. In this study, we viewed a student's answer to one of the following two questions as one of her e-frames:

- What counts as a legitimate mathematical contribution?
- By what standards should the mathematical contribution be evaluated?

3. 2. Participants

Two participants, Alice and Brittany (pseudonyms), agreed to participate in this study. Both participants were mathematics majors at a large state university in the northeast United States. At the time of the study, both students had completed a transition-to-proof course in the previous semester, which the university requires as a prerequisite for a real analysis course. However, neither student was taking real analysis in the semester when this study occurred. Alice and Brittany were instead taking other proof-oriented courses and planned to take real analysis in a future semester. Thus, both students could potentially have enrolled in a real analysis course, but had not done so.

Alice and Brittany both claimed that they enjoyed their transition-to-proof course. Both students evinced a deductive proof scheme (Harel & Sowder, 2007) and exhibited competence at writing and understanding proofs. While watching the lectures, both students actively tried to make sense of the material.

Alice was an honors sophomore mathematics major who was intending to pursue certification to teach secondary mathematics, who earned an A in her transition-to-proof class. Brittany was a junior mathematics major who earned a B in her transition-to-proof class. To avoid misinterpretation, our aim is not to compare the productivity of Alice's and Brittany's frame or to evaluate the quality of Alice or Brittany's interpretation of the lectures that they observed. We do not make claims about who is the better mathematics student. Instead our aim in this paper is to show that Alice and Brittany's different interpretation of the same lecture can be attributed to the different e-frames that they hold.

3. 3. The lecture

The lecture studied in this paper consisted of the first two class videos from a real analysis course.[1] Each class video lasted between 60 and 70 minutes. The instructor of the course was Professor Francis Su, who won two major national teaching awards from the Mathematical Association of America. The lectures consisted of Professor Su beginning the real analysis course by constructing the rational numbers and then the real numbers from the integers.

3. 4. Procedure

Prior to conducting the study, the research team studied the lecture and parsed the lecture into five to ten minute segments in which coherent mathematical content was being presented. In

[1] The lectures are available at analysisyawp.blogspot.com

each clip we identified any important ideas that we felt were being conveyed. We used this parsing to create an interview protocol. After each segment of the lecture was played, participants were asked, "what, if anything, was valuable to you?" and "what did you take away from this?" as well as specific questions pertaining to the mathematical content that Su presented in that clip.

Each participant met individually with the first author of the paper once a week for four video-recorded clinical interviews (Hunting, 1997). Interview 1 was a one-hour interview in which the participant discussed their experience in their transition-to-proof course to provide the interviewer with a sense of the participants' understanding of the content of the course (particularly with number theory, functions, and proof) as well as their learning strategies and dispositions.

Interviews 2, 3, and 4 were two-hour interviews in which the research team attempted to explore the e-frames, ways of knowing, and any associated mental schemes that each participant used to interpret the mathematical lectures. During each interview, the participant watched Professor Su's lecture and was instructed to stop the video whenever they observed something that was important, interesting, confusing, or otherwise noteworthy. The interviewer would also stop the tape to probe the participant's thinking when the professor had stated something that the research team had identified as important or at the end of a segment, as we described above.

Between the interviews, the members of the research team engaged in concurrent data analysis. After each interview, each member of the research team listened to recordings of the interview and formed initial hypotheses about the e-frames that the participants were using to interpret the lectures. The research team would meet to synthesize these initial hypotheses and develop questions that would allow us to test the viability of these hypotheses. The next interview began with the interviewer asking the participants these questions, which was then followed by them resuming watching the lecture videos. After all four interviewers were conducted, we transcribed each interview.

3. 5. Retrospective analysis

Our retrospective analysis had two main purposes:

(i) we first aimed to analyze broad characteristics of Alice and Brittany's behavior in our interview to give *an account of* the e-frames that they are using;

(ii) we then analyzed specific interpretations that they gave to Professor Su's lectures and used their e-frames to give *an account for* these interpretations (c.f., Mason, 2002).

We first gave an account of Alice and Brittany's e-frames as follows: for each segment of the lecture, we summarized Alice and Brittany's comments. We focused on any instance in which Alice or Brittany described or evaluated what they felt was the mathematical contribution that Professor Su made or was intending to make. Because we regularly asked Alice and Brittany what they thought Professor Su was trying to convey and what, if anything, was valuable, our data contained many comments from Alice and Brittany about Professor Su's mathematical contributions. By analyzing commonalities in each participant's responses across the interviews, we revised the hypotheses developed during concurrent analysis and, as needed, developed new hypotheses about their e-frames.

We then engaged in the following iterative process to refine our hypotheses: For each hypothesis about a participant's e-frame, each member of the research team read the transcripts in their entirety, identifying all instances that either supported or contradicted the hypothesis. We evaluated a specific hypothesis as not viable if one of the three conditions occurred: (i) we found few instances supporting the hypothesis; (ii) we found many instances that were inconsistent with the hypothesis; or (iii) we found a single significant instance that strongly contradicted our hypothesis. If a hypothesis was evaluated as unviable, we would often refine our hypothesis and repeat this process. Other times, we would judge the hypothesis as fundamentally inaccurate and discard it. After this iterative process, we had a set of e-frames for each participant that were highly grounded in the data for each participant.

We then used these e-frames to give an account for students' interpretations of lectures as follows: We identified excerpts in which Alice and Brittany had different interpretations of what Professor Su said in a segment of the lecture, which was a common occurrence. We chose differences that we felt were representative of the data set. With those differences, we described the difference between Alice and Brittany's interpretations in terms of how they framed and evaluated the mathematical contribution that they felt that Professor Su was making. Through an interpretive analysis, we accounted for Alice and Brittany's different interpretations using the e-frames that we posited.

4. Results

4. 1. Alice's e-frames

4. 1. 1. One needed to define a concept to be able to reason about it.

E-frame 1: Making claims and providing justifications about a concept requires a precise definition of the concept.

E-frame 2: A precise definition of a concept is a mathematical contribution.

E-frame 1 provided Alice with a criterion on which she judged whether a mathematical justification was a legitimate contribution. E-frame 1 warranted e-frame 2, that providing a precise definition of a concept was a legitimate contribution.

There were multiple instances that indicated Alice held these e-frames throughout the interviews. For example, in the first interview, the interviewer asked Alice what the real numbers were. Alice's response was revealing: "That's an excellent question. [long pause] I don't know. I don't know the formal definition of a real number". This was representative of Alice's tendency to express an epistemic need to see concepts defined, which she displayed throughout the interviews. For instance, in Interview 1, Alice was asked if the fractions 9/15 and 12/20 were "the same thing". She responded:

> "You need to assign a definition. 'Same thing' does not tell me anything[…]So if I have two of the same shirt, are they the same shirt? No, if I'm wearing one, then one is being worn and one's not. But in terms of just shirts yeah, they're the same shirt. So based on how we want to define 'the same thing', they may or may not be".

In Interview 4, Alice reiterated this point, stressing, "we need very well-defined definitions so that we can get very clear implications". At four other points in our interviews, Alice objected to questions about concepts that were not explicitly defined, saying she found them ambiguous and unanswerable because terms in the concepts were not defined. The importance that Alice assigned to concepts being defined led her to continually seek out definitions when she watched the lectures.

4. 1. 2. When constructing a system, you need to distinguish between what you know through experience and what you are allowed to know within the system.

E-frame 3: Justifications contributing to logical knowing are legitimate mathematical contributions.

E-frame 4: When providing a logical justification, you can only employ claims that are *a priori* or have been previously logically justified. You cannot employ claims that you know psychologically.

E-frame 3 specifies that logical justifications are contributions while e-frame 4 delineates criteria on which they should be evaluated.

As Professor Su constructed the rational numbers, Alice continually distinguished between what she knew psychologically (i.e., what she knew based on her previous experience with the rationals) and what had been justified logically (i.e., axioms, definitions, and statements proven in the classroom context). At 14 different points, Alice stressed the need to differentiate between the two, reminding herself and the interviewer that "we only assumed that we have knowledge about the integers"[2] and "we don't know anything about what [rational numbers] do or look like if they are not an integer". Alice was careful to only use definitions and propositions that were proven in class when justifying claims about the rationals.

4. 1. 3. The mathematical contribution of these lectures.

E-frame 5: The intellectual contribution of these lectures was providing a framework so we can know statements about the rational numbers logically.

E-frame 6: Systematization is valuable when you characterize a more complicated system in terms of a simpler system.

We believe that E-Frame 5 was evoked by Alice in these lectures as a consequence of the prior e-frames that we discussed. Alice desired logical justifications for claims, which is only possible if these claims are defined precisely. E-frame 6 is a criterion that Alice used to judge the significance of the particular systematization that she observed, which we illustrate below. When Alice was asked why Professor Su was constructing the rational numbers, she responded as follows:

Alice: One thing that I have always seen in both physics and math is that, if we can, we always want to go with something more elementary. [In math] I know first we start with our natural numbers. Then we say, what the natural numbers are, a representation of the empty set, and recursive sets of the empty set, ... so 0 was the empty set, 1 was the set of the empty set, and 2 was the set of the set of the set of the empty set, something like that. I feel like there is a search to get even more elementary.

At several other points, Alice became reflective on the nuanced relationship between what she knew psychologically and what she knew logically about the rationals. For instance, in the conclusion of the last lecture, the interviewer asked Alice "how do you understand the rationals?". Her response was as follows:

Alice: [I understand the rationals] on a very simplified level. [The rationals] are just fractions of an integer, numerator and denominator, and I've been working with those types of fractions all my life. So I know exactly what they make, what they look like, how to treat them on a very simplistic level. But on a construction level, we are trying to build them. It's like I want to already know this but the attitude is that it is newly explored material which is a little ironic. It's the attitude that you kind of have to have.

In this excerpt, Alice distinguishes between what she knows on a "simplified level" (what we call knowing in a psychological sense) and at the "construction level" (knowing in a logical sense), noting that you are trying to construct what you already know simplistically (justifying logically what you know psychologically).

[2] Professor Su began his lectures by quoting Kronecker, who said, "God made the integers. All else is the work of man," and did not define the set of integers or operations upon them.

4. 2. Brittany

4. 2. 1. Definitions were used to enhance understanding.

E-Frame 1: The mathematical contribution of a definition is to help Brittany psychologically know a concept.

E-frame 1 describes a criterion by which the significance of the contribution of a definition should be judged. E-frame 1 was evidenced by Brittany in multiple ways. First, at six points Brittany recognized that Professor Su's characterization of the rational numbers (as equivalence classes of ordered pairs) differed from her understanding of fractions, stating at the end of the lectures that she "wouldn't do it [constructing the rationals as equivalence classes] that way" and that rationals were "basically just a fraction of one integer on top of another one". She assumed that the purpose of these alternative characterizations was to provide her with an alternative way to think about the rational numbers. For instance, when asked what she thought the purpose of this presentation was, she responded that she learned "a new way of thinking about the rationals".

Brittany also did not see merit in Professor Su defining aspects of the rational numbers, saying "it's too obvious", because presumably the entire class already understood fractions. Our interpretation is that from Brittany's perspective, such definitions could not enhance her understanding (e.g. "but it's [the definition of positive rationals] not valuable for clarification of anything because we already know"), because she already psychologically understood the concepts being defined.

4. 2. 2. Good definitions are comprehensible.

E-frame 2: Good mathematical definitions are comprehensible

E-frame 2 also provides a criterion on which the quality of a definition should be judged. While Brittany never explicitly described what she thought was a "good definition", at five points she complimented Professor Su's definitions because of their clarity and simplicity. For instance, Professor Su's definition of order on the rationals (i.e., how you define a < b when a and b are rational numbers) was "pretty good" because "it's simple and understandable".

4. 2. 2. You could use what you knew about the rationals to answer the questions that Professor Su discussed.

E-frame 3: When justifying a mathematical statement, it is permissible and desirable to use one's psychological understanding.

E-frame 3 provides a criterion by which mathematical justifications can be evaluated. Brittany rarely expressed a distinction between what she knew logically and what she knew psychologically. Only twice during our four interviews did Brittany question what she was allowed to assume. At 18 other points, she invoked facts about the rational numbers that had not been stated in the lectures to answer questions about the rational numbers. To elaborate on this further, we consider how Brittany reacts to Professor Su's justifications of statements about the rational numbers, which proceeded logically from the definitions that he produced (definitions that Brittany thought were "a new way of thinking about the rationals"). For instance, Professor Su illustrated how each integer z could be represented as the equivalence class of ordered pairs $[(z, 1)]$, Brittany was able to explain why this made sense, but then remarked, "it's just simple to think of it as Z is a subset of Q. I think that would be a simpler way of saying it"[3]. Brittany often expressed frustration at these justifications, which she felt were needlessly complicated.

[3] In our interviews, Brittany was able to explain how the equivalence classes of integers that Professor Su introduced in his lectures represented the integers, which we do not include in this paper for brevity. We only note here that

4. 2. 4. The mathematical contribution of these lectures

E-frame 4: The goal of the lectures was to enhance her psychological knowledge of the rational numbers.

We believe that Brittany evoked this e-frame as a consequence of the earlier e-frames. Each of the earlier e-frames indicated that mathematical contributions of this lecture—that is, Professor Su's definitions and proofs about rational numbers—were presented to enhance Brittany's understanding of the rational numbers and therefore should be easy to comprehend. One way that Brittany evinced e-frame 4 was when she viewed the purpose of the entirety of the lectures as to provide a review about the rational numbers. This failed to satisfy the criterion in e-frame 4 because she felt that she already psychologically knew the relevant statements about the rational numbers introduced by Professor Su.

When asked about the main purpose of the lectures, Brittany cited the construction of the rational numbers and remarked that this "was important to take away." When asked what it meant to construct the rationals, Brittany responded, "I think he was just going over properties of it—order, addition, multiplication, what it means putting them all on the number line". In general, Brittany was frustrated because she wanted to learn new material and did not find value in what she perceived as an extended review, as illustrated in the following exchange:

Interviewer: So what I'm hearing you say is it's more interesting to talk about things you don't know than things you do know, to answer some questions that you might not really know that are interesting?

Brittany: Yeah, I think that's like true for everything.

4. 3. Different interpretations of the same lecture

In this sub-section, we present clips from Professor Su's lectures and describe Alice's and Brittany's reactions. Our aim is to illustrate how Alice's and Brittany's different e-frames led them to interpret these clips in different ways and then to make the broader point that a professor effectively conveying the material depends on the e-frame of the student observing the lecture.

4. 3. 1. Motivating questions. Early in lecture 1, Professor Su presented motivating questions on a PowerPoint slide. These questions included, "What does it mean for a series of numbers to converge? What is a limit? Are there 'enough' numbers to capture all limits?[...]What does it even mean for a sequence of numbers to converge when you're not referencing a limit? There's a question. Some really tough questions." Alice interpreted these questions as follows:

Alice: I started realizing that these were questions that were probably going to be addressed throughout the course so then I understood why he was asking them. It was kind of a mindset I need to be in. I wasn't trying to answer these questions whenever he asked them, but really trying to get myself into the mindset of questioning certain definitions. It prompted me to get in what I think would be a good mindset in this class.

Interviewer: I was going to ask you if you tried answering any of these questions, and you said that you didn't.

Alice: I briefly thought about them but then I realized that I really didn't have the grounds. I didn't know the definitions. I thought about each question. I understood that really I haven't questioned these at all and that I accepted many of them. That allowed me to get into a mindset of, 'I can't just accept these facts anymore. I have to bring these questions back and this is the attitude you have to face in this class'.

Brittany's understanding was beside the point. She did not see the need for a complicated explanation for why Z was represented in Q because clearly the integers were a subset of the rationals.

In this excerpt, Alice discussed how the questions prompted her to consider the definitions of the concepts involved in the questions and motivated the lectures in the early part of the course, which consisted of defining the terms in the questions in terms of the integers. We account for this with Alice's e-frame 1: that making and justifying claims about concepts requires a definition of that concept. Alice's desire for these definitions can be accounted for by her e-frame 2: that providing precise definitions of concepts is a mathematical contribution. Finally, Alice described Professor Su's concepts as invoking an "attitude" and "mindset" that one cannot simply rely on their prior understanding (what we refer to as Alice's psychological knowing) which aligns with Alice's e-frame 3 and e-frame 4 calling for Alice to distinguish between her psychological and logical knowledge of the rationals.

When Brittany was asked what she was thinking about when she saw the questions, she said she found the questions "interesting" and "I was visualizing a number line in my head". Hence, Professor Su's questions were also motivating for Brittany, but they prompted her to use her intuition to think about what the answers to these questions might be and how they might relate to her mental models for understanding the real numbers. Hence, Professor Su's questions also evoked an e-frame for Brittany, but it was a different one than Alice. It was Brittany's e-frame 4, that the goal of these lectures was to enhance her psychological knowledge of rational and real numbers.

4. 3. 2. Well-defined operations. In lecture 2, Professor Su defined addition on the rational numbers (<(a, b)> + <(c, d)> = <(ad+bc, bd)>). He then wanted to show that this binary operation was well-defined. To illustrate what he meant by well-defined, Professor Su presented two other candidates for addition, one of which was well-defined but useless (a binary operation whose output is always <(0, 1)>) and another that was not well-defined (<(a, b)> + <(c, d)> = <(a+c, b+d)>). Alice claimed she understood what Professor Su meant by the term well-defined, saying "we can put in different elements of the same equivalence class, and we should still expect the same result". Nonetheless she objected, "when he says this definition is well-defined, the specific definition requirements for something being well-defined was not gone over. The term well-defined was actually not well-defined". Finally, Alice noted that if she were actually taking this class, she would look up the definition of well-defined outside of class. Our interpretation was that Alice understood the concept of a well-defined operation psychologically, but without a formal definition, she could not understand the concept logically. This is because of e-frame 1 that logical reasoning about the concept requires precise definitions. Therefore, she found Professor Su's presentation inadequate.

Brittany viewed Professor Su's definition of well-defined favorably:

Brittany: I like the definition of well-defined. It was really clear and understandable because well-defined is a word we use a lot.

Our interpretation is that Brittany found Professor Su's examples as adequate to get a good sense (or psychological understanding) of what the concept of well-defined meant. We account for Brittany's comments with Brittany's e-frame 2: that good definitions are comprehensible. Because Brittany psychologically understood Professor Su's definition, she valued it.

4. 3. 3. The definition of addition. In lecture 2, Professor Su defined addition by <(a,b)> + <(c,d)> = <(ad+bc, bd)>. When Alice was asked what Professor Su was trying to convey, Alice responded that providing this definition was necessary.

Alice: [Without the definition], we wouldn't know what addition is. We want to keep that mentality that the whole thing that we are doing is we are defining that construction, so we need to make these definitions.

We account for Alice's comment with her e-frame 1 and e-frame 2. One could not reason about addition without defining it so it was a necessary contribution.

> Alice: Half of me wants how we get to that exact definition[...]As we have seen, there are well-defined functions that [we don't want...]Assume we don't have any knowledge of the rationals, why this and not the others?

Alice proposed one such criterion for evaluating a definition for addition was verifying that the definition implied that <(a, 1)> + <(b, 1)> = <(a+b, 1)>.

We account for Alice's comments with e-frame 4, that one could not use their previous knowledge about the rationals in justifying claims about the rationals. Alice desired a justification for the adequacy and choice of that particular well-defined definition *independently* of what Alice knew psychologically. As the following excerpt reveals, Alice knew Professor Su's definition of addition would "work", but for now, we must "assume we don't have any knowledge of the rationals":

> Alice: The other half of me, well I know how to get to this. Do I really want to see him lay it out or do we just accept this definition? I know why cause it works and that's just what I'm told[…]I feel like a lot of this would be considered valuable but I wouldn't say its significant and new. It's hard because it's like we are discovering something we already know.

Our interpretation of this excerpt is that although Alice appreciates the need to justify that Professor Su's definition of addition is an adequate one (it "would be considered valuable"), a part of her does not want to see this justified because, based on her experience, she knows it is going to work, even though e-frame 4 requires logical knowledge to justify Professor Su's choice.

When Brittany was asked about the definition, she thought the definition that Professor Su provided was adequate, saying, "I liked the definition because it's true. I can see how he got it. I thought it was going to be that. It proves I know what's going on". However, later in the interview, Brittany also complained that she saw little value in the lecture in its entirety, saying, "it's not that useful because I already know what addition is, know what rational numbers are, and what fractions are".

We account for Brittany's comments as follows. Brittany thought the definition provided by Professor Su was comprehensible, satisfying the criteria specified in e-frame 2. However, Brittany did not think that Professor Su's description of addition enhanced her understanding since she already knew how to add rational numbers. Therefore, the definition did not satisfy the criterion for a mathematical contribution specified in Brittany's e-frame 1.

4. 3. 4. An alternative proof. Professor Su would often state well-known facts about the rational numbers as theorems and then prove these theorems. In Interviews 2 and 3, Alice said these proofs were useful because they reminded the class that they needed to have the attitude that they knew nothing about the rational numbers. Thus, due to her e-frame 4, Alice believed that even obvious claims needed to be justified from basic principles about the integers. In contrast, Brittany was unsure why Professor Su was justifying things that were obviously true and sometimes remarked that the notation that he was using was unnecessarily cumbersome. We conjectured that Brittany's frustration was due to the fact that she felt that she already (psychologically) knew how to justify claims about fractions based on her experiences as an elementary and secondary student. Thus Brittany's e-frame 3 suggests that using psychological knowledge in reasoning is desirable. To explore this hypothesis, we started Interview 4 by presenting Alice and Brittany with the following proof of the addition of any two rational numbers and asking the participant if it would be useful for Professor Su to use:

Claim. Assume a, b, c, and d are integers and assume that $b \neq 0$ and $d \neq 0$. For any rational numbers, $\frac{a}{b}$ and $\frac{c}{d}$, $\frac{a}{b} + \frac{c}{d} = \frac{ad+bc}{bd}$.

Proof.
$\frac{a}{b} + \frac{c}{d}$
$= \frac{ad}{bd} + \frac{c}{d}$ (since $\frac{a}{b} = \frac{ad}{bd}$)
$= \frac{ad}{bd} + \frac{bc}{bd}$ (since $\frac{c}{d} = \frac{bc}{bd}$)
$= \frac{ad+bc}{bd}$ (since the two terms have like denominators).

Alice immediately rejected the proof as inadequate.

> Alice: So here [the second line of the proof] what we did is we multiplied by 1 essentially, by multiplying by d over d but *we have to know how to multiply rationals to do that*. We have to know that 1 times a certain rational does not change the amount[...]But then here [the last step] we have to assume that we also know how to add rational numbers with like denominator. *But that was also not really part of how we constructed or defined the rationals.* Or at least not in the last class. (italics were our emphases).

In the two italicized excerpts, we see Alice's recognition that one cannot use common (psychological) knowledge about the rationals to justify properties when you are constructing the rationals. We account for this with Alice's e-frame 4, that justifications cannot import facts that are known psychologically if they have not been established logically.

In contrast, Brittany thought the proof was adequate, saying several times, "I guess it would be a good proof". Her only concern was that the proof would be too simple, saying, "it just seems so obvious, like everyone knows, so I don't think it would be necessary". Hence, this proof would be a permissible mathematical contribution, although perhaps not a useful one. We account for this with Brittany's e-frames as follows. Brittany's e-frame 3 specifies that it is acceptable and desirable to use one's psychological knowledge when writing a proof. The proof that she evaluated did so and Brittany saw no problems with this. However, Brittany's e-frame 4 specified that the purpose of these lectures were to enhance her psychological understanding. Since the reasoning in the proof was obvious to her, the proof failed to satisfy that criterion.

5. Discussion

5. 1. Summary of main results

The purpose of this paper was to illustrate the phenomena that students with different e-frames may interpret the same mathematics lecture in different ways. Alice distinguished between logical and psychological ways of knowing mathematics and she viewed the intellectual contribution of Professor Su's lectures as providing a logical basis for her psychological understanding of the rational numbers. Providing this logical basis involved supplying definitions and justifying facts using only what had been explicitly defined by Professor Su until that point. Although Alice sometimes did not find this to be interesting, she understood why it was necessary (section 4.3.3). Brittany perceived the contribution of the lecture to be to enhance her psychological understanding of the rational numbers. Since she already felt that she had a robust psychological understanding of the rationals, she did not see much value in the lectures.

In this paper, we focus on a lecture of the systematization of the rational numbers. However, we use the comparative case study to illustrate what we believe is a more general phenomenon: students' e-frames about what is a mathematical contribution act as an interpretive filter to the mathematics that they observe.

5. 2. Limitations

Having Alice and Brittany view videotaped lectures allowed us to understand their perceptions of lectures as they occurred, but was inauthentic in several respects. For instance, Alice and Brittany were not enrolled in the course, their task during the study was not to master the material, and they did not work on real analysis outside of our interviews. The students might have behaved differently if they were attending actual lectures and had a strong motivation to learn the material. Further, we deliberately chose to take a non-evaluative stance in evaluating Alice's and Brittany's e-frames or the quality of their interpretation of Professor Su's lectures. We recommend future research in more authentic contexts and in other content domains that explicitly explore the link between students' e-frames and their understanding of the mathematics that they study.

5. 3. Implications for lecturing

A key takeaway from this paper is that even if a mathematics professor clearly explains the ideas that she wishes to convey, students may not grasp the point of the lecture if they do not hold e-frames that allow them to perceive the mathematical contribution that the lecturer is making. This implies that a lecturer not only needs to provide students with the opportunities to internalize the mathematical contributions that she is making but she must also help students develop the e-frames that enable them recognize the mathematical contributions and capitalize on these opportunities. We concur with Solomon (2006) that if advanced mathematics courses are to be effective, epistemology cannot be ignored.

We observe an interesting pedagogical challenge in using a lecture as an impetus for students to adjust their e-frames. In section 4.3.1, Professor Su's motivating questions prior to defining the rational numbers evoked e-frames in both Alice and Brittany, but the e-frames these questions evoked were different. To Alice, these questions evoked a mindset to seek out the definitions of the concepts of these questions. To Brittany, this led her to seek out comprehensible answers to the questions that Professor Su posed. In our opinion, both interpretations of Professor Su's comments were sensible. This illustrates an important point. The e-frames that a professor's comments invokes in a student are likely related to the e-frames that the student already holds.

The preceding analysis suggests one reason that collaborative inquiry-based learning may be an attractive alternative to lecturing. What counts as a mathematical contribution in a classroom is a sociomathematical norm. The analysis of Yackel and Cobb (1996) illustrates how sociomathematical norms can be established with negotiation between the teacher and students as the students are engaged in authentic mathematical activity. Having students engaged in activities such as systematization with feedback from their teacher and classmates may provide students with a better sense of what the mathematical contributions of these activities are than simply having a professor explain this to the students in lecture.

A Case Study in Constructing Set-based Meanings for Conditional Truth

Alec Hub
Northern Illinois University
ahub1@niu.edu

Paul Christian Dawkins
Northern Illinois University
pdawkins@niu.edu

We present a case study of Hugo's construction of Euler diagrams to develop set-based meanings for mathematical conditionals. This episode arose in a teaching experiment guiding students to reinvent mathematical logic from their reasoning about meaningful mathematical statements. We intended for Hugo to develop a subset meaning for conditional truth. Hugo successfully identified and used this condition, but he also introduced another formally equivalent meaning for conditional truth. We discuss the shifts in his thinking necessary for developing set-based reasoning and how this case influenced our goals for logic learning.

Keywords: logic, Euler diagrams, conditionals, teaching experiment

Though the modern formalizations of mathematical logic and language are relatively young (Frege, 1879; Russell, 1903), these accounts have become integral to the normative understanding of the language of proof-oriented mathematics. Azzouni (2006) argues that the essential novelty was developing a formal language in which meaning and truth are defined in purely syntactic ways. Because students must abide by these formal conventions of language to some degree, many transition to proof courses teach mathematical logic (Selden, 2012). However, the existing literature provides relatively little insight about logic instruction and the meanings that students must develop from that instruction (exceptions include Antonini, 2001; Bardelle, 2013; Barnard, 1995; Durand-Guerrier, 2003; Hawthorne & Rasmussen, 2014).

Regarding instruction, logic can be taught using everyday statements (e.g. Epp, 2003), formal syntax (e.g. Hawthorne & Rasmussen, 2014), or mathematical statements (e.g. Dubinsky & Yiparaki, 2000). Regarding student learning, there are various ways in which a student may affirm a conditional such as "If an integer *x* is a multiple of 6, then *x* is a multiple of 3":

1. as an empirical generalization inducted from a series of examples,
2. based on properties such as the spacing of these multiples on the number line,
3. as the result of a proof (maybe implicitly) using the theorem "if a|b and b|c, then a|c,"
4. as a subset relation between the set of multiples of 6 and the set of multiples of 3, or
5. as not false because there is no multiple of 6 that is not a multiple of 3.

We know little about students' *meanings* (Thompson, Carlson, Byerley, & Hatfield, 2013) for conditional truth, how they develop, and which should be privileged by logic instruction. We find it useful to distinguish between those meanings for conditional truth that intrinsically rely on the mathematical content of the sentence (examples 1-3) and those that rely on generalizable criteria (examples 3-5). We place 3 in both categories because the theorem used to prove is mathematically specific, but one can generalize the criterion that a conditional is true if there is a proof of the conclusions from the hypotheses (Weber & Alcock's, 2005, warranted conditional). How and when is it important for students to develop generalizable meanings for conditional truth and even to become reflectively aware of such meanings?

The Current Investigation

In this report, we lay some foundation for investigating these questions through a detailed case study of one students' learning about conditional truth and contrapositive equivalence. By documenting particular students' pathways of learning, we can discern important challenges and opportunities for instruction. This case comes from a series of teaching experiments attempting to guide undergraduate students to reinvent mathematical logic (Dawkins & Cook, 2015, in press). We taught logic by presenting students with meaningful mathematical statements all of the same logical form (disjunctions, conditionals, then multiply quantified). By letting students assign truth-values, reflect on their strategies, and construct negations, we intended for students to reinvent truth-functional logic as a formalization of their own reasoning and languaging.

We frame our findings in terms of student *meanings*, which Thompson et al. (2013) define as the set of inferences available to a student as a result of understanding something in a particular way. To illustrate this in our context, consider the tools available to a student for interpreting a mathematical statement and deciding its truth-value. While our participants exhibited various strategies for interpreting general statements, many times their reasoning focused either on examples, properties, or sets (which correspond respectively to examples 1, 2-3, and 4 above). By interpreting the sentence in terms of examples or properties, varying truth conditions and insights became available to students, which are parts of the *meaning* of the sentence for that student. We will thus discuss example-based, property-based, or set-based meanings. While students assigned statements their normative truth-values using all three, we found that reasoning with sets often afforded students the most fruitful strategies (Dawkins & Cook, 2016). Thus, in the experiment featured in this paper we attempted to guide students toward set-based truth conditions, which for conditional statements can be stated: *The conditional "If for $x \in S, P(x)$, then $Q(x)$" is true if and only if* $\{x \in S|P(x)\} \subset \{x \in S|Q(x)\}$*."* We call this the *subset meaning for conditional truth* (or *subset meaning* for brevity). The primary contributions of this study are 1) documenting this student's resources and challenges in developing the subset meaning and 2) documenting the novel meaning he created to affirm the contrapositive of a true conditional.

Conceptual analysis of conditional truth

We value Euler diagrams as a means of representing set relations relative to compound statements. The student featured in this report was familiar with similar diagrams from previous instruction (likely Venn diagrams), but he did not have fully normative meanings for how the diagram referred to mathematical objects. Dawkins and Cook (2015) point out at least one important meaning for understanding such diagrams as mathematicians do: the negation of a property corresponds to the complement of the set with the original property. Dawkins and Cook (2015) demonstrate that not all students associate the negation of a property with the complement set of examples, but such an understanding seems necessary for understanding why contrapositive conditionals have the same truth value (Figure 1).

Original conditional		Contrapositive conditional	
"If for $x \in S$ $P(x)$, then $Q(x)$." is true whenever $\{x \in S\|P(x)\}$ $\subset \{x \in S\|Q(x)\}$		"If for $x \in S$ not $Q(x)$, then not $P(x)$." is true whenever $\{x \in S\|\sim Q(x)\}$ $\subset \{x \in S\|\sim P(x)\}$	
Figure 1: Euler diagrams demonstrating why contrapositives have the same truth-value.

Rather, students may associate the negation of a property with a proper subset of the complement – e.g. "not acute" means "obtuse," or "not even" means "odd" – or they may associate the negation with an overlapping property – e.g. "not a rectangle" means "is a parallelogram." Such *semantic substitutions* (Dawkins & Cook, 2016) do not afford the set structure that we intend for students to develop. Students' choices of semantic substitutes demonstrate a strong preference for familiar categories precluding the Euler diagram's novel partitions.

Background and Study Design

This study investigates Hugo's learning during the time he and his partner, Elya, worked on the set of conditional statements provided by the teacher/researcher (the second author). These students were recruited from a Calculus 3 class at a mid-sized university in the United States, but the experiment took place in one-hour sessions outside of class. The task progression for each type of statement – disjunction, conditional, and multiply-quantified – included: 1) assigning truth-values to all of the provided statements, 2) look for patterns in how they determined whether the statements were true or false, 3) consider the sets of examples that made each statement true and the sets that made them false, and 4) constructing negations. Hugo and Elya spent 2.5 sessions studying mathematical disjunctions prior to working on conditionals. This paper focuses on the subsequent 2.5 sessions they spent studying conditionals, especially the second such session from which Elya happened to be absent. Table 1 presents some conditionals they studied. After the students assigned truth-values and looked for patterns, the interviewer asked Hugo and Elya to "Think about the set of all things that satisfy the *if* part and the set of all things that satisfy the *then* part. And tell me about the relationship between those two." This was particularly intended to prompt students to formulate the subset meaning for conditional truth.

1. If a number is a multiple of 3, then it is a multiple of 4.
2. If a number is a multiple of 3, then it is a multiple of 6.
3. If a number is a multiple of 6, then it is a multiple of 3.
4. If a number is not a multiple of 6, then it is not a multiple of 3.
5. If a number is not a multiple of 3, then it is not a multiple of 6.
6. If a triangle is not acute, then it is obtuse.
7. If a triangle is obtuse, then it is not acute.
8. If a triangle is not acute, then it is not equilateral.
9. If a quadrilateral is a rectangle, then it is a square.
10. If a quadrilateral is a rectangle, then it is a parallelogram.
11. If a quadrilateral is not a rhombus, then it is not a rectangle.

Table 1: Sample conditionals that Hugo and Elya studied.

Consistent with teaching experiment methodology (Steffe & Thompson, 2000), the teacher/researcher consistently formed second-order models of student understanding and tested those models through subsequent questioning. These models were informed by findings from previous studies (Dawkins & Cook, 2015, 2016), as were the learning goals articulated earlier in the paper. The data analysis consisted of iterative analysis throughout the experiment and retrospective analysis of the video recordings and artifacts of student work afterward. The analysis presented in this paper focused particularly on the pair's construction of set-based meanings for conditionals, especially as facilitated by Euler diagrams. Retrospective analysis similarly consisted of developing second-order models of Hugo's understanding by forming and testing hypotheses using the corpus of his mathematical activity. Dawkins and Cook (2015, 2016) present more thorough accounts of the teaching and data analysis methodologies.

Results

On Hugo and Elya's first pass through the set of conditionals, they assigned to each the normative truth-value. They quickly recognized that an example that satisfied the *if* part and not the *then* part was a counterexample (their *counterexample criterion*). Based on their work with disjunctions, they understood that a single counterexample made a general statement false and they could articulate general conditions for declaring statements false. For instance, after the first five statements Hugo explained, “If we can come up with a case that fits the first [antecedent] but does not fit the second [consequent], then it [conditional] has to be false. We only need one case.” Even in the case of positive statements, Hugo focused on examples by populating Elya’s set-based explanations with particular examples. When she explained, “[Statement] Five would be true, because every multiple of 3—every multiple of 6 is a multiple of 3. So if it’s not a multiple of 3 it can’t be a multiple of 6,” Hugo elaborated, “Like 17, is not multiple of 3 but it is also not a multiple of 6.” Elya inferred statement 5 from statement 3, which we call a *contrapositive inference*, but her later work suggests that she did not understand contrapositive equivalence as a general property of conditionals. We hypothesize that her understanding of multiples supported her inference rather than reasoning about abstract logic or set relations. In addition to focusing on examples, Hugo also affirmed some conditionals using property relations. Regarding statement eight, he said, “Not acute would mean either a right triangle or an obtuse triangle. Neither of those can be equilateral so that would be true.”

After Elya and Hugo assessed all the provided conditionals, the interviewer asked them to look for patterns in the statements and why they were true or false. The pair noticed that many statements contained the same properties and identified the relationships commonly referred to as inverse (e.g. #3,4) and converse (e.g. #6,7) conditionals. After some discussion and conjectures about the truth-values of these related statements, the interviewer asked the pair to consider the sets related to each part of the statements. The conversation proceeded:

H(1): I’d say, if the statement is true then the set for the first part—I’m sorry the set of the second part will be included in the set of the first part.

I(2): Okay. Why do you say that?

H(3): Um, because if we said that it’s true then when we pick—something that’s true for the first part, then it has to be included in the second part for the whole statement to be true.

I(4): So its sounds to me like you’re saying there’s two possibilities. One is to say that the set—the *if* set can be sort of inside of—or contained in the *then* set. Or you can say the *then* set is contained in the *if* set. Which one do you—are claiming? So you’re saying, if the statement is true then what was the relationship here?

H(5): Then the—*then* will be inside *if*.

I(6): Okay. What do you think [Elya]?

E(7): I think the *if* has to be in the *then* but *then* doesn’t have to be in the *if*. ‘Cause there—when we looked at 3 there’s all the multiples of 6 are contained in multiples of 3 but all multiples of 3 are not contained in multiples of 6.

I(8): Do you agree with that, [Hugo]?

H(9): Yeah I think I’m good with that […]

I(10): What are thinking about in a particular example?

H(11): Uh, you wanna talk about [statement] 3. Um in like a circle, and multiples of 3—3,6,9,12. Um, multiples of 6 will be included in that circle. Like 6 and 12 are multiples of 6. So there’s an additional circle inside that includes some numbers but does not include others.

I(12): Okay, but sort of which are you calling the *if* part and which circle are you calling the *then*?

H(13): The *then* part would be the bigger one. The inside would be *then*—sorry other way around. *Then* is on the outside. *If* is in.

This appeared to be the first time Hugo reasoned about conditionals using sets, and, from the researcher perspective, his general explanation (turn 5) was inconsistent with his earlier semantic reasoning about the given statements. Once the interviewer pushed Hugo to explain his reasoning in a particular semantic context (turn 10), he recognized the subset meaning for conditional truth (turn 13) but even after this episode he sometimes returned to his intuition that the *then* set is contained in the *if* set. We conjecture that this intuition may be supported by the relationship between the properties in true conditionals. For instance, statement three is true because being a multiple of 6 means being a multiple of 2 and a multiple of 3, meaning the *if* property entails the *then* property. This explanation seems consistent with Hugo's use of the word *included* in turns 1 and 3. Hugo's population of the Euler diagram with numbers (Figure 2) appeared to serve as a bridge between his example-based meanings and the set reasoning the interviewer invited.

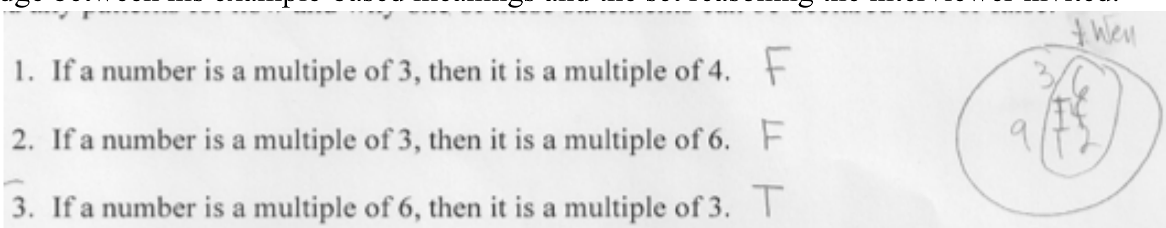

Figure 2: Hugo's Euler diagram for statement 6.

Hugo and Elya began to use these Euler diagrams to explore the truth of the various conditionals provided. By the end of the first session on conditionals, Elya was able to produce an explanation for why two contrapositive statements were both true as portrayed in Figure 1, but Hugo showed little evidence of understanding her reasoning. The next session afforded Hugo opportunity to independently develop his understanding of conditional truth because Elya happened to be absent. To encourage rediscovery of contrapositive equivalence, the interviewer invited Hugo to explore multiple related statements – original, inverse, converse, and contrapositive – with the same Euler diagram. The dialogue proceeded:

I(14): So look at [statements] 2 through 5 then. 'Cause 2 through 5 are gonna be—again—its a bunch of the same options but the same kinds of parts.

H(15): Two—the number is a multiple of 3. We got a circle—they're all multiples of 3—3, 6, 9, 12. Then it is a multiple of 6. [draws a circle around the 6 and 12].

I(16): Okay so is this true or false? So if it's a multiple of 3, then it's a multiple of 6.

H(17): We said it was false because our set was this circle of multiples of 3, and then if you only want multiples of 6—you have this but you still have the 3 and the 9 which aren't included in the little circle.

In turn 15, Hugo produced the diagram shown in Figure 3, labeling the outer circle "if 3x" and the inner circle "then 6x." In turn 17, Hugo did not rely on his counterexample meaning, but rather declared statement 2 false because the sets failed to satisfy the subset condition ("aren't included in the little circle"). When the interviewer asked him to consider statement 3 (the converse), he expected Hugo to refer to the same diagram. Instead Hugo began modifying the position of the circles around the example numbers. This suggested that Hugo's meaning for the diagram did not merely reflect the invariant relationship between the multiples of 3 and 6. Instead, Hugo tied the circles' meaning to the statement structure – *if* and *then* – such that shifting to the converse altered the diagram. The interviewer recreated the original diagram and encouraged Hugo to interpret statements 3-5 using the same diagram:

I(18): Okay, so we can sort of stick with the circles. But now what's—so in the second statement, or now actually it's number 3, what is it we're saying?

H(19): If is a multiple of 6, we put the *if* here [switches *if/then* labels]. Then it's a multiple of 3. So if we only talk about this, this set of numbers, does that included inside of 3x? Yes.
I(20): Yea, all the multiples of 6 here are multiples of 3. Okay, right. I agree, so this one is true.
H(21): So again, if the *if* is encased, enclosed, inside the bigger then circle, then it's true. […]
I(22): I want you to try to use the same picture to talk about 4 and 5.
H(23): If it is not a multiple of 6, so—if its not in this circle, so we're talking about outside the little circle. […] Does that make sense?—If not multiple of 6 then it is not a multiple of 3. So we're talking about anything outside of that. Well 9 is still a multiple of 3, 15 is still multiple of 3. So that would be false.
I(24): Okay, where are the non-multiples of 3?
H(25): Non-multiples of 3 would be outside the little circle infinitely, so that would be—oh non multiples of 3. That would be—[marks diagram]—So if it is not a multiple of 6. So we said it's outside the little circle. Then it is not multiple of 3, not multiple of 3 would be outside the bigger circle. So our set of numbers is inside the big circle and outside of this, but also outside the big circle.
I(26): Right, so what numbers are outside the big circle? Just give me a few examples.
H(27): 7, 11 […]
I(28): If it's a non multiple of 6 then it is a non-multiple of 3.
H(29): It's not a multiple of 6, like 3, 3 is multiple of 3 though.
I(30): Yea, so your counter-examples, like you said are these. 'Cause they're non-multiples of 6 that in fact are multiples of 3. Which, so I agree. [Statement] 4 is false for that reason. 3 is a counter-example. […]
H(31): So we have a ton of numbers that prove it yes but we have all the counterexamples would be inside the big circle and outside the little circle. [Reads statement 5] So if we're only talking about number that are not multiples of 3. So if anything outside the big circle—well our multiples of 6 are inside the circle, so if we talk about anything outside of the circle, obviously we're not going to contain multiples of 6. So if our set of numbers are outside the big circle, then yeah, none of those are multiples of 6. So that would be true.

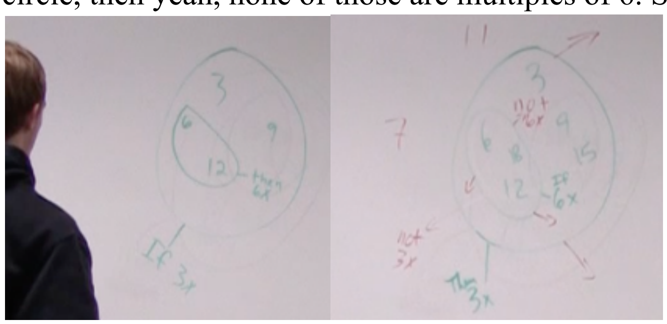

Figure 3: Hugo's diagram at turns 17 and 25

Once Hugo recognized that he could use the same diagram to assess the converse (turn 19), he explicitly cited the subset meaning to affirm statement 3 (turn 21). The interviewer's prompt to use the same diagram for statements 4 and 5 required Hugo to attend to the negation/complement relationship. In turn 23 he associated the complement of the inner circle with the non-multiples of 6, but he avoided coordinating the complement of both sets by identifying a counterexample (the criterion he used the previous day). In turns 25 and 31, Hugo recognized that his counterexamples exemplified a class of numbers represented by the space between the inner and outer circles. Thus while his identification of a counterexample built upon his previous day's work, he now displayed a set-based meaning for counterexamples afforded by the Euler diagram.

When Hugo considered statement 5, he associated the first condition with the complement of the outer circle. However, instead of affirming this statement by the subset meaning as portrayed in Figure 1, Hugo argued that non-multiples of 3 (numbers outside the outer circle) could not be multiples of 6 (inside the inner circle). Stated another way, the intersection between the non-multiples of 3 and the multiples of 6 was empty. This *empty intersection meaning for conditional truth* again allowed Hugo to avoid coordinating two negations by parsing statement 5 as "if a numbers is a *non-multiple of 3*, then it is not a *multiple of 6*."

The interviewer invited Hugo to consider the relationships among statements 2-5 in terms of converses and inverses. With interviewer prompting, Hugo acknowledged that since #4 was the inverse of #3 and #5 was the converse of #4, one could go from #3 to #5 by taking both the converse and inverse. Hugo said, "But if we have an if-then statement that's true, we take the inverse and the switch [their term for converse]—we switch it and take the inverse, then—so far we've proved that it would be true. […] I'm observing [this pattern] but I'm trying to articulate why that is." Thus, he observed that these statements shared the same truth-value and conjectured that this pattern might hold generally, but he was unable to justify why this occurred.

Discussion

Our initial goals in this section of the teaching experiment were for Hugo and Elya to develop the subset meaning for conditional truth and to use that meaning to justify contrapositive equivalence. Elya used set-based meanings spontaneously while Hugo needed to develop tools to move beyond his example and property-based meanings. We claim that Hugo's Euler diagram, initially produced to record his example-based reasoning, served as a transformational record (Rasmussen & Marrongelle, 2006). It both allowed him to generalize his example-based meaning for counterexample and later allowed him to relate inverses, converses, and contrapositives.

Unlike prior study participants who struggled to associate negative properties with complement sets (Dawkins & Cook, 2015), Hugo developed this relationship in his interpretation of the diagram. However, he avoided coordinating two complements simultaneously for statements 4 and 5, as would be required by the subset meaning. He instead used counterexample and empty intersection meanings. While we could view this negatively as it falls short of adopting a purely syntactic and content general understanding of conditional truth – as one might desire in teaching formal logic – Hugo's empty intersection meaning is logically equivalent to the subset meaning. Furthermore, he showed flexibility in parsing and interpreting the given statements, which could be fruitful in proof-oriented mathematical activity. We appreciate how the Euler diagram afforded Hugo valid mathematical inferences even if he could not justify those inferences, much as Elya's semantic understanding supported contrapositive inferences. Hugo alternatively drew upon semantic information (about multiples or geometric shapes), linguistic competencies (parsing negative statements), and logical criteria (the subset meaning) to interpret the various statements provided, which we anticipate to be more consistent with proof-oriented reasoning than purely syntactic operations in a formal language.

This paper contributes to our understanding of students' construction of logical structure in semantically rich settings and reveals hurdles and opportunities in students' development of set-based meanings for compound statements. As was portrayed in the introduction, we prioritize students like Hugo and Elya developing generalizable meanings for mathematical truth. However, based on cases like Hugo's we also value the flexibility to affirm the same statement in multiple, formally equivalent ways. Further study should continue to shed light on viable pathways for students to abstract their semantic reasoning into generalizable, syntactic tools and how these tools can be harnessed in students' subsequent proof-oriented activity.

A New Methodological Approach for Examining Mathematical Knowledge for Teaching at the Undergraduate Level: Utilizing Task Unfolding and Cognitive Demand

Erica R. Miller
University of Nebraska-Lincoln

In 2010, Charalambous published an article that examined the relationship between mathematical knowledge for teaching and task unfolding at the elementary level. As a result of this study, Charalambous evidence to support the claim that there is a positive relationship between a teacher's MKT and the cognitive level of enacted task. Drawing upon this finding, the purpose of this study is to propose a new methodological approach examining mathematical knowledge for teaching at the undergraduate level. While this approach draws upon results concerning MKT at the K-12 level, it primarily focuses on examining undergraduate instruction through the lens of task unfolding and cognitive demand. To illustrate how this methodology can be used, the paper concludes by presenting two case studies that demonstrate how the methodology can be used to examine mathematical knowledge for teaching undergraduate Precalculus courses.

Keywords: Mathematical Knowledge for Teaching, Cognitive Demand, Task Unfolding, Undergraduate Instruction

The combination of low pass rates in first-year undergraduate mathematics courses (Saxe & Braddy, 2015) with low percentages of students who persist on to complete STEM majors (Ellis, Kelton, & Rasmussen, 2014) has brought attention to the need to improve mathematics instruction at the undergraduate level. Commonly, undergraduate instructors are viewed as qualified teachers because they are considered experts in the content area they are expected to teach. However, Bass (1997) points out that "knowing something for oneself or for communication to an expert colleague is not the same as knowing it for explanation to a student" (p. 19). Even though they may spend half of their professional live teaching, professors often receive little to no professional preparation or development as teachers. In order to better understand how we can prepare teachers at all levels, it is important to understand the knowledge that is entailed in teaching. Just as accountants, engineers, and economists rely on specific mathematical knowledge, mathematics teachers rely on their own special domain of mathematical knowledge.

Clearly a teacher must know the math that they expect their students to learn, but what other mathematical knowledge is part of this domain? To answer this question and better define this domain, educational researchers have begun to focus on mathematical knowledge for teaching (MKT). Mathematical knowledge for teaching has been defined as "the mathematical knowledge needed to perform the recurrent tasks of teaching mathematics to students" (Ball, Thames, & Phelps, 2008, p. 399). At the K-12 level, MKT has been studied extensively, but few studies exist at the undergraduate level. While researchers have studied MKT in various ways, this study focuses on examining MKT at the undergraduate level by observing and interviewing experienced instructors. Examining teaching by examining the actual practice of teaching will not only bring to light the knowledge that instructors use in the classroom, but also provides a more accurate description than one could take from hypothetical reasoning, personal reflection, or third-party insight.

Mathematical Knowledge for Teaching

Studies have shown that content knowledge is not a predictor of teaching quality and student outcomes (Begle, 1972; Greenwald, Hedges, & Laine, 1996; Hanushek, 1981, 1996). However, Lee Shulman proposed in 1986 that there is content knowledge that matters for teaching. The key difference that Shulman identified was that teacher content knowledge must be connected to domain-specific pedagogical knowledge. Shulman formalized the idea of *pedagogical knowledge for teaching*, "which goes beyond knowledge of subject matter per se to the dimension of subject matter knowledge for teaching" (p. 9). In 1987, Shulman called for researchers and practitioners to pay more attention to the *professional* knowledge of teaching, including pedagogical content knowledge.

Existing Research on MKT

Several frameworks have been developed to describe the professional mathematical knowledge that teachers use (e.g., Rowland, Huckstep, & Thwaites, 2005; McCrory, Floden, Ferrini-Mundy, Reckase, & Senk, 2012; Baumert & Kunter, 2013) including Ball et al.'s (2008) framework for mathematical knowledge for teaching. Ball and her colleagues built off of Shulman's (1987) idea of pedagogical content knowledge and found that there was content knowledge that mattered for teaching and that a focus on this content benefited teaching and learning. Hill, Rowan, and Ball (2005) showed that at the elementary level that "teacher's *content knowledge for teaching mathematics* [emphasis added] was a significant predictor of student gains" (p. 396). While content knowledge for teaching does require general content knowledge, it also includes content knowledge that is *usually* not taught in undergraduate or graduate mathematics courses (i.e., common unproductive ways of thinking and developmentally appropriate definitions). Therefore, the content knowledge that undergraduate instructors have gained through their formal education may not be the same as content knowledge they need to know for teaching.

More recently, research on MKT has been conducted at all levels of K-12 (McCrory et al., 2012; Krauss, Baumert, & Blum, 2008); however, there still are relatively few studies that study MKT at the undergraduate level. Speer, Smith, and Horvath (2010) conducted a literature review to search for empirical research on the practices of collegiate teachers of mathematics. As a result, the authors found that they only were able to identify five articles in their search. While some may argue that this gap exists because MKT frameworks developed at the K-12 level can be extended to the collegiate level, the authors point out that "there are important differences between college and pre-college teachers and teaching" (p. 100), such as level and depth of content and pedagogy knowledge. In another article, Speer, King, and Howell (2014) focus on the problems that result from assuming that research on MKT at the K-12 level can be extended to MKT at the collegiate level. The authors claim that "relatively little attention has been paid to the ways in which MKT theory is or is not applicable to teachers at secondary and post-secondary levels" (p. 106) and challenge researchers to explore "the types of knowledge entailed in the work of [collegiate] teaching...through the same kinds of careful study of the mathematical demands of teaching that sparked the early work on mathematical knowledge for teaching (Ball and Bass 2000)" (p. 119).

Studying MKT at the Undergraduate Level

To address this gap in the research, the purpose of this study is to draw upon previous research in order to propose a methodological approach to examining MKT at the undergraduate level from the perspective of practice. In particular, the methodological approach used in this study was inspired by Charalambous' (2010) study that found a positive relationship between teachers' MKT and the cognitive demand of tasks enacted in the classroom. Studies have shown that the cognitive demand of a task is related to student learning (Boaler & Staples, 2008; Hiebert & Wearne, 1993; Stein & Lane, 1996), but enacting tasks at a high level of cognitive demand is difficult for teachers to do (Stein, Grover, & Henningsen, 1996; Hiebert & Stigler, 2004). Building upon these findings, Charalambous (2010) hypothesized that there was a connection between teachers' MKT and their ability to enact tasks at a high level of cognitive demand. To test this hypothesis, he utilized the Learning Mathematics for Teaching (LMT) assessment to measure teachers' MKT and analyze the cognitive demand of enacted tasks. What he found was that teachers' scores on the LMT were positively associated with their ability to enact tasks at a high level of cognitive demand. While it would be desirable to replicate this study to look for similar results at the undergraduate level, no comparable measure of MKT exists. However, I propose that it is possible to use the combination of task unfolding and cognitive demand as a lens to examine MKT at the undergraduate level.

Task Unfolding and Cognitive Demand

Before I explain the details of the new methodological approach I propose for studying MKT at the undergraduate level, I first want to further develop the underlying theoretical frameworks that this methodological approach builds upon: task unfolding and the Task Analysis Guide (Smith & Stein, 1998). In the third subsection, I connect these frameworks by presenting Charalambous' (2010) characterization of task unfolding by the cognitive demand.

Task Unfolding

Stein et al. (1996) defined a *mathematical task* as "a classroom activity, the purpose of which is to focus students' attention on a particular mathematical idea" (p. 460). They also describe the phases involved in the unfolding of a mathematical task and the factors that influence this unfolding. In 2007, Stein, Remillard, and Smith generalized task unfolding to apply to curriculum unfolding more generally, but the underlying process remained the same. In Figure 1, the rectangle boxes represent the three phases of task unfolding. The *written task* describes how the mathematical task is represented in the written curriculum or instructional materials. The *intended task* describes the teacher's plan for implementing the task during instruction. Finally, the *enacted* task captures how the mathematical task is actually implemented during instruction. While each phase has an impact on student learning (represented by the triangle in Figure 1), studies have shown that the enacted task has the greatest impact (Carpenter & Fenemma, 1988). The bottom oval identifies some factors that influence how teachers plan out a task for implementation in the classroom and how the task is actually implemented in the classroom. Finally, it is important to note that the return arrows from the enacted task and student learning represent the impact that these will have on future teaching actions.

Cognitive Demand of Tasks

In order to differentiate between tasks of different types, Smith and Stein (1998) also considered the cognitive demand of a task. They defined *lower-level demand tasks* as "tasks that ask students to perform a memorized procedure in a routine manner" and *higher-level demand tasks* as "tasks that require students to think conceptually and that stimulate students to make connections" (p. 269). Each of these categories was then broken down into two subcategories:

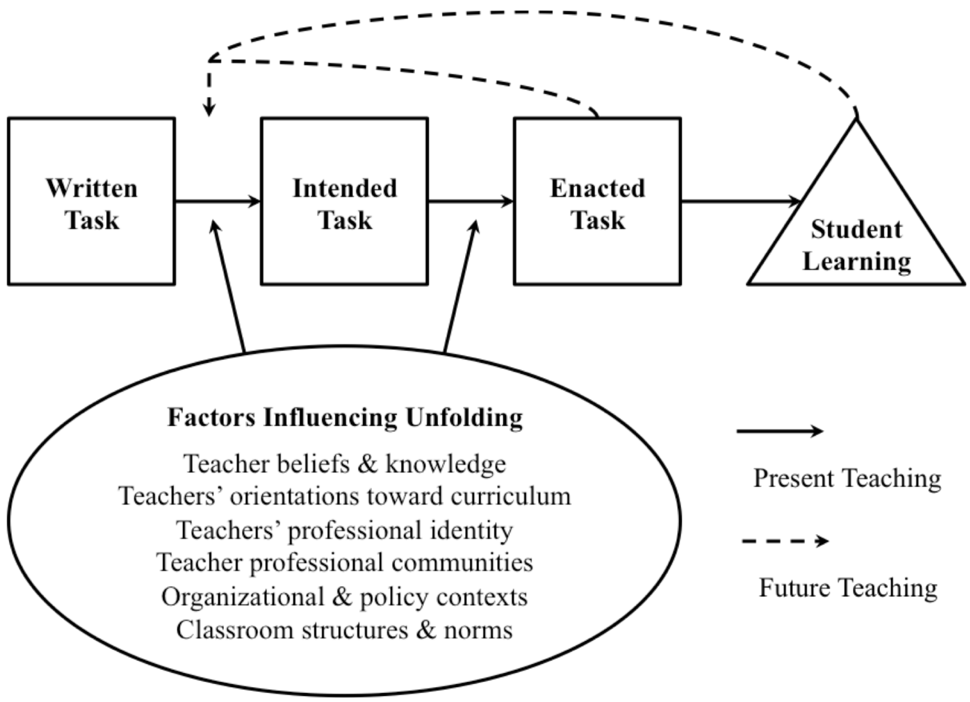

Figure 1. The phases and factors influencing task unfolding.

memorization, *procedures without connections*, *procedures with connections*, and *doing mathematics*. Smith and Stein (1998) differentiated procedures *with* and *without* connections as representing differing levels of cognitive demand. They separated these two types of tasks in order to categorize mathematical tasks that "use procedures, but in a way that *builds connections to the mathematical meaning*" of the underlying concept as a higher-level demand task. Doing mathematics tasks are categorized as higher-level demand tasks that require "students to explore and understand the nature of relationships" (p. 347). To aid in differentiating between the different types of tasks, Smith and Stein developed the Task Analysis Guide, which lists characteristics of the four types of mathematical tasks. Later, when utilizing the Task Analysis Guide to code the third phase of task unfolding, Stein et al. (1996) added a third type of lower-level demand task called *unsystematic exploration*. This type of task, which applies to only the third phase of task unfolding, describes declines in cognitive demand that are characterized by "motivated student engagement, well-intentioned teacher goals for complex work, and well-managed work" but "the cognitive activity…was not at a high enough level to be characterized as engagement in complex mathematical thinking and reasoning" (p. 478).

Categorizing Task Unfolding Using Cognitive Demand

In their 1996 study, Stein et al. utilized the Task Analysis Guide to analyze a sample of 144 tasks that were implemented in reform-oriented classrooms. They focused on the transition from the second to the third phase of task unfolding and found that the majority of the tasks were coded as maintaining or declining in cognitive demand. They also found that "the higher the cognitive demands of tasks at the set-up phase, the lower the percentage of tasks that actually remained that way during implementation" (p. 476). This finding provides confirming evidence for the claim that tasks with high cognitive demand are difficult to enact (NCTM, 2014, p. 17). In 2010, Charalambous conducted a similar case study, but explicitly categorized task unfolding

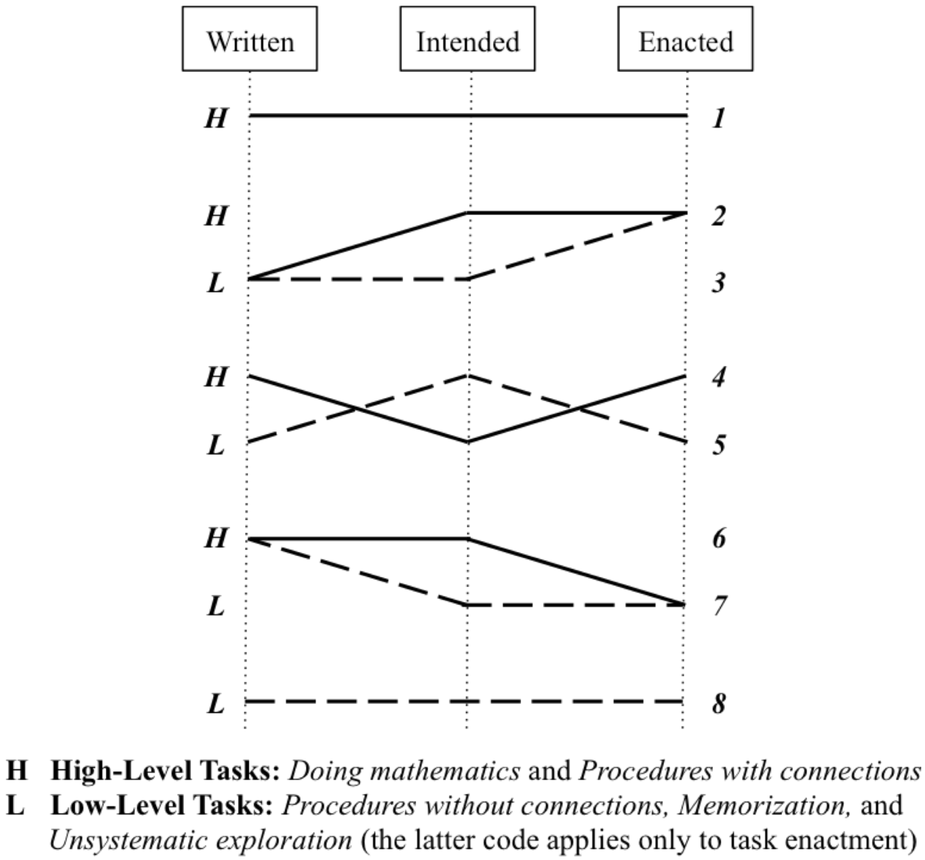

Figure 2. Categorization of possible types of task unfolding.

by the type of path they follow (Figure 2). In his categorization, Charalambous utilized the Task Analysis Guide to code cognitive demand as high or low at each phase in task unfolding, which resulted in eight possible types that a task unfolding could follow. It is worth noting that Charalambous only observed five of the eight possible task unfolding (Types 1, 5, 6, 7, & 8 in Figure 2) in the cases he studied and I added in the type numberings for ease of reference.

Studying MKT at the Undergraduate Level

Using these frameworks, I propose that it is possible to use the combination of task unfolding and cognitive demand as a lens to examine MKT at the undergraduate level. This methodological approach to studying MKT at the undergraduate level theoretically makes sense for several reasons. First, tasks are central elements of teaching due to the fact that they focus on the work that students do in the classroom. In particular, Doyle (1983) argues that tasks are central to students' learning because their enactment focuses students' attention on mathematical ideas and defines students' ideas of what it means to do math. Second, there is a growing body of research that supports the view that instruction should focus on engaging students in mathematical rich tasks. "Principles to Actions" (NCTM, 2014) synthesizes the research on mathematical tasks as resulting in three major findings: (1) not all tasks are equal in terms of the opportunities they provide for student thinking and learning, (2) student learning is greatest in classrooms where tasks are consistently enacted at a high level of cognitive demand, and (3) tasks with high cognitive demand are the most difficult to enact (p. 17). Third, it is important to note that cognitive demand is not an invariable feature of a task. Factors that can influence the cognitive demand of enacted tasks include students' understanding of the task objectives, teachers' interpretation and setup of the task, and teachers' content knowledge (Stein et al., 1996; Charalambous, 2010). The final reason why I believe that this methodological approach is defensible is due to the fact that studies have found a positive relationship between teachers' MKT and enacting cognitively demanding tasks (Charalambous, 2010; Baumert et al., 2010).

In the new methodological approach that I describe below, there are two stages of analysis: one that focuses on categorizing the unfolding of the task by considering the cognitive demand and another that examines the mathematical knowledge for teaching that influenced the unfolding of the task. After explaining each stage of analysis, I provide the reader with two case studies of what it looks like to apply this methodological approach in practice.

Stage 1: Categorizing Task Unfolding by Cognitive Demand

Data. In order to characterize task unfolding by cognitive demand, data should be collected for each phase in the task unfolding process. To capture the written task, any formal curriculum materials, such as textbooks and teacher guides, or informal instructional materials, such as activities developed by the teacher, should be collected. To capture the intended task, data corresponding to how the teacher intends to implement the task during instruction, such as the teacher's lesson plan, should be collected. Finally, to capture the enacted class, data corresponding to the actual implementation of the task in the classroom, such as a video observation, should be collected. To aid in capturing the enacted task, the researcher may find it helpful to refer to the observation protocol used by Rogers & Steele (2016).

Process. Once the data has been collected, the cognitive demand of the written, intended, and enacted tasks should be analyzed using the Task Analysis Guide (Smith & Stein, 1998). In each phase of unfolding, the task should be coded as memorization, procedures without connections, procedures with connections, doing mathematics, or unsystematic exploration. Recall that unsystematic exploration should only be used to categorize the final enactment phase of task unfolding. Also, the Task Analysis Guide contains detailed descriptors of these tasks that should aid the researcher in assigning codes. While Smith and Stein have not published any formal training on how to use the Task Analysis Guide, Charalambous (2010) describes how he trained his coders. One thing that is important to note is that the rest of the analysis only depends on the level of cognitive demand and not the finer-grained analysis of whether or not a high-level task is coded as procedures with connections or doing mathematics. However, utilizing the Task Analysis Guide will aid in making the distinction between high- and low-level tasks more clear.

Product. Once the cognitive demand at each phase in the task unfolding has been analyzed using the Task Analysis Framework, the researcher can categorize the task unfolding using the path types (Figure 2). One could examine MKT without first categorizing the task unfolding, Charalambous' finding that MKT and the cognitive demand of task enactment are positively related suggests that examining tasks that are enacted at a high-level of cognitive demand will provide more opportunities to examine MKT. For this reason, the researcher should ideally identify paths of Types 1, 2, 3, or 4 and utilize these in the second stage of analysis.

Stage 2: Examining MKT

Data. To examine MKT, the researcher needs to look at the factors that influence the transformation of task between phases. To capture how the written task is interpreted by the teacher and transformed into the intended task, the researcher should conduct a semi-structured interview with the teacher before the observation. To capture how the interpreted task is transformed into the enacted task during instruction, the researcher should conduct another semi-structured interview with the teacher after the observation. To aid in the development of the pre- and post-observation interview protocol, refer to Appendix B from Rogers and Steele (2016) and Appendix A of this paper. To allow for an in-depth analysis, it may be beneficial to choose only one or two of the tasks that were enacted at a high-level of cognitive demand to probe into during the post-observation interview. Also, since the intent of this methodology is to study MKT at the undergraduate level from the perspective of practice, stimulated-recall (Bloom, 1953) should be used during the post-observation interview in an attempt to get at the mathematical knowledge that the teacher used in the moment during instruction, as opposed to purely reflective thoughts.

Process. Once the data has been collected, the researcher can begin to analyze the transition between phases of task unfolding in order to examine MKT. Since the purpose of this analysis is to examine MKT at the undergraduate level, the researcher is essentially building a theory for undergraduate MKT. For that reason, the pre- and post-observation interview responses should be analyzed using grounded theory (Strauss & Corbin, 1994). To do this type of analysis, the researcher begins with open coding of the data. As the researcher begins to identify categories that emerge during open coding, they should utilize the constant comparison method (Glaser & Strauss, 1999) to organize the codes into categories and subcategories. To fully develop a theory, the researcher must reach saturation, which is the point "when no new information seems to emerge during coding" (Strauss & Corbin, 1998, p. 136). It is important to note that if the researcher's purpose is to only better understand how some aspect of the world works, as opposed to create a formal theory that explains this aspect, they may conclude their study before reaching theoretical saturation.

Product. Depending upon whether or not the grounded theory analysis was taken all the way through theoretical saturation, the results of the second stage of analysis will differ. If the researcher's purpose is to better understand MKT at the undergraduate level looks like, then completing this analysis will give us a partial description. Although this partial description may fall short of a formal theory, it would still contribute much to the field, since there are currently so few studies that examine MKT at the undergraduate level. However, eventually, I believe that our goal should be to develop a formal theory for MKT at the undergraduate level. By developing a complete picture of MKT at the undergraduate level, we will have a more complete picture of what knowledge is required when teaching at the undergraduate level. Also, developing a theory from the ground up for MKT at the undergraduate level will allow us to see how it is similar to and different from MKT at the K-12 level.

Case Studies

To demonstrate how to use this methodological approach to study MKT at the undergraduate level, I have included two case studies below. The data used in these case studies were collected during the Fall 2015 semester at a mid-size research university in the Midwest. The instructors were selected primarily due to their experience teaching these courses and because they had been identified within the department as strong teachers. At the time of data collection, Greg was a fifth-year graduate student who was teaching Trigonometry for the third time. He had also earned his M.S. in pure mathematics and was nearing the end of his doctoral work. Kelly was a third-year graduate student who was teaching College Algebra + Trigonometry for the third time. After earning her Masters in Engineering, Kelly earned her M.S. in pure math and was just beginning her doctoral work. The data I collected for analysis included the written lesson guides (which are provided by the department), the instructor's intended lesson plans, pre-observation interviews, video observations of enacted lesson, and post-observation interviews. For the pre-and post-observation interviews, I utilized the protocols in Appendix A. For this case study, I will focus on one task that each instructor enacted at a high-level of cognitive demand.

Greg. The task that I analyzed for Greg focused on demonstrating how to use the law of sines to find a side length in a non-right triangle (Figure 3). Since this task called for the specific procedure that was to be used, required limited cognitive demand for completion, was not connected to the concept underlying the procedure, focused on producing a correct mathematical answer, and required no explanation, it was categorized as a procedures without connections task. In his lesson plan, Greg decided to remove the goal statement from the task so that students would have to recognize which procedure to use. Since this task was situated in the lesson right after the law of sines and cosines had been discussed, I still categorized it as procedures without connections because the procedure was evident from prior instruction and the placement of the task. However, when this task was enacted, it took on another form.

Goal: To study how to use the law of sines to find the length of an unknown side.
Exercise: Solve for x in the triangle below.

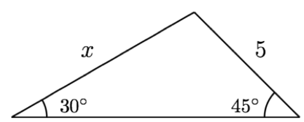

Figure 3. Greg's written task.

When Greg introduced this task during class, a student immediately suggested that they use the law of sines to solve for *x*. However, when Greg asked, "What does the law of sines tell us in this case?", a student responded by saying, "Break this into two triangles." Greg recognized that the student was attempting to follow the procedure that they had used previously when deriving the law of sines. Greg affirmed that the student's idea would work, but then focused on explaining why we don't have to follow the steps of the derivation and instead can just use the final result. During this enactment of the task, the focus shifted from producing a correct answer to developing a deeper understanding of the mathematical process of derivation. For this reason, I coded the enacted task as procedures with connections. By doing this first stage of analysis, I was able to identify Greg's task as a Type 3 task unfolding.

During the second stage of analysis, several aspects of Greg's MKT were brought to the surface. In analyzing how Greg transformed the written task in his lesson plan, Greg depended on his previous experience teaching this course to identify areas where students might struggle with this problem. During the pre-observation interview, Greg said that he knew that students often struggle to figure out what procedure will help them solve a problem. For that reason, Greg removed the goal statement in order to give students an opportunity to learn how to identify what procedure is appropriate. When Greg enacted the intended task during class, he shifted his attention from identifying the procedure to unpacking the mathematical process of derivation. To do this, Greg had to interpret the mathematical statements made by his students. This involved both assessing whether or not the student's idea was mathematically sound and what they did and did not understand about the process of derivation. Finally, Greg had to determine an appropriate way to explain the process of derivation and connect it back to the original task.

Kelly. The task that I analyzed for Kelly focused on introducing the short-run behavior of polynomials and reviewing the concept of long-run behavior (Figure 4). Instead of introducing and reviewing these ideas generally, the task provided a concrete example to work with.

However, since the task required limited cognitive demand for completion, was not connected to the concept underlying the procedure, focused on producing a correct mathematical answer, and required no explanation, I coded it as a procedures without connections task. In her lesson plan, Kelly modified the task by graphing the polynomial at the beginning, asking students to identify relationship between the graph's behavior around zeros and the multiplicities of the zeros (as opposed to just telling them), connecting short-run behavior to the simple power functions x, x^2, and x^3, relating the multiplicities and number of zeros to the degree, and considering how long-term behavior would change if the leading coefficient was negative. Because her intended task now required students to explore and understand the mathematical concept of short-run behavior, access relevant knowledge and make appropriate use of it when working through the task, analyze the task and actively examine constraints, and put forth considerable cognitive effort, I coded it as doing mathematics. When Kelly enacted this task in the classroom, the only thing that she modified was when she graphed the function. Instead of graphing the polynomial first, they utilized the function to identify the zeros, talked about the multiplicities, and briefly explored the general idea of short-run behavior and how it is connected to the multiplicities before graphing $p(x)$. The enacted task added the complexity of requiring students to think generally about short-run behavior instead of relying on a graphical representation and did not remove any complexity of the problem. Therefore, I still coded it as doing mathematics. By doing this first stage of analysis, I was able to identify Kelly's task as a Type 2 task unfolding.

During the second stage of analysis, several aspects of Kelly's MKT were brought to the surface. In analyzing how Kelly transformed the written task in her lesson plan, Kelly intentionally highlighted mathematical connections and patterns instead of focusing on providing definitions. To help students make connect the idea of multiplicities with short run behavior, Kelli utilized "anchor" examples (x, x^2, and x^3) that captured the complexity of the relationship, but through simplified and easily accessible representations. One way that Kelly attended to complexity was by ensuring that the task provided enough variety (such as multiple zeros with both even and odd multiplicities) that students could recognize patterns and waiting to consider additional complexity (such as a negative leading coefficient) at the end. When Kelly enacted the intended task during class, her decision to wait and graph and polynomial after talking generally about short-run behavior required her to critically analyze the mathematical ability of her students. Forming mental representations of graphs and using these to identify graph features is a complex task for students. However, Kelly determined that her students were able to handle this challenge and successfully implemented this modification during the task enactment.

Discussion

As these cases illustrate, utilizing the frameworks of task unfolding and cognitive demand can help reveal MKT by focusing the analysis on the mathematical knowledge entailed in transforming written task into a classroom activity. The cases presented provide a glimpse into what MKT at the undergraduate level looks like, but are far from providing a complete picture. In particular, the analysis done here is really only representative of the first phase of grounded theory of open coding. To develop categories and subcategories or potentially even a general theory for MKT at the undergraduate level, further analysis must be done. As I mentioned previously, these two cases were selected from a larger data set that contains many more cases that can be analyzed. In the Fall 2016, I observed 39 instances of task unfolding in Precalculus classrooms. This semester (Spring 2016), I'm observing six Precalculus instructors three times each, so I anticipate that my complete data set will include around 90 instances of task unfolding.

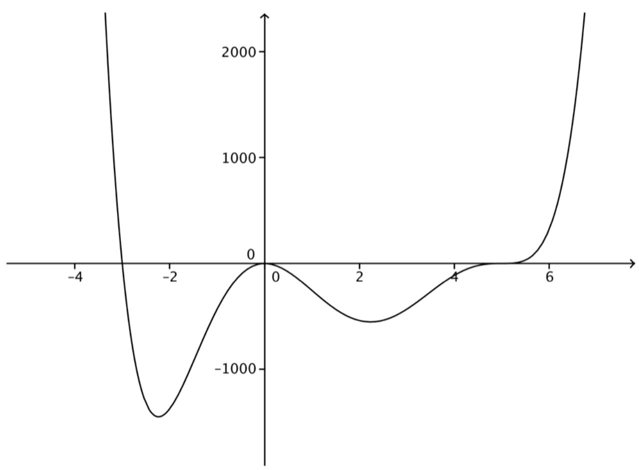
Use the example $p(x) = x^2(x+3)(x-5)^3$ to introduce vocabulary ("zeros" and "multiplicity") and prepare students for the upcoming activity. *On the Board: (When drawing the graph of* $p(x)$*, it may make sense to demonstrate inputting the formula into your calculator and finding the graph that way. Display the graph first in the standard window. Then point out that it's hard to see behavior because the lines are too steep. Adjust the window to have ymin=-500 and ymax=500. Point out that we don't need to spend more time figuring out the zeros on the calculator because we already know these values from our previous work. Be sure to label the zeros as ordered pairs on the graph to emphasize their meaning.)*

Students may have trouble understanding that having a factor of x implies having 0 as a zero. To make this clearer, write $x^2(x+3)(x-5)^3 = (x-0)^2(x+3)(x-5)^3$.

Ex. 1 Let $p(x) = x^2(x+3)(x-5)^3$.
Find zeros and their multiplicities:
To find zeros, find when $p(x) = 0$.
Solve: $0 = x^2(x+3)(x-5)^3$
Happens when $x^2 = 0$, $x+3 = 0$, or $(x-5)^3 = 0$
Happens when: $x = 0$, $x = -3$, or $x = 5$
Hence,

zero	multiplicity
0	2
-3	1
5	3

Expand: $p(x) = x^6 - 12x^5 + 30x^4 + 100x^3 - 375x^2$
Degree of $p(x)$: 6



Long term behavior: Resembles $y = x^6$
Short-run behavior:
Bounces off x-axis: at $(0,0)$
Crosses x-axis: at $(-3,0)$ and $(5,0)$

Figure 4. Kelly's written task.

There are several limitations to both the case studies I presented and the general methodological approach I suggested. For sake of continuity, I will address the limitations of the case studies first and then consider the methodology. One limitation of the cases presented here is that the instructors were graduate students and not faculty members. This distinction may impact the MKT I uncover, since graduate students are generally less-experienced teachers than faculty members and are still learning how to teach. However, studies have shown that experience is actually not a predictor of MKT (Ball, Lubienski, & Mewborn, 2001). It is also important to note that at many doctoral-granting universities, graduate students primarily teach first-year courses, so my sample is representative of the population. Also, my case study is limited in that it considers instructors who have taught a course 3 or more times as experienced. If utilizing a more-traditional K-12 definition of experienced teachers, these instructors would still be considered novices. However, relative to the total population of graduate instructors teaching Precalculus courses, my instructors would be considered experienced.

There are two main limitations that I have identified in the methodological approach I suggest for studying MKT at the undergraduate level. First, one must consider how to handle intended tasks that are not from a written curriculum, intended tasks that are not enacted, and enacted tasks that are not included in the intended lesson plan. Of the 39 instances of task unfolding that I observed last fall, 19 fit into one of these categories. However, I believe that this limitation does not trivialize the analysis. In these cases, the Stage 1 and 2 analyses can still be done if data was collected for at least two of the phases. A second limitation of the methodology is that it is designed under the assumption that MKT only influences the transition between phases. While research does support the fact that it is involved in these transitions (Brophy, 1991, 2001; Stein, Baxter, & Leinhardt, 1990), it is worth considering whether or not any opportunities to examine MKT may be lost by limiting the analysis in this way. Finally, by restricting the unit of analysis to mathematical tasks, the methodology does not consider how MKT might be related to other aspects of teaching, such as designing and providing feedback on assessments. However, if one considers the 19 high-leverage practices (TeachingWorks, 2017) that Ball and colleagues identified as the basic-fundamentals of teaching, task unfolding captures the majority of these practices.

Even with its limitations, the methodological approach I proposed for examining MKT has many strengths. First, the methodology itself is independent of the content and level of instruction. Therefore, it can be used to study MKT K-12 courses, other undergraduate courses besides Precalculus, or even graduate courses. Second, the methodology is flexible in that it can be used to generate formalized theories of MKT or less-formal descriptions and characterizations. Third, utilizing the frameworks for task unfolding and cognitive demand focuses the analysis on specific teaching actions. This is beneficial examining teaching holistically can easily overwhelm a researcher and make it difficult to focus on MKT. However, by utilizing the frameworks of task unfolding and cognitive demand, this methodology provides a structure that begins to reveal the mathematical knowledge involved in the complex work of teaching. Finally, the primary strength of this methodology is that it provides a way to study MKT at the undergraduate level through careful study of the practice of teaching. Instead of utilizing existing frameworks for MKT that were developed at the K-12, it examines MKT at the undergraduate level independently. However, it still draws upon the research and findings at the K-12 level, but in a careful and systematic way that still attends to the unique characteristics of undergraduate instruction.

Appendix A

Pre-Observation Interview Protocol

1. Have you previously used this task in a class before?
2. Where did this task come from?
3. Did you make any changes to this task?
4. What is the mathematics that you intend students to learn through this task?
    a. Why did you want your students to learn this mathematics?

   b. What about this task made you believe it is an appropriate way to learn this mathematics?

Post-Observation Interview Protocol

1. Did you get to all of the tasks that were in your lesson plan?
   a. Why or why not?
2. Did you change any of the tasks that were in your lesson plan?
   a. Why or why not?
3. During the pre-observation interview, you said that the intended learning outcome for this task was __________________. Was that learning outcome the same during class?
   a. Why or why not?
   b. Do you believe that the intended learning outcome was achieved?
4. During this part of the task, it seemed like you were unpacking the mathematics to make it comprehensible for your students.
   a. What exactly were you trying to unpack?
   b. Why did you decide to unpack this?
   c. How did you determine a way to unpack this?
5. During this part of the task, it seemed like you were making mathematical connections across topics, assignments, representation, or domain.
   a. What exactly were you trying to connect?
   b. Why did you want to connect these things?
   c. How did you make these connections?
6. During this part of the task, it seemed like you removed some mathematical complexity to make it more comprehensible for your students?
   a. What exactly did you remove?
   b. Why did you decide to remove that?
   c. How did you maintain the mathematical integrity of the task?
7. During this part of the task, it seemed like you added some mathematical complexity to make it more challenging for your students?
   a. What exactly did you add?
   b. Why did you decide to add that?
   c. How did you maintain the mathematical integrity of the task?
8. During this part of the task, you elicited and interpreted student thinking.
   a. What response(s) did you anticipate?
   b. Why did you elicit student thinking here?
   c. How did you interpret what the student said mathematically?
9. During this part of the task, you used the following mathematical representation(s).
   a. What exactly were you trying to represent?
   b. Why did you use this (these) representation(s)?
   c. How did you use this (these) representation(s)?

Mathematical Actions, Mathematical Objects, and Mathematical Induction

Rachel Arnold
Virginia Tech

Anderson Norton
Virginia Tech

Proof by mathematical induction is arguably the most difficult proof technique for students to master. We explain this difficulty within an action-object framework. Specifically, we report on results from clinical interviews with two mathematics majors in which the first author administered tasks designed to elucidate each student's understanding of logical implications as mental objects. We found that the framework explains much of the difficulty inherent in proof by induction, even the students' struggles with hidden quantifiers.

Keywords: Action-object theory, Logical implication, Mathematical induction, Proof

Beyond the difficulties students experience with proof in general (Weber & Alcock, 2004; Mariotti, 2006; Stylianideas, 2007), mathematical induction poses particular challenges (Baker, 1996; Harel, 2002; Michaelson, 2008; Movshovitz-Hadar, 1993; Stylianides, Stylianides, & Philippou, 2007). Proof by induction involves the implication that if a proposition holds for some integer k, then the proposition holds for the integer k+1. Students often conflate this inductive assumption with the assumption that the proof holds for any k (Avital & Libeskind, 1978; Ron & Dreyfus, 2004). Using the notation P(k) to represent the proposition applied to k, there needs to be a distinction between the implication $P(k) \rightarrow P(k+1)$ and P(k) itself.

For example, consider the proposition, P(n): The sum of the first n odd natural numbers is n^2. The proposition holds for n=1, and assuming it holds for some natural number k, we can show that it also holds for k+1. Suppose that $1 + 3 + \cdots + (2k-1) = k^2$; then adding 2k+1 (the next odd number) to both sides of the equation, we get the sum of the first k+1 natural numbers on the left side of the equation, and on the right side of the equation, we get $k^2 + 2k+1 = (k+1)^2$. Thus, we have proven that the proposition holds for n=1 and that, if P(k) is true, then P(k+1) is also true. Therefore, P(n) is true for all natural numbers.

The purpose of this paper is to investigate the cognitive origins of students' difficulties in mastering proofs by induction. More specifically, we apply an action-object theory to the logical implication $P(k) \rightarrow P(k+1)$ in order to study how a complete understanding of induction might develop. Most mathematics majors can prove logical implications (Harel & Sowder, 2007), but proof by induction imposes an additional requirement: the inductive implication, $P(k) \rightarrow P(k+1)$, must be taken as a single object rather than a relation between two objects, P(k) and P(k+1) (Dubinsky, 1986). Our study contributes empirical results to support this claim within a revised action-object framework.

We begin our report with a review of literature on students' difficulties in understanding proof in general and proof by induction. Then we introduce our action-object framework for investigating such difficulties. Next, we describe the tasks we used to investigate students' understandings within that framework. Finally, we report on results that answer the following four questions.

1. How do college mathematics majors understand logical implications?
2. Are action-object distinctions useful in modeling these understandings?
3. How do these understandings contribute to their mastery of proof by induction?

4. What other factors contribute to, or detract from, mastery of proof by induction?

Research on Students' Difficulties with Proofs and Proving

Harel and Sowder (2007) defined a conjecture as "an assertion made by an individual who is uncertain of its truth" (p. 808). Correspondingly, they defined proving as the process of removing doubts about such assertions. Recognizing the reciprocal role that conjecturing plays in proving, Boero, Lemut, and Mariotti (1996) referred to a cognitive unity between these two activities, and several researchers have described ways in which students switch back and forth between conjecturing and proving as they attempt to construct proofs (Arzarello, Andriano, Olivero, & Robutti, 1998; Herbst, 2006; Saenz-Ludlow, 1997; Weber & Alcock, 2004). For example, Cifarelli (1997) found that, "[students'] self-generated hypotheses went hand-in-hand with their conception of carrying out of purposive activity designed to test the viability of their hypotheses" (p. 20).

Harel and Sowder (2007) referred to a second kind of switching, between ascertaining and persuading. The role of persuasion in proof emphasizes its social dimension and subjective nature. In learning to make convincing arguments, students need to do more than ascertain truth for themselves; they must also find ways to convince others. Mathematical communities (such as mathematics classrooms) can specify criteria for convincing arguments. de Villiers (1999) specified six purposes these arguments might serve: verification, explanation, systemization, discovery, communication, and intellectual challenge. Additionally, mathematicians often place value on the aesthetic qualities of a proof (Sinclair, 2006).

To classify ways that students might attempt to ascertain and persuade, Harel and Sowder (2007) identified three broad proof schemes: external, empirical, and deductive. Generally, mathematics educators aspire for their students to progress toward deductive proofs because: (1) unlike external proof schemes, they include personal meaning that relates to ascertaining; and (2) unlike empirical proof schemes, they provide persuasive power via logical explanation (NCTM, 1989). Table 1 summarizes the three broad proof schemes, along with their subcategories.

In contrast to our aspirations, students generally rely on empirical or external proof schemes (Harel & Sowder, 2007), and poor performance in proving persists in college, even among mathematics majors (Selden & Selden, 2003; Weber, 2001). Proofs by mathematical induction pose particular challenges for mathematics students (and teachers), from high school through college (Avital & Libeskind, 1978; Baker, 1996; Ron & Dreyfus, 2004; Stylianides, Sylianides, & Philippou, 2007). In a conceptual analysis, Ernest (1984) speculated several possible reasons for students' difficulty, including their understandings of logical implication in general. Several empirical studies have followed, elucidating the role of such factors.

In a study of elementary and secondary school preservice teachers, Stylianides, Stylianides, and Philippou (2007) identified three specific difficulties underlying students' poor performance with proofs by mathematical induction: (1) understanding the necessity of establishing a base case (usually $n=1$); (2) interpreting the meaning of the inductive step, $P(k)$ implies $P(k+1)$; and (3) accepting that the proposition might hold beyond the cases covered by induction. In discussing the first two difficulties, the researchers cited prior work by Dubinsky (1986) suggesting that, in order to develop a mature understanding of proof by mathematical induction, students need to understand logical implication as an object: "Similar to what we found, many sophomores in Dubinsky's study tried to prove $P(k+1)$ rather than $P(k) \rightarrow P(k+1)$" (p. 162).

Table 1. *Harel and Sowder's (2007) Proof Schemes*

Class	Sub-category	Description
External Proof Schemes		
	Authoritarian	Relies on external authority, such as a text or teacher
	Ritual	Focuses on format (such as two-column proof) over substance
	Non-referential symbolic	Focuses on symbol manipulation rather than underlying concepts
Empirical Proof Schemes		
	Inductive	Relies on measurements from specific examples
	Perceptual	Relies on perceptions of specific examples
Deductive Proof Schemes		
	Transformational	Based on operational thinking and logical inference that generalizes across an entire class
	Axiomatic	A transformational proof scheme that begins from axioms.

We return to Dubinsky's work in the next section as part of a more general discussion of action-object theory. Here, we note that the conflation of the proposition P(k) with the implication P(k) → P(k+1) can lead students to conflate proofs by induction with the fallacy of assuming what is to be proved (Movshovitz-Hadar, 1993). Further, even successful mathematics students have difficulty accepting the truth of the implication without knowing the truth of the proposition itself: "How can you establish the truth of P(k+1) if you don't even know if P(k) is true?" (Avital & Libeskind, 1978, p. 430).

Harel (2002) explicitly connected students' poor performance in mathematical induction to their proof schemes, as characterized by Harel and Sowder (2007; see Table 1). In a study of preservice secondary school teachers enrolled in a college number theory course, Harel (2002) found that students' proof schemes largely fell into the empirical and external categories, particularly the authoritative and non-referential symbolic subcategories of the external proof scheme. Furthermore, he found that students' proof schemes strongly influenced the ways they understood the method of mathematical induction. He argued that students rely on authoritative schemes because they are introduced to the method before they have an intellectual need for it. He suggested a need-driven instructional approach that could build from students' empirical proof schemes toward transformational proof schemes that would support a complete understanding of the method.

The instructional approach utilizes pattern generalization, which is in the purview of the empirical proof scheme. However, the approach emphasizes patterns in the process rather than patterns in the results of that process, supporting a form of reasoning that Harel (2002) calls *quasi-induction*. In the previously shared example of summing odd integers, instruction that supports quasi-induction might involve drawing students' attention to the way one perfect square follows from the previous one, rather than the pattern of perfect squares itself. For instance, $(4+1)^2 - 4^2 = (2 \cdot 4+1)$, and this pattern holds across any pair of consecutive perfect squares so that

$(k+1)^2 - k^2 = (2k+1)$. Because quasi-induction and its process pattern generalizations focus on students' own mental actions rather than empirical observations, it is transformational in the Piagetian sense (Piaget, 1970), and Harel (2002) refers to it as a manifestation of the transformational proof scheme.

Action-Object Framework

Action-object theories of mathematical development derive from Piaget's (1970) genetic epistemology, in which mathematics is understood as a product of psychology: Mathematical objects arise as coordinations of mental actions through a process called reflective abstraction. Within that framework, the enterprise of mathematics education is to specify the mental actions that underlie mathematical objects and how they might be coordinated--composed and reversed--with one another to construct those objects. For example, mathematics education researchers have described how whole numbers, like 5, arise as objects for children through coordinated activities of unitizing, iterating, partitioning, and disembedding (Piaget, 1942; Steffe & Cobb, 1988; Ulrich, 2015).

Dubinsky (1986) adopted a Piagetian perspective to extend action-object theories to advanced mathematics. He developed the APOS framework to explain students' mathematical development through processes of interiorizing *actions* as *processes*, then encapsulating those processes as *objects* that can be acted upon; *schema* organize processes and objects so that students can make sense of mathematical situations. Similarly, Sfard (1991) described the reification of actions as objects, thus distinguishing objects from pseudo-objects. Unlike mathematical objects, pseudo-objects are merely figures or symbols, with no basis in action, so they cannot be de-encapsulated. For example, high school students learn rules for manipulating expressions within algebraic equations, but for many students, the expressions themselves have no reference to underlying actions (Sfard & Linchevski, 1994).

Action-object theories point to two essential features of logico-mathematical development—that students begin to construct new mathematical objects by coordinating their available mental actions and that new mental actions become available for acting on those objects. For example, students can construct the cube as a mathematical object by coordinating mental rotations, and once they have constructed the cube, they can consider new actions, like reflecting the cube about a plane through its center. The double arrow in Figure 1 represents these two essential features.

$$\text{Actions} \rightrightarrows \text{Objects}$$

Figure 1. Actions and objects.

In the domain of proof and proving, we might consider logical implication as a mental action that transforms one assertion into another. In formal logic, this transformation is referred to as *modus ponens* (P implies Q, and P is true, therefore Q is true). It has three kinds of reverse actions: negation (P is true and Q is false); inversion, which relies on the converse of the implication (Q implies P); and *modus tollens* (P implies Q, and Q is false, therefore P is false), which relies on the contrapositive of the implication (not Q implies not P). Whereas the contrapositive of the implication is logically equivalent to the original implication, its converse is not.

“Performance on logical inferences involving modus ponens is usually reasonably good, but performance on those tasks involving modus tollens is weak, as is a full understanding of inferences involving if-then statements” (Harel & Sowder, 2007, p. 826). From a Piagetian perspective, these latter two findings go hand-in-hand. A full understanding of any mathematical object relies on the ability to reason reversibly (Piaget, 1970), so students will not have a full understanding of inferences involving if-then statements until they can reason with modus tollens as well as modus ponens. In other words, a logical implication would arise as a mathematical object for students only after they begin to coordinate modus ponens and modus tollens as reverse actions.

In referring to quasi-induction, Harel (2002) was making an action-object distinction in the development of mathematical induction. The logical implication $P(k) \rightarrow P(k+1)$ begins as an action wherein students have to carry out the transformation from the k^{th} case to then $(k+1)^{st}$ case. True induction arises from the objectification of this action (see Figure 2). “In quasi-induction one views the inference, $P(n-1) \rightarrow P(n)$, just as one of the inference steps—the last step—in a sequence of inferences that leads to P(n). In mathematical induction on the other hand, one views the inference, $P(n-1) \rightarrow P(n)$, as a variable inference form, a placeholder for the entire sequence of inferences” (Harel, 2002, p. 26). Based on this action-object framework, our study focuses on the actions and objects of mathematical induction, including the two sides of the implication, the implication itself, and three ways of reversing it: converse, contrapositive, and negation.

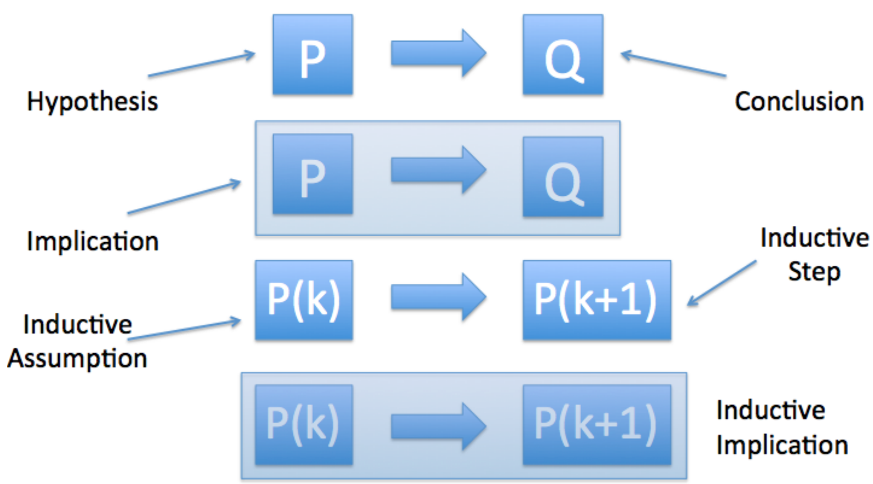

Figure 2. The actions and objects of logical implication.

Methods

To investigate the actions and objects of mathematical induction, the first author conducted clinical interviews with each of two college students, Trevor and Laura, who had completed an *Introduction to Proofs* course, which included instruction on mathematical induction. One student, Trevor, earned an A in the course, and the other student, Laura struggled in the course, earning a grade of C. In this paper, we share results from our analysis of the interview with the higher performing student, Trevor.

The one-hour interview was video-recorded and consisted of tasks designed to elicit the actions and objects those students had available for reasoning with proofs by mathematical induction. In the remainder of this section, we describe those tasks and our video analysis of the interview with Trevor.

Tasks

Interview tasks included three types (see Table 2). Type A tasks were designed to assess student understanding of logical implication. We included questions in both a familiar context (number theory) and an unfamiliar context (homology). In both contexts, students were given a statement and asked to provide truth values for its converse, its contrapositive, and its negation.

Type B tasks assessed student understanding of the components of mathematical induction (e.g., P(1) and P(k)) and how they might support an inductive proof. Type C tasks assessed student ability to construct a formal proof, both in general and by induction. Sample tasks are listed in Table 2.

Table 2. Sample interview tasks.

<table>
<tr><th>Task Type</th><th>Sample Task</th></tr>
<tr><td>A: Logical implication</td><td>Suppose the statement S is true. Evaluate whether the statements (a)-(c) are true, false, or uncertain.
1. S: If two topological spaces are homeomorphic, their homology groups are isomorphic.
a. If two topological spaces have isomorphic homology groups, the spaces are homeomorphic.
b. If the homology groups of two topological spaces are not all isomorphic, the spaces are not homeomorphic.
c. There is a pair of homeomorphic topological spaces whose homology groups are not all isomorphic.
2. S: Every even natural number can be written as the sum of two prime numbers.
a. If a number is not the sum of two primes, it is odd.
b. There is an even number that is not the sum of two primes.
c. If a number is odd, it is not the sum of two primes.</td></tr>
<tr><td>B: Induction components</td><td>Each of the following scenarios relates to a proposition P(n), where n is a positive integer. Decide whether: (a) the given information is enough to prove P(n) without induction (i.e., induction is not necessary); (b) the given information is enough to prove P(n) with induction; or (c) or the given information is not enough to prove the proposition.
1. P(1) is true; there is an integer $k \geq 1$ such that P(k) is true.
2. P(1) is true; there is an integer $k \geq 1$ such that $P(k) \rightarrow P(k+1)$.
3. P(1) is true; for all integers $k \geq 1$, $P(k) \rightarrow P(k+1)$.</td></tr>
<tr><td>C: Non-inductive formal proof</td><td>Let k be an integer. Prove that if 36 divides k, then 81 divides k^2.</td></tr>
<tr><td>D: Inductive formal proof</td><td>Prove that beginning with zero, every third even number is divisible by 6.</td></tr>
</table>

During each interview, the first author posed tasks to the student one at a time by handing the student a slip of paper. The student was given paper to write notes and was provided opportunities to ask clarifying questions. After the student's response to each task, the interviewer would ask follow-up questions, probing the student's reasoning. For example, for Type B tasks (see Table 2), the interviewer might asked the student what additional information (s)he would need in order to show that the proposition would hold for all positive integers.

Video Analysis

Each researcher independently engaged in video analysis through an action-object lens. In this initial analysis, we focused on collecting facts about student understanding from each task type, without consideration of how performance on tasks of one type predicted performance on tasks of another type. We analyzed the students' spoken explanations for the Type A tasks to assess if they understood logical implication as an object, or if they instead viewed implication as an action between two objects, the hypothesis and the conclusion. For Type B tasks, we inferred which components of mathematical induction the students objectified and what actions they could perform on those objects. Finally, for Type C tasks, we evaluated the students' success in proving statements with and without mathematical induction.

In a second iteration of analysis, the researchers jointly considered how well the action-object framework explained student responses and how the students' performance on tasks of one type predicted their performance on later tasks. In particular, we looked for connections between the students' conceptualization of logical implication and their success in proof by mathematical induction. More specifically, we examined how the students' performance on Type A tasks predicted their objectification of the components of induction and the subsequent actions the student could perform on these components in Type B tasks. We considered whether students' objectification of logical implication and the components of mathematical induction (Type A and Type B tasks) explained additional challenges they experienced in proof by mathematical induction when compared to proof without induction (Type C tasks). In light of previous research, we considered explanations alternative to action-object theory for these differences. For example, what challenges did students experience in the components of mathematical induction because of hidden quantifiers (Shipman, 2016)? Selected transcription was used to support our analyses.

Results

We focus on the results of our video analysis of the interview with the higher-performing student, Trevor. Trevor seemed to treat logical implication as an action on two objects (P and Q), rather than a single object itself ($P \rightarrow Q$). This was evidenced throughout the interview, but particularly when he explained his reasoning for his responses to Type A tasks.

As we outline below, we infer from Trevor's spoken and written reasoning that he conceptualizes the negation, converse, and contrapositive of the implications in Task A via transformations on the objects of the implication, the hypothesis and conclusion. The more complicated the transformation process became, the more Trevor struggled with assessing the validity of the new statement.

The easiest transformation for him was by far the negation. In Task A1c, Trevor was asked to state the negation of the implication $P \rightarrow Q$ as a follow up to his response that the statement was false. Trevor replied, “the negation is P implies not Q … if you’ve already violated your assumption by saying that P is false then it doesn’t really matter what happens to Q because you don’t really care because P isn’t true.” He also wrote “P → ~Q” on his interview paper. Trevor’s explanation of why he believes the negation is P → ~Q seems to indicate the following thought process. To negate the implication, he first considers negating P and Q individually. We infer that Trevor is considering whether ~P → ~Q could be the negation. He concludes that P should not be negated, misusing the fact that an implication is vacuously true when P is false. Thus, he arrives at his conclusion that the negation should be P → ~Q. In considering the negation of the hypothesis and conclusion separately, Trevor treated implication as an action on objects, rather than an object itself. And, because Trevor believed the negation was P → ~Q, he needed only to construct ~Q as an object to assess the truth value of the entire statement.

Determining the truth value of the converse statements in Task A was slightly trickier for Trevor because it involved a reverse transformation of the implication. When considering the converse in Task A1a, Trevor began by writing out and separating the two statements in the implication (see Figure 3). He then claimed that the statement was uncertain, using the following justification: “Just because you know that the forward direction is true, there’s nothing implying that the reverse direction is true, in this case.” Prompted for a term to describe the statement in question, Trevor correctly labeled it as the converse statement. These responses indicate that Trevor treated the original statement in two parts, with implication as an transformation between them--a transformation that he could reverse. His representation of the original statement seemed to support his reasoning in comparing the reverse (converse) statement to the original.

Figure 3. Trevor’s representation of the original implication in Task 1a.

In response to Task A2c, Trevor paused for about 12 seconds, looking at the statement in question. Finally, he responded as follows:

> That one I’m going to say ‘uncertain’ because this one [pointing to the original statement] just says that if you have a naturally even number then you can express it as the sum of two primes. But it doesn’t [flips right hand over] flip the… Inverse statement isn’t true necessarily, saying that, if a number is odd, it’s not the sum of two primes. But… I feel like I’m drawing outside information into saying this next part, but being a prime number, you can’t be an even number…

Trevor went on to explain (based on his assumption that all primes are odd) that the sum of two primes will always be even. Thus, he justified the truth of the converse statement based on the context of the task. He knew that, in general, the converse would not necessarily follow from the original implication. However, once again, determining the relationship between the original statement and its converse required Trevor to perform a "flip" wherein he treated the two sides of the implication as separate objects.

While Trevor seemed to recognize the statements in tasks A1a and A2c as the converse of each implication relatively quickly, Trevor did not recognize the contrapositive statements in both tasks of Type A without significant prompting. In fact, the most challenging Type A tasks for Trevor were the contrapositive statements because they appeared to require him to combine two transformations, reversal and negation, on the objects of the implication. We note that this additional transformation, as compared to his handling of the converse, created substantially more struggle for Trevor. This is evidenced by Trevor's responses to the Task A1b, where the mathematical context was unfamiliar. After several minutes of little progress and after the first author prompting him to see the relationship between the statement *S* and its contrapositive, Trevor stated, "It's the negation of the reverse order, which is true in general. I do remember that… I don't remember the word but, 'If P then Q is true', then 'not Q implies not P' is generally true." Trevor's explanation indicates the two transformations, reversal and negation, he performs to obtain the contrapositive from *S*. Further, like in Task 1Ac, Trevor uses the term "negation" to mean the negation of each individual statement P and Q. If he was indeed referring to the "negation of the reverse order," he would have $\sim(Q \rightarrow P)$ and hence Q and $\sim P$, which is not the contrapositive of $P \rightarrow Q$.

In Task A2a, Trevor had to again determine the truth value of the contrapositive of statement *S* in the familiar setting. Despite having just solved Task A1b, he still did not recognize the statement as the contrapositive and struggled to determine its validity. This supports our previously mentioned inference that the additional transformations necessary for Trevor to mentally construct the contrapositive are enough to blur his connection of the truth value of *S* to its contrapositive. Further, Trevor relied on his knowledge of primes to reason through his answer, ignoring the logical equivalence connection altogether. Rather than viewing the entire implication as an object that could be manipulated, he focused on the meaning of the hypothesis and conclusion separately. Consequently, we infer that Trevor's reliance on mathematical context demonstrated that he was not viewing the logical implication as a single object, rather an action on objects.

Contrasting Trevor's performance on Type A tasks in the unfamiliar versus familiar mathematical setting reveals the mental actions and objects that Trevor seemed to have available. First, because the hypothesis and conclusion of statement *S* in the unfamiliar setting (Task A1) did not carry mathematical meaning for Trevor, he seemed to conceptualize them rather quickly as pseudo-objects (Sfard, 1991). He did not devote time to framing the statements as objects with mathematical meaning. Therefore, he was more able to perform his transformations on *S* that were necessary for him to construct each new statement in Tasks A1a-c. However, in the familiar setting, Trevor got stuck trying to first construct the pieces of the implication as mental objects because they carried mathematical meaning that he believed he could unpack. As a result, he was delayed in the process of carrying out his transformations. This was particularly evidenced in Trevor's performance on Task A2a when he struggled to execute his two step action sequence of transforming the implication *S* into its contrapositive.

Next, Trevor's responses to the Type B tasks indicated that he understood how to combine components of an inductive proof, but he seemed to rely heavily on a procedure learned in class. In this way, he seemed to rely on an authoritarian proof scheme (Harel & Sowder, 2007, see Table 1). In particular, he treated induction as a sequence of objects: a base case, an inductive assumption, and an inductive step. Like his treatment of logical implication in the Type A tasks, Trevor separated the inductive implication into two objects—the assumption and the step. This reasoning was evidenced in his response to Task B2 in Table 2 where he was given P(1) and the existence of an integer k for which P(k) implies P(k+1).

> We have everything we need to do induction on this case because we have a base case that P(1) is true. And then can lump P(k) into our inductive assumption and then use P(k) implying P(k+1) to form our inductive step and follow that all the way through to all of the natural numbers.

These criteria helped him successfully distinguish which scenarios could generate a proof by induction, but a conceptual limitation became apparent. Specifically, it was clear that Trevor viewed induction as a connected sequence of three objects as follows. Trevor first checked for a base case, object one. He then linked the base case to his second object, the inductive assumption, by checking that k began at 1 for the remaining information. Once he was satisfied that this connection existed, he was able to consider the final object, the inductive step. Because of this ordered thought process, Trevor did not seem to notice that the inductive implication was missing from Task B1. In what follows, Trevor was concerned with making sure that k began at 1. He argued that if k were 3, he would still have a kind of inductive step but that the step size would be 2 instead of 1.

> We can say that P(k) is true for this given integer, but we don't really know where k is, so I don't think we can construct an inductive argument because we don't know where k is relative to 1. But if k is 3, for example, we don't know what happens at 2, and so we haven't proved it for all of the natural numbers. So even if we were to say like skip two steps, then we leave out all of the evens, for example.

We contrast this to Trevor's performance on Task B2 where he was given P(1) and that there exists an integer k≥1 such that P(k) implies P(k+1). Here, overlooking the existential quantification of k (which we address below), Trevor was satisfied with his initial action of joining the base case to the inductive assumption and completed his object sequence as follows.

> We have everything we need to do induction on this case because we have a base case that P(1) is true. And then can lump P(k) into our inductive assumption and then use P(k) implying P(k+1) to form our inductive step and follow that all the way through to all of the natural numbers.

Trevor's above response to Task B2 also surfaced a new issue in successful proof by induction: a student's ability to recognize the role of quantification in the inductive implication. Initially, Trevor overlooked the quantification of k in Tasks B1 and B2. His sequencing of inductive objects led to a correct conclusion (but for the wrong reason) that Task B1 did not have enough information, and an incorrect conclusion that Task B2 had enough information for proof by induction. However, upon seeing Task B3—which gave P(1) and that for *all* integers k≥1, P(k) implies P(k+1)—and after much prompting from the interviewer, Trevor exposed the role of quantification. He then went back to Task B2 and said there was not enough information to use induction.

While Trevor's object sequence may not lead to a mastery understanding of induction, it did allow for him to systematically outline the necessary components in a proof by induction. For the Type C task shown in Table 2, Trevor had no trouble establishing base cases, and he seemed to understand the purpose of induction.

> We can establish as many base cases as we want… 0 can be represented as something times 6; 6 can be represented as something times 6; so can 12; 18; all the way up. So you're going to have to use induction because you can't really prove every number, without sitting here and writing them all out. So you know that the inductive assumption is going to say that, assume for all numbers, k, greater than or equal to 0, but…

He struggled in establishing an inductive step and consequently completing the proof of the inductive implication: "I know what argument I want to make, but I'm not sure how to make it." His difficulty stemmed from an inability to formulate a useful representation of every third even integer. However, when prompted about what P(k+1) meant in this case, Trevor clearly understood, and also confirmed, that "k+1" did not literally mean add 1 to k. He proposed that "k+1" really meant k+6 in this case, and when asked why, he replied "because [k] is just an arbitrary number and you want to prove that the *next one* [is true]." So, Trevor did seem to understand how the inductive step should work, and arguably he could have been successful in his proof without this formulation issue.

Conclusions and Implications

Prior research identified several potential hurdles in students' mastery of proof by induction. Among these, Stylianides, Stylianides, and Philippou (2007) highlighted understanding the necessity of establishing a base case and interpreting the meaning of the inductive step. Neither student in our study demonstrated any difficulty in understanding the necessity of the base case. In fact, Trevor consistently included the base case as a critical component for inductive proofs. However, both students misconstrued the meaning of the inductive step, and the action-object framework was especially helpful in explaining why. Additionally, we uncovered a new issue not captured by prior research: students' struggles with the role of quantification in proofs by induction. We believe that our action-object framework can also be used to explain this struggle.

In line with research on proof in general (Harel & Sowder, 2007; Selden & Selden, 2003; Weber, 2001), the two students in our study relied on external proof schemes to make inductive arguments. Still, a student's ability to follow a procedural sequence of objects (base case, then inductive assumption, followed by inductive step) without a mastery of induction can allow for successful proof by induction. Separating the inductive implication into two objects, P(k) and P(k + 1), makes the process more accessible to the typical student because the typical student already handles implications in pieces (Avital & Libeskind, 1978; Dubinsky, 1986; Movshovitz-Hadar, 1993). Thus, students who have not constructed logical implications as objects can write successful proofs. However, they do not have a complete understanding for how the process works. When the inductive proof calls for some modification to the standard format (as arose in Trevor's struggles to formulate P(k + 1)) students can become confused about how to proceed.

Our results support findings from prior studies indicating that treatment of logical implications is a major mediator in students' understandings of proof by induction (Ernest, 1984; Dubinsky, 1986). Our study also affirms limitations on students' treatment of logical implications–even among high performing students like Trevor (Harel & Sowder, 2007). We consider some ways to address these limitations using our action-object framework, but first we consider the unanticipated limitation regarding students' treatment of hidden quantifiers.

Both of the students we interviewed struggled to recognize quantifiers in the statements of Type B tasks. When Trevor was asked whether there was a difference between Tasks B2 and B3 (see Table 1), he replied that they were the same. When asked if he was sure, he noticed that one sentence had the words "such that" and again overlooked the quantifiers. Other researchers have noticed students' difficulty in accounting for hidden quantifiers in proving mathematical statements (Seldon & Seldon, 1995; Shipman, 2016). In particular, Barbara Shipman discussed just how prevalent this issue of hidden quantifiers is among students and how it leads to errors in logic in proof by contradiction. The inductive implication $P(k) \rightarrow P(k + 1)$ is an implication with hidden quantifiers. $P(k)$ and $P(k + 1)$ are open statements that have no truth value until k is quantified. What we really mean when we write $P(k) \rightarrow P(k + 1)$ is "for all $k \geq 1$, $P(k) \rightarrow P(k + 1)$." Students often suppress the significance of the hidden quantification of k in the inductive implication, and consequently in their conceptualization of proof by induction.

In proof by contradiction, Shipman (2016) noted that failure to recognize hidden quantifiers can lead to correct conclusions for the wrong reason, or incorrect conclusions about the validity of a statement. She also noted that oftentimes students' mistreatment of quantifiers leads to the erroneous proof of a "for all" statement by example. In our study, we found that Shipman's observations also appear to hold true in the context of proof by induction. In Task B1, Trevor came to the correct conclusion that more information was needed but for the wrong reason. He bypassed the hidden quantification of k and focused on whether $P(k + 1)$ was true. In Task B2, Trevor's oversight of the quantification of k led to an erroneous induction proof by example. Trevor conflated showing the inductive implication was true for one k with showing the implication was true for all k. We conclude that students might be able to complete the proof of the unquantified inductive implication $P(k) \rightarrow P(k + 1)$ by breaking it down into procedural steps. However, in the absence of a memorized, quantified inductive assumption, their proofs by induction are not quite logically complete.

Students' struggles with the role of the quantification of the inductive implication in creating a logically complete proof by induction may be related to their construction of implication as a mental object. In particular, dissecting quantified statements in the context of mathematical induction places an increased cognitive demand on students that is less easily navigated if a student conceptualizes an implication as an action on objects. Because a student must work with additional objects when they are unable to mentally construct the implication as a single object, the student's cognitive resources available for addressing quantification are reduced. Our claim is supported by Trevor's performance on problems in his introduction to proofs course where the sole focus was quantification. For example, on the first exam, Trevor was given the following two statements and asked to label them as true or false and justify his answer.

1. There exists a real number x such that for all real numbers y, $2x - 3y + 7 = 14 - 6y$.
2. There exists a real number x such that for all real numbers y, $xy + 3x = 2y + 6$.

Trevor earned a perfect score on this problem, showing no problems with understanding quantifiers, even when mixed. Thus, his struggles with quantification during his clinical interview were unexpected. We speculate that Trevor's treatment of logical implication as an action on objects was an inhibiting factor.

Our study indicates that constructing logical implications as objects and identifying hidden quantifiers are prerequisite knowledge for developing transformational proof schemes for mathematical induction. Thus, similar to Harel (2002), we consider instructional activities that should be included in Proofs courses, leading into formal instruction on mathematical induction. Harel had suggested introducing quasi-induction as a means of focusing students' attention on the logical implication that related the inductive assumption to the inductive step, by explicitly relating P(k) to P(k + 1) for specific values of k. Results from our study attest to the value of that approach, assuming it supports the objectification of the implication, in general.

Tasks of Type A (see Table 1), in addition to their value in assessing whether students have constructed logical implications as objects, might also support that construction as students are challenged to transform a given logical implication into other forms (negation, converse, and contrapositive). Furthermore, our study suggests that instructors should give attention to how students handle hidden quantifiers, and tasks of Type B might reinforce the role of hidden quantifiers in proofs by induction. We recommend further study to test the efficacy of these different task types in supporting students' development of transformational schemes for proof by induction.

Examining Students' Procedural and Conceptual Understanding of Eigenvectors and Eigenvalues in the Context of Inquiry-Oriented Instruction

Khalid Bouhjar, Christine Andrews-Larson, Muhammad Haider
Florida State University

and Michelle Zandieh
Arizona State University

This study examines students' reasoning about eigenvalues and eigenvectors as evidenced by their written responses to two open-ended response questions. This analysis draws on data taken from 126 students whose instructors received a set of supports to implement a particular inquiry-oriented instructional approach and 129 comparable students whose instructors did not use this instructional approach. In this chapter, we offer examples of student responses that provide insight into students' reasoning and summarize broad trends observed in our quantitative analysis. In general, students in both groups performed better on the procedurally oriented question than on the conceptually oriented question. The group of students whose instructors received support to implement the inquiry-oriented approach outperformed the other group of students on the conceptually oriented question and performed equally well on the procedurally oriented question.

Key words: eigenvalues, eigenvectors, linear algebra, inquiry-oriented, student thinking

Linear algebra is a mandatory course for many science, technology, engineering, and mathematics (STEM) students. The theoretical nature of linear algebra makes it a difficult course for many students because it may be their first time to deal with abstract and conceptual content (Carlson, 1993). Carlson (1993) also posited that this difficulty arises from the prevalence of procedural and computational emphases in students' coursework prior to linear algebra, and that it might therefore be difficult for students to connect new linear algebra topics and their previous knowledge. To address this issue, researchers have developed instructional materials for Inquiry-Oriented Linear Algebra (IOLA; http://iola.math.vt.edu/) and strategies to help students develop more robust, conceptual ways of reasoning about core topics in introductory linear algebra (e.g. Wawro, Rasmussen, Zandieh, & Larson, 2013; Zandieh, Wawro, & Rasmusen, 2016; Andrews-Larson, Wawro, & Zandieh, 2017).

Instructors who were not involved in the development of these kinds of research-based, inquiry-oriented instructional materials have been shown to encounter challenges when implementing such materials (Johnson, Caughman, Fredericks, & Gibson, 2013). Under an NSF-supported project Teaching Inquiry-Oriented Mathematics: Establishing Supports (TIMES), Johnson, Keene, & Andrews-Larson (2015) designed and implemented a system of instructional supports based on research in instructional change in undergraduate mathematics education and teacher learning and professional development in settings ranging from K-20 (e.g. Henderson, Beach, & Finkelstein, 2011). These supports included sequences of student activities with implementation notes, a three-day summer workshop, and weekly online workgroups during the semester instructors implemented the materials in their teaching. This chapter examines differences in performance and reasoning of students whose instructors received these supports through the TIMES project (TIMES students) as compared to students whose instructors did not receive these supports (Non-TIMES students). In particular, we examine assessment data to identify differences in student performance and reasoning about eigenvectors and eigenvalues.

In this work, we draw on data from an assessment that was developed to align with four core introductory linear algebra concepts addressed in the IOLA instructional materials: linear independence and span; systems of linear equations; linear transformations; and eigenvalues and eigenvectors (Haider et al., 2016). In the assessment, there were two questions that addressed eigenvalues and eigenvectors: question 8 and 9. Question 8 was a procedurally oriented question related to the eigenvalue of a given matrix and question 9 focused on conceptual understanding of the eigenvectors. The research questions for this analysis are:

- How does the performance of students whose instructors received TIMES instructional supports for teaching linear algebra compare to the performance of other students?
- How did students reason about eigenvectors and eigenvalues in the context of questions designed to assess aspects of student's procedural and conceptual understanding? How did reasoning differ for students of TIMES versus Non-TIMES instructors?

Literature

Linear algebra is a course in which students struggle to develop conceptual understanding (Carlson, 1993; Dorier & Sierpenska, 2001; Dorier, Robers, Robinet & Rogalski, 2000). Across the literature on the teaching and learning of eigenvalues and eigenvectors, procedural thought processes feature prominently. For example, Stewart and Thomas (2006) pointed to ways in which students often learn about eigenvalues and eigenvectors, where a formal definition is often linked to a symbolic presentation and its manipulation. For the purpose of this paper, we will draw on the following formal definition for eigenvectors and eigenvalues:

> Suppose A is an nxn real-valued matrix and x is a non-zero vector in $\mathbb{R}^n$. We say the vector x is an eigenvector of the matrix A if there is some scalar λ such that $Ax = \lambda x$. Further, in this case, we say that λ is the eigenvalue associated with the eigenvector x.

Thomas & Stewart (2011) highlighted a difficulty students find when faced with formal definitions for eigenvalues and eigenvectors: these definitions contain an embedded symbolic form ($Ax = \lambda x$), and instructors often move quickly into symbolic manipulations of algebraic and matrix representations such as transforming $Ax = \lambda x$ to $(A - \lambda I)x = 0$. Their findings that students struggle to make sense of formal definitions, struggle to make use of geometric representations of eigenvectors, and exhibit procedural orientations toward eigenvectors suggest that such treatments might not provide sufficient opportunities for students to make sense of the reasons behind these symbolic shifts (Thomas & Stewart, 2011).

Schoenfeld (1995) used eigenpictures in the 2x2 case ("stroboscopic" pictures) to show x and Ax at the same time by using multiple line segments on the x-y-axis. He observed that graphical representations of eigenvalues and eigenvectors got little attention in the literature and that a picture may benefit more than algebraic presentations. It is also documented more generally in linear algebra that students struggle to coordinate algebraic with geometric interpretations (e.g. Stewart & Thomas, 2010; Larson & Zandieh, 2013) and the students' understanding of eigenvectors is not always well connected to concepts of other topics of linear algebra (Lapp, Nyman, & Berry, 2010).

To support students in developing a better understanding of the formal definition and associated interpretations of the eigenvalues and eigenvectors, researchers have developed a variety of instructional interventions (e.g. Tabaghi & Sinclair, 2013; Zandieh, Wawro, & Rasmusen, 2016). This paper examines student learning outcomes associated with the geometrically motived instructional approach detailed in Zandieh, Wawro, & Rasmussen (2016) when paired with TIMES instructional supports; the approach will be described in Data Sources & Study Context.

Theoretical Framing

Researchers often make reference to conceptual understanding and procedural understanding when discussing students' reasoning about mathematical concepts (Hiebert, 1986). Hiebert and Lefevre (1986) defined conceptual knowledge as a "knowledge that is rich in relationships. It can be thought of as a connected web of knowledge, a network in which the linking relatonships are as prominent as the discrete pieces of information" (pp. 3-4). According to Hiebert and Lefevre (1986) students have procedural knowledge if they can combine the formal language and symbol representation systems with algorithms or rules in order to complete mathematical tasks.

In this paper, we also draw on Larson and Zandieh's (2013) framework for students' mathematical thinking about matrix equations of the form $Ax = b$. This framework details three important interpretations, relationships between geometric and symbolic representations within each interpretation, and the complexity entailed in shifting among interpretations. The interpretations are: (1) a linear combination interpretation, in which b is viewed as a linear combination of the column vectors of A with x functioning as the set of weights on the column vectors of A, (2) a system of equations interpretation in which x is viewed as a solution and A is seen as a set of coefficients, and (3) a linear transformation interpretation in which x is viewed as an input vector, b as an output vector, and A as the matrix that transforms x into b.

We argue these interpretations are helpful for making sense of students' reasoning, but that the framework may need to be modified or expanded to more fully account for student reasoning in the context of eigenvalues and eigenvectors. In the context of eigenvectors and eigenvalues, students need to coordinate a transformation interpretation with the equation $Ax = \lambda x$, where the matrix A transforms the vector x by stretching, shrinking, and/or reversing the direction of vector x. Additionally, students need to shift to a systems interpretation and consider when the equivalent system $(A - \lambda I)x = 0$ has a non-trivial solution in order to make sense of standard procedures for computing eigenvalues and eigenvectors.

Data Sources & Study Context

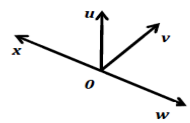
In previous work, we have developed an assessment aligned with the inquiry-oriented linear algebra (IOLA) instructional materials used in the TIMES project (Haider et al. 2016). This paper-and-pencil assessment consists of 9 items, most of which include an open-ended response component. The assessment was administered at the end of the semester, and students were allocated one hour to complete the assessment.

In this analysis, we examine assessment data from 126 students across six TIMES instructors and 129 students across three Non-TIMES instructors from different institutions in the US. Non-TIMES linear algebra instructors were selected from either the same institutions as TIMES instructors or a similar institution (e.g. preferably one from a similar geographic area, with similar size of student population, with similar acceptance rate) to collect assessment data for comparison of TIMES and Non-TIMES students. In this study, we focused on an in-depth analysis of students' reasoning on the assessment questions related to eigenvalues and eigenvectors. Both items are shown in Figure 1.

8. Is $\lambda = 2$ an eigenvalue of $\begin{bmatrix} 3 & 2 \\ 1 & 2 \end{bmatrix}$? Why or why not?

9. Suppose the vector x is a real-valued eigenvector of the matrix M and that the entries of M are also real-valued.

a. What could be the result of the product Mx? (Check all that apply.)



- ☐ i: Mx could be u
- ☐ ii: Mx could be v
- ☐ iii: Mx could be w
- ☐ iv: Mx could be $\mathbf{0}$
- ☐ v: Mx could be x
- ☐ vi: None of the above

b. Explain your reasoning for your choice(s) in part a.

Figure 1. Assessment items related to eigenvectors and eigenvalues[1]

The inquiry-oriented approach to learn eigenvalues and eigenvectors associated with this study is characterized in detail elsewhere (Zandieh, Wawro & Rasmussen, 2016).

Methods of Analysis

To answer our research questions, our analysis has two main components. The first component of our analysis is quantitative in nature, as we aim to compare learning outcomes of students whose instructors received TIMES instructional supports to those who did not. The second component of our analysis is qualitative in nature, as we work to identify students' ways of reasoning on both the more procedurally oriented assessment item (Q8) and the more conceptually oriented item (Q9). We follow Kwon, Rasmussen & Keene's (2005) approach for distinguishing assessment items that are conceptually oriented from those that are procedurally oriented. In particular we consider Q8 to be more procedurally oriented in that there is a commonly taught procedure that students can directly invoke (with some interpretations) to produce a correct answer to the question. There is no such standard procedure for Q9, so we consider it to be more conceptually oriented. In our qualitative analysis, we also look for similarities and differences that emerge from considering the two groups.

To facilitate our quantitative analysis, we needed to score students' responses to the two assessment items. Specifically, we needed to develop a uniform system for assigning a number of points to students' responses that provide an overall assessment of the quality of their response and the understanding reflected in that response. Question 9a required students to select which subset of 6 possible options were appropriate responses, so 1 point was awarded to each of the possible options for correctly selecting or not selecting that option. Both Question 8 and Question 9b were open ended response questions, and both of these were scored on a scale of 0 to 3 points. The condensed version of the grading scheme for assigning points to open ended response questions can be found in Appendix A. Additionally, Appendix A includes some explanation of

[1] Question 9 was retrieved from http://mathquest.carroll.edu and developed as part of an NSF-supported project entitled Project MathVote: Teaching Mathematics with Classroom Voting. For related research, see Cline, Zullo, Duncan, Stewart, & Snipes (2013).

how this grading scheme aligns with our coding categories for *how* students reasoned, which are described in greater detail below. Student work exemplifying common ways of reasoning with explanation of points awarded are provided in the findings section.

To ensure agreement regarding points assigned to each response, two researchers looked at every student's attempt and assigned a score independently before comparing with each other. If the two researchers assigned a different score to a particular student, they then discussed according to the codebook and agreed on a common score for that student. If both researchers disagreed about a particular score, then a third researcher was consulted to reach a consensus.

Once scores had been assigned to all student responses, descriptive statistics were generated to examine the overall performance of students on the eigenvalue and eigenvector questions and to compare TIMES students with Non-TIMES students for both questions. We were unable to control for factors such as students' mathematical background, major, and instructor's teaching experience, so this is an unavoidable limitation for our statistical analysis. However, we tried our best to choose TIMES and Non-TIMES students either from same school or from similar schools. This helps us establish similarity of students in TIMES and non-TIMES classrooms. Hence, we compared the mean scores of TIMES and Non-TIMES students using two-tailed t-tests to identify when differences of means were statistically significant.

In order to facilitate our qualitative analysis of students' reasoning, we examined student responses to the open-ended portions of question 8 and question 9. After examining the data several times and refining the categories of the students' reasoning about item 8, we sorted students' responses into 5 broad categories: (1) reasoning about the determinant, (2) reasoning about $A - \lambda I$ without computing a determinant, (3) other, (4) students who explicitly indicated they did not know, and (5) who left the item blank. Details about the categories are in Table 2.

In examining students' responses to question 9, we found it helpful to distinguish responses that were conceptually aligned with the formal definition for eigenvectors and eigenvalues from those that were not. We were specifically interested in student reasoning that appropriately coordinated interpretations of $A, x,$ and λ in the context of the matrix equation $Ax = \lambda x$. In particular, we say a student response "uses the eigen-concept" when there is evidence a student is coordinating $M, x,$ and λ in at least one of the following ways:

- Algebraically: The matrix M is a fixed matrix that transforms the (nonzero) eigenvector x in a particular way, namely such that the resulting vector Ax is a scalar multiple (λ) of x.
- Geometrically: this can be interpreted to mean that multiplying x by A has the effect of
    - stretching x in the same direction or opposite direction, or
    - causing the resultant vector to lie along the same line as the vector x.

If a student drew on a transformation interpretation to make sense of Ax but did not coordinate this appropriately with λx in one of the ways mentioned above, we did not say that the student's response used the eigen-concept.

We grouped students' responses to question 9 into five categories: (1) responses that used the eigen-concept, (2) responses that focused on the role of the matrix M in a way that did not use the eigen-concept, (3) other, (4) responses in which the student explicitly indicated he or she did not know, and (5) responses that were left blank. Details about the categories are in Table 3.

After coding students' responses to Q8 and Q9, we aggregated these responses into tables, organized by the category assigned to each response and number of points awarded. We also separated TIMES from Non-TIMES students in counting the number of responses in these discrete categories. This allowed us to look for patterns in which approaches were conceptually oriented, which approaches lent themselves to arriving at correct answers, and differences in approaches taken by TIMES and Non-TIMES students.

Findings

In order to answer our research question about how TIMES students compared to Non-TIMES students, we first present our quantitative analysis of students' performance on questions (Q8) and (Q9), separating students of TIMES instructors from students of Non-TIMES instructors. We then summarize findings from our coding of students' approaches to these same questions, providing examples of responses that highlight important trends in student reasoning.

Overview of differences in student performance

We highlight three central trends from our quantitative analysis. First, TIMES students outperformed Non-TIMES on both items, with a strongly significant difference of means on the conceptual item. Second, both TIMES and Non-TIMES students did better on the procedurally oriented item than on the conceptually oriented item. Third, correlations between students' performance on both the conceptual and procedural items were weak for students in both groups, suggesting that the two items assessed relatively different aspects of student understanding. Note that the last trend is not part of answering our research questions, it is more of a side observation that emerged from our quantitative analysis and what we take it to mean.

To compare the performance of TIMES students with Non-TIMES students, we first computed the mean and standard deviation for question 8, question 9a and 9b. To make a 'cleaner' comparison, we have separately included the mean and standard deviation of part a and part b of question 9. We also compared question 8 with question 9b as they are naturally comparable items.

The data presented in Table 1 showed that on the procedurally oriented question (Q8) the mean score of TIMES students was greater than that of Non-TIMES students, but this difference of means was not statistically significant with the available sample size. Similarly, there was not a statistically significant difference in means on question 9a. However, in comparing the performance of students in both groups on question 9b, we noticed that TIMES students performed significantly better than the Non-TIMES students. The results of t-test indicated that this difference of means was statistically meaningful. In this way, TIMES students outperformed Non-TIMES students on the conceptually oriented question.

Question	All Students	TIMES Students	Non-TIMES Students	p-value (two-tailed)
Q 8 3 Points	Mean: 1.85 SD: 1.31	Mean: 1.98 SD: 1.24	Mean: 1.71 SD: 1.37	$t(125) = 1.73$ $p = .08 > .05$
Q 9 (part a only) 6 Points	Mean: 3.73 SD: 1.68	Mean: 3.74 SD: 1.76	Mean: 3.71 SD: 1.61	$t(249) = 0.56$ $p = .88 > .05$
Q 9 (part b only) 3 Points	Mean: 0.79 SD: 1.03	Mean: 1.05 SD: 1.12	Mean: 0.54 SD: 0.86	$t(125) = 4.29$ $p < 0.001$

Table 1: Summary of results of quantitative analysis

Overall, students performed better on the procedurally oriented question (Q8) than the conceptually oriented question (Q9). We compared Q8 to Q9b and found that the difference of means for all students between Q8 and Q9b was also statistically meaningful with p-value (two-tailed) less than 0.001.

Since both problems we investigated in this study were related to eigenvectors and eigenvalues, one might think that students' performance on the two items should be correlated. However, quantitative analysis revealed a positive but weak correlation between students' performance on the two questions, the Pearson correlation coefficient r = 0.30 for all students. Recall that a correlation coefficient measures the degree of relationship between two variables and ranges from -1 to 1, where the sign indicates the direction of the relationship and the distance from zero indicates the strength of the relationship (e.g. 1 means the two variables are highly correlated and 0 means there is very little or no correlation between the two variables). For TIMES students, the correlation between the two items was r = 0.36 as compared to the correlation for Non-TIMES which was r = 0.22. This suggests two things: first, that the two items measure *different* aspects of student understanding of eigenvalues and eigenvectors. Second, it shows that performance on the procedurally and conceptually oriented questions was more highly correlated for TIMES students.

Trends in student reasoning on procedurally oriented question (Q8)

In this section, we provide our qualitative analysis of question 8. In particular, we highlight two common approaches to this problem: approaches that involve reasoning about the determinant, and approaches that involve reasoning about $A - \lambda I$ without computing a determinant. The majority of students who reasoned about the determinant responded correctly. Reasoning about $A - \lambda I$ was a less common approach but more frequently observed among TIMES students. Further, we argue that students who reasoned about $A - \lambda I$ showed more evidence of conceptual understanding. A summary of our coding and scoring of student responses is shown in Table 2.

Reasoning about the determinant was the most common approach observed in students' responses to question 8, and students who used this kind of approach tended to do so without making conceptual errors;[2] 146 out of 255 students (57% of all students). We note two interesting trends within those who used this approach distinguishing TIMES from Non-TIMES students. First, more TIMES students using this approach made computational errors (usually when factoring the characteristic polynomial) than did Non-TIMES students – such errors are evidenced by 2 point responses in our coding. On the other hand, fewer TIMES students using this approach made *conceptual* errors than did Non-TIMES students – such errors are evidenced by 1 point responses in our coding. In the TIMES instructional approach (previously described under study context), the standard algorithm for finding eigenvalues and eigenvectors is intended to emerge in relation to student-invented strategies on the third of fourth day of instruction in the unit, so we conjecture Non-TIMES students may have spent more time practicing this procedure in comparison to TIMES students.

---

[2] We align our conceptions of conceptual and procedural errors with our definitions for conceptual and procedural understanding. We refer to an error as conceptual when there is evidence that a student does not understand an important underlying idea or relationship. We refer to an error as procedural when a student incorrectly performs a step in a mathematical process that is not central to the idea being assessed (e.g. an error in computation or algebraic manipulation). Examples of conceptual errors include incorrectly interpreting the value of the determinant to decide if something is an eigenvalue, or computing the determinant of A rather than the determinant of $A - \lambda I$. Examples of procedural errors include incorrectly factoring the characteristic polynomial or making an error when row reducing $A - \lambda I$.

A less common approach to solve problem 8 was by reasoning about $A - \lambda I$ without computing a determinant. Overall, 48 out of 255 students (19%) used such determinant-free approach to solve the problem. This approach was more common among TIMES than Non-TIMES students, and far more TIMES students successfully responded to the problem in this way with no or few conceptual errors. Indeed, 70% (19 out of 27) of TIMES students and only 38% (8 out of 21) Non-TIMES students who used this approach did so with minimal conceptual errors.

		TIMES, n = 126				Non-TIMES, n = 129

Table 2: Summary of Students' Approaches and Scores on Q8

Students whose responses were categorized as "other" showed little or no evidence of understanding related to the definition or computation of eigenvectors and eigenvalues. We noticed that twice as many Non-TIMES students as TIMES students gave a response categorized as 'other.' However, TIMES and Non-TIMES students left the item blank at similar rates, but a larger number of Non-TIMES students explicitly mentioned that they "don't know".

Examples of student reasoning about Q8

In this section, we examine examples of common approaches identified in our analysis of students' responses to question 8. We provide one example response coded as 'reasoning about the determinant.' and one example responses coded as 'reasoning about $A - \lambda I$ without using the determinant.' We highlight the use of multiple representations in these responses, and connections between these representations and the formal definition of eigenvectors and eigenvalues.

Response 2.a. was awarded full points because the student correctly found the roots of the characteristic polynomial, noted that 2 was not one of those roots, and concluded that 2 is not an eigenvalue.

We note that in response 2.b., the student began with the equation $Ax = \lambda x$, rewrote this as $Ax - \lambda x = 0$, and then factored this to write $(A - \lambda I)x = 0$. The student then computed the

	2.a. Response awarded three points	2.b. Response awarded three points

Figure 2: Responses to Q8 coded as "reasoning about the determinant"

entries of the matrix $A - 2I$, rewrote this as a homogeneous matrix equation which he or she translated into a system of equations, correctly solved, and correctly concluded that because the solution is the zero vector that 2 **is not** an eigenvalue of the given matrix.

Trends in student reasoning on conceptually oriented question (Q9b)

We now focus on responses to question 9. Overall, students' responses to this item were split relatively evenly among responses that used the eigen-concept, responses that focused on the role of the matrix M without using the eigen-concept, and students who wrote that they did not know or left the answer blank. However, TIMES students' responses used the eigen-concept at much higher rates than Non-TIMES students, and with greater success. See Table 3.

The most commonly observed response to Q9 involved using the eigen-concept, with 99 out of 255 (39%) total responses coded in this way. This approach was more common among TIMES students than Non-TIMES students (61/126 vs 38/129). Further, TIMES students who used this approach gave correct responses to the question at higher rate than Non-TIMES students; the ratio of TIMES students who used the eigen-concept in fully or mostly correct ways to those who used the eigen-concept in mostly incorrect ways was 44:17 whereas that ratio for Non-TIMES students is 18:20.

The second most commonly observed trend on Q9 involved responses that focused on the role of the matrix M without using the eigen-concept. We noted that students using this approach tended to be mostly or completely incorrect, and that more Non-TIMES students than TIMES students used this approach (29/126 TIMES as compared to 40/129 Non-TIMES students). We noticed that 14/29 (48%) of the TIMES students and 12/40 (30%) Non-TIMES students used this approach did so with some conceptual understanding but not using the eigen-concept. We argue these responses indicated some conceptual understanding because they drew on appropriate transformation interpretation of a matrix times a vector. However, the understanding reflected in these responses was incomplete in that the interpretation did not explicitly use the eigen-concept by coordinating that interpretation with the result of that multiplication also corresponding to a scalar times that same vector.

		TIMES, n = 126				Non-TIMES, n = 129			
		3 pts	2 pts	1 pts	0 pts	3 pts	2 pts	1 pts	0 pts
Responses using the eigen-concept Times: 61 Non-Times: 38	$Mx = \lambda x$ with explanations	9	14	4	0	5	3	2	0
	• Stretching • Same direction • Scalar multiple • Same line as x	10	11	12	1	2	8	16	2

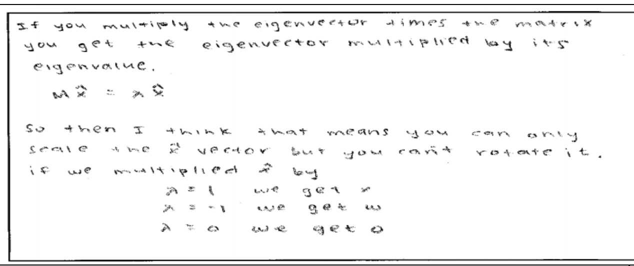
Responses focusing on the role of the matrix M without using the eigen-concept Times: 29 Non-Times: 40	Specific entries are suggested for matrix M that would yield different outputs	0	0	12	8	0	0	11	15
	Descriptions are given about how the matrix M transforms the input vector to yield different outputs (without suggesting specific entries of M)	0	0	2	7	0	0	1	13
Others		0	0	0	11	0	0	0	15
I don't know		0	0	0	10	0	0	0	11
Blank		0	0	0	17	0	0	0	25

Table 3: Summary of Students' Approaches and Scores on Item 9

There was little difference between TIMES and Non-TIMES Students who used approaches classified as 'other.' In this category, we saw no evidence of using the eigen-concept. TIMES and Non-TIMES students said they "Don't know" at similar rates, but more Non-TIMES students left the item blank than TIMES students.

Examples of student reasoning about Q9

We provide examples of common approaches identified in our analysis of students' responses to question 9. Specifically, we provide two example of responses coded as "using the eigen-concept" and two example responses coded as "focus on the role of the matrix M without using the eigen-oncept." Response 4.a. used the eigen-concept by writing the equation $Mx = \lambda x$ and suggesting values of λ (e.g. 1,-1,0) that corresponded appropriately to possible outputs. It was awarded full credit because the student linked this reasoning to all three possible outputs. Responses 4.b. used the eigen-concept in a slightly different way than the previous example. Rather than writing $Mx = \lambda x$ and suggesting appropriate values of λ, this student justified selections of correct output vectors by describing the role of M as stretching the vector x by a factor or in its direction. It was awarded just 2 points due to the omission of the 0 vector. Many students in our study who used the eigen-concept omitted the 0 vector as a possible eigenvector.



If you multiply the eigenvector times the matrix you get the eigenvector multiplied by its eigenvalue.

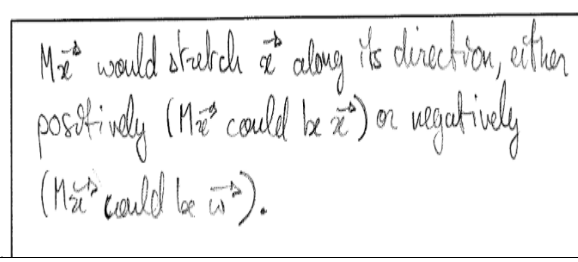
$M\hat{x} = \lambda\hat{x}$

So then I think that means you can only scale the $\hat{x}$ vector but you can't rotate it. if we multiplied $\hat{x}$ by

$\lambda = 1$ we get x

$\lambda = -1$ we get w

$\lambda = 0$ we get 0



$M\vec{x}$ would stretch $\vec{x}$ along its direction, either positively ($M\vec{x}$ could be $\vec{x}$) or negatively ($M\vec{x}$ could be $\vec{w}$).

4.a. Response awarded three points	4.b. Responses awarded two points

Figure 4: Responses to Q9 coded as using the eigen-concept

The next two examples presented in Figure 5 responses focus on the role of the matrix M as a transformation that can transform the vector x in many ways (not limiting to outputs that must lie along the same line as x). Student 5.a.'s response suggests that the student sees the matrix M not as a fixed matrix that transforms the eigenvector in a particular way; the student suggested different matrices that correctly produced the output vectors he/she selected – he/she considered M as the identity matrix I to produce x, $-I$ to produce w and the zero matrix to produce the zero vector. In addition, a matrix M with generic entries also was suggested as a transformation that can transform x into the other two incorrect vectors u and v.

$\begin{bmatrix}1&0\\0&1\end{bmatrix}\begin{bmatrix}x\\y\end{bmatrix}=\vec{x}$ $\quad\begin{bmatrix}a&b\\c&d\end{bmatrix}\begin{bmatrix}x\\y\end{bmatrix}=\vec{u},\vec{v}$ $\begin{bmatrix}0&0\\0&0\end{bmatrix}\begin{bmatrix}x\\y\end{bmatrix}=0$ $\begin{bmatrix}1&0\\0&-1\end{bmatrix}\begin{bmatrix}x\\y\end{bmatrix}=\vec{w}$ x is a real valued eigenvector & M is a matrix and matrix m could transform $\vec{x}$ into anything $0, \vec{w}, \vec{u}, \vec{v}$ given the right 'm'.	The matrix M could rotate X to either u or v. It could also stretch reflect it to be w. And it could also be the identity matrix to give back X.
5.a. Response awarded one point	5.b. Response awarded one point

Figure 5: Responses to Q9 focused on the role of M without using the eigen-concept

Response 5.b. similarly focuses on the role of the matrix M, arguing it could rotate x to produce u or v, "stretch reflect" to produce w, and that it could be the identity matrix to "give back" x. This combination of what the student believes the matrix could be indicates that the student did not use the eigen-concept. Responses 5.a. and 5.b. were both awarded 1 point because both were interpreting the matrix M as a transformation and making some true statements, though in ways that did not use the eigen-concept.

Discussion

We see this paper contributing to the literature in three primary ways. First, we document the effectiveness of a particular instructional approach that is detailed in the literature (see Zandieh, Wawro, and Rasmussen, 2016; Plaxco, Wawro, & Zandieh, this volume). Second, we document aspects of students' reasoning about eigenvectors and eigenvalues (including how students draw on a transformation interpretation in ways that do and do not use the eigen-concept). Finally, we consider and discuss links between conceptual and procedural understandings of eigenvectors and eigenvalues documented in our study.

Our findings presented above are consistent with findings of previous studies examining student learning outcomes in inquiry-oriented instructional settings at the undergraduate level (e.g., Kwon, Rasmussen, & Allen, 2005), though we are excited that this study was conducted on a larger scale involving instructors not involved in the development of the curricular materials. These findings also are consistent with a broader body of literature documenting the benefits of student-centered approaches to learning in undergraduate mathematics (Freeman et al., 2014). We conclude our paper with a discussion of the kinds of conceptual understandings observed in our analysis, and the insights these offer into what is entailed in a conceptual understanding of eigenvectors and eigenvalues.

As mentioned in our theoretical framework, conceptual understanding has been broadly defined by some in terms of the richness of connections among ideas (Vinner, 1997; Hiebert & Lafevre, 1986). More recently, Star (2005) has argued that conceptions of conceptual and procedural knowledge in mathematics education are under-articulated in a way that promotes ideological rather than empirical examination, and relationships between conceptual and procedural understandings merit greater examination. With this in mind, we now reflect on the kinds of conceptual understandings observed in our analysis, and discuss three different kinds of connections we consider to be important aspects of students' conceptual understanding of eigenvectors and eigenvalues.

First, we consider the use of appropriate interpretations of a matrix times a vector to be an important aspect of students' understanding of eigenvalues and eigenvectors. On the conceptually oriented question (Q9), this involved drawing on a transformation interpretation as characterized by Larson & Zandieh (2013). In our data, many students showed evidence of interpreting Mx, the product of a matrix M and its eigenvector $x,$ in ways that use the eigen-concept. A smaller number of students interpreted Mx with a transformation lens, but in a way that did not use the eigen-concept.

This leads to our second aspect of students' understanding of eigenvalues and eigenvectors: using the eigen-concept in the context of finding eigenvalues. Relatively few showed evidence of using the eigen-concept on the procedurally oriented question by reasoning about $A - \lambda I$ without taking the determinant. We argue this approach provided more evidence of conceptual understanding: providing and converting between multiple representations (e.g. $Ax = \lambda x$ and $(A - \lambda I)x = 0$, written as matrix equations and systems of equations), linking those representations to the eigen-concept, and offering reasons for their conclusion in terms of a matrix equation or system of equations in their response. It is possible that a student who used the standard procedure to determine if 2 is an eigenvalue on this problem also had a deep conceptual understanding of how and why that procedure works; it is also possible that a student who used the standard procedure knew this procedure only as a sequence of steps to be executed without knowing how or why the procedure worked. Further work is needed to tease out this distinction.

This leads to the final aspect of conceptual understanding of eigenvectors and eigenvalues relevant to our analysis, which includes coordinating with the Invertible Matrix Theorem (IMT). A standard procedure for finding eigenvalues and eigenvectors draws on the argument that $Ax = \lambda x$ has a non-trivial solution x for some scalar λ if and only if $(A - \lambda I)x = 0$; one can argue through the IMT that this happens when $\det(A - \lambda I) = 0$. Among students who did not use the determinant in their response to the procedurally oriented question, there was a need to draw on equivalent ideas from the invertible matrix theorem. In these responses, we observed students noting and leveraging the following relationships:

- $(A - \lambda I)$ is invertible if and only if $(A - \lambda I)x = 0$ has a trivial solution. If $(A - \lambda I)x = 0$ has only the trivial solution, then λ is <u>not</u> an eigenvalue of the matrix A.
- If the columns of $A - \lambda I$ are linearly dependent or one column is a scalar multiple of the other (in the case of a 2x2 matrix), then $(A - \lambda I)x = 0$ has nontrivial solution so λ is an eigenvalue of the matrix A.
- If $rref(A - \lambda I)$ has no free variable then $(A - \lambda I)x = 0$ has only the trivial solution, which means λ is not an eigenvalue of the matrix A.

We argue that these kinds of responses from students who did not use the previously mentioned standard procedure offer insight into conceptual connections that are both important and potentially natural for students to make as they come to make sense of standard algorithms.

Overall, students in our study correctly solved a procedural question related to eigenvalues (as in Q8) at about twice the rate they offered an appropriate conceptual understanding of $Ax = \lambda x$ (as in Q9). This suggests there is a disconnect between students' understanding of standard procedures for finding eigenvalues and the formal definition of an eigenvector and eigenvalue, and that students are more able to execute the standard procedure than draw a conceptual understanding aligned with the formal definition. This points to a need to push students to think more about core understandings as they connect to procedures rather than just assess students' ability to execute standard procedures. Indeed, many connections are needed to explain why a standard procedure for finding eigenvalues and eigenvectors works and how it connects to the formal definition of eigenvalues and eigenvectors. However, we argue that there is little value in being able to compute eigenvectors and eigenvalues without being able to appropriately interpret the meaning of the result of such computations. The inquiry-oriented approach of the IOLA instructional materials taken up by instructors who received TIMES instructional supports appears to be a promising way of beginning to address this issue, but more work is needed to better understand the ways in which students come to develop and coordinate the interpretations needed for a robust understanding of eigenvectors and eigenvalues.

Appendix A: Grading scheme for assigning points to open-ended response questions 8 and 9b

Q #	Points Awarded and Criteria
8	3 points: Method 1: Full points were awarded to students who reasoned about the determinant to arrive at the correct conclusion without making computational or conceptual errors. Examples of this kind of reasoning are shown below. i) $\det(A-\lambda I)=0$ implies $(\lambda-1)(\lambda-4)=0$ implies $\lambda=1$ or $\lambda=4$ implies $\lambda=2$ is not an eigenvalue for the matrix A. ii) $\det(A-2I)=-2\neq 0$ implies $\lambda=2$ is not an eigenvalue for the matrix A. iii) $\det(A-\lambda I)=\begin{vmatrix}3-\lambda & 2\\ 1 & 2-\lambda\end{vmatrix}=(3-\lambda)(2-\lambda)-2=\lambda^2-5\lambda+4$. Substituting 2 in the characteristic equation gives $4-10+4=-2$ implies $\lambda=2$ is not an eigenvalue for the matrix A. Method 2: Full points were awarded to students who reasoned about $A-\lambda I$ without using the determinant to arrive at the correct conclusion without making any computational or conceptual errors. Examples are shown below. i) $(A-2I)\begin{bmatrix}x\\ y\end{bmatrix}=0$ implies $x=0$ and $y=0$ which is the trivial solution, so $\lambda=2$ is not an eigenvector for the matrix A. ii) $(A-2I)\cong\begin{bmatrix}1 & 0\\ 0 & -2\end{bmatrix}$, and the column vectors of this matrix are not linearly dependent, so $\lambda=2$ is not an eigenvalue. iii) $rref(A-2I)$ does not have a free variable, so $\lambda=2$ is not an eigenvalue iv) The first column of $(A-2I)$ is not a scalar multiple of the second column
	2 points: Two points were awarded to students to students who take a conceptually correct approach (either by reasoning about the determinant or by reasoning about $A-\lambda I$ without using the determinant) but either • made a computational error (e.g. factoring the characteristic polynomial incorrectly) or • did not offer a clear conclusion about whether 2 is an eigenvalue or not, or • arrived at the correct conclusion without a full explanation of why
	1 point: One point was awarded to students whose response included some evidence of conceptual understanding, but who made a conceptual error (which might be accompanied by a computational error).
	0 points: No points were awarded to students who left the page blank, or whose response: (i) gave no evidence of conceptual understanding, or (ii) said something like "I don't know." Example of responses we considered to include no evidence of conceptual understanding are "Yes, because $A=PDP^{-1}$" and "I say it is… because… there are 2's in the problem."
9b	3 points: Three points were awarded to students whose response appropriately coordinated with the eigen-concept, referenced (either by directly naming or by explicitly referring to their work shown in 9a) all three correct vectors and provided a correct rationale for this selection.
	2 points: Two points were awarded to students whose response provided at least two correct explanations (e.g. $Mx=\lambda x$ is written and student writes that "an eigenvector tells you the direction of stretching") but did not identify and explicitly describe what happens to all three correct vectors.
	1 point: One point was awarded to students who either i) Provided one correct explanation (e.g. by either writing "$Mx=\lambda x$" or "an eigenvector tells you the direction of stretching") and explicitly connected this explanation to at most one correctly selected vector ii) Suggested components of M that would transform x into one of the given choices, such as $M=I, -I, or\ 0$.
	0 point: No points were awarded to responses that do not coordinate with the eigen-concept, do not suggest components of M that would transform x into one of the given choices, says I don't know, or leaves the page blank. An example of student response to question 9 which was awarded 0 point was "all are the same size."

Students' Understanding of Test Statistics in Hypothesis Testing

Hypothesis testing is a key concept included in many introductory statistics courses. Yet, due to common misunderstandings of both scientists and students, the use of hypothesis testing to interpret experimental data has received criticism. With statistics education on the rise as well as an increasing number of students enrolling in introductory statistics courses each year, there is a need for research that investigates students' understanding and curriculum effectiveness of hypothesis testing. This paper describes results obtained from a larger study designed to explore introductory statistics students' understanding of one sample hypothesis testing. In particular, this paper explores students' understanding of test statistic as a component of hypothesis testing. APOS Theory is used as a guiding theoretical framework. This paper focuses on three students' understandings of test statistic when performing hypothesis tests on real world data.

Key Words: Hypothesis Testing, Statistics, Test Statistic

Introduction

The use of statistics is crucial for numerous fields, such as business, medicine, education, and psychology. Due to its importance, according to the *Guidelines for Assessment and Instruction in Statistics Education College Report*, more students are studying statistics, and at an increasingly younger age (GAISE College Report ASA Revision Committee, 2016). In the United States today, the *Common Core State Standards for Mathematics* calls for students to "understand statistics as a process for making inferences about population parameters based on a random sample from that population" (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010, p. 81). More recently, the *GAISE College Report* calls for nine goals for students in introductory statistics courses, including "Students should demonstrate an understanding of, and ability to use, basic ideas of statistical inference, both hypothesis tests and interval estimation, in a variety of settings" (GAISE College Report ASA Revision Committee, 2016, p. 8). In other words, in an introductory statistics course, students should understand and be able to apply hypothesis testing in various situations.

Hypothesis testing is an important tool of statistical inference (Krishnan & Idris, 2015). However, the use of hypothesis testing to interpret experimental data has received criticism (Nickerson, 2000; Nuzzo, 2014) due to the common misunderstandings of both scientists and students when using this method (Batanero, 2000; Dolor & Noll, 2015; Vallecillos, 2000). Rather than abandon the inference method entirely, researchers have called for improving the education and understanding of hypothesis testing. For example, LeMire (2010) developed a framework to revise and improve instructional content on hypothesis testing. Even still, there are few studies on student understanding of hypothesis testing as a whole (Smith, 2008). Our larger research goal is to supplement these efforts by first analyzing how students come to understand hypothesis testing and then develop instructional materials to cultivate this understanding. What follows is a brief summary of the literature on student understanding of hypothesis testing.

Literature Review

Research suggests that although students are able to perform the procedures surrounding hypothesis testing, students lack a strong understanding of the concepts and their use (Smith, 2008). It is suggested that hypothesis testing and the area of inferences "is probably the most misunderstood, confused and abused of all statistical topics" (Batanero et al., 1994, p. 541). Textbooks and instructors often give a specific step-by-step script to follow when performing hypothesis testing, not connecting or allowing the students to see the idea as a whole. Link (2002) suggested this practice as a six-part procedure, which leads many students to look for key words and phrases as guides when solving hypothesis testing problems. He also found evidence that supports the belief that students can correctly substitute values into a formula selected from a formula sheet, yet they do not have a full understanding of hypothesis testing in its entirety.

In an attempt to move away from a procedural approach, and due to the rise of statistical education, calls for reform have led to a shift from an emphasis on procedural understanding to conceptual understanding (GAISE College Report ASA Revision Committee, 2016; Krishnan & Idris, 2015). Ways to teach for conceptual understanding have been varied. For example, Hong & O'Neil (1992) suggested that to foster this conceptual understanding in hypothesis testing, conceptual instruction should be presented prior to the procedural instruction with emphasis on the use of diagrammatic problem representations. In contrast, Chandrakantha (2014) suggested that utilizing technology that allows students to visualize and work hands-on with data will enhance student understanding of concepts such as hypothesis testing.

Other research focuses on identifying students' misconceptions with various parts of hypothesis testing in order to improve conceptual understanding. Specifically in introductory statistics courses, students appear to experience a "symbol shock" (Schuyten, 1990), which provides an obstacle for students interpreting particular questions (Dolor & Noll, 2015; Lui & Thompson, 2005; Vallecillos, 2000). Vallecillos (2000) found that students have trouble with not only the symbols, but also with the formal language and meaning behind the concepts involved in hypothesis testing, including words such as 'null' and 'alternative' hypothesis. Students interviewed were not able to accurately describe what these terms mean and how they impact the decision to either accept or reject within the test (Vallecillos, 2000). Furthermore, Williams (1997) during two different interviews with 18 students, found that the term 'significance' was not well understood. Students gave vague and inadequate descriptions of what 'significance' means in the context of hypothesis testing. Even after the final exam, students continued to confuse terminology and still had a poor understanding of the concept. Mathematical symbolism presents challenges across all levels (Rubenstein, 2008), especially as most students' school mathematics experiences give little or no attention to the idea of reading mathematics as a language (Adams, 2003).

With statistics education reform on the rise, as well as an increasing number of students enrolling in introductory statistics courses each year, there is a need for research that investigates students' understanding and curriculum effectiveness of hypothesis testing, a concept taught in almost every introductory statistics course (GAISE College Report ASA Revision Committee, 2016; Krishnan & Idris, 2015). Literature in this area focuses on students' lack of understanding of hypothesis testing, ways to teach for conceptual understanding of hypothesis testing, and misconceptions with various parts of hypothesis testing. Particular parts of hypothesis testing that have received the most attention in literature are hypotheses and p-value. Test statistics contribute to understanding a p-value, but there is a lack of literature on this concept (Smith, 2008). Thus, we focus our attention on the following research question:

> What are students' understandings of test statistic, as a component of hypothesis testing as a whole, in two distinguished real world situations?

The next section will introduce test statistics within the scope of one-proportion hypothesis testing.

Test Statistic

A test statistic, according to the textbook *Elementary Statistics Using Excel*, is "a value used in making decisions about the null hypothesis," (Triola, 2014, p. 415). While the definition provided is simplistic, the actual concept of test statistic in hypothesis testing is complex. Assuming the null hypothesis is true, a test statistic is found by converting a sample statistic, such as a sample proportion or a sample mean, to a standardized score. Although we discuss test statistic as one mathematical term or value, there is a distinction between test statistics calculated from sample proportions versus sample means. Specifically, in our study, the distinction is between the normal distribution and the Student's t distribution.

When calculating a test statistic for a sample representing a population mean or proportion, we are referring to a standardized value that represents the extremeness of a sample in regards to what is expected. For proportions, students use the normal distribution as an approximation to the binomial distribution, and thus calculate test statistics, which are z-scores. For means, students learn about test statistics in hypothesis testing using the normal distribution (z-scores) and the Student's t distribution (t-scores). Although these distributions appear similar, the distinction occurs depending on what we know about our sample. In particular, if we know the population standard deviation, then we know the center, shape, and spread of the data, and can use the normal distribution (z-scores). However, if the population standard deviation is unknown and we only have the sample standard deviation as an estimate, then we can use the Student's t distribution to represent the center, shape and spread of the data. Because of the greater variability associated with smaller sample sizes, t-scores are greater than or equal to z-scores for the same value of n, but as n approaches infinity, the limiting value of the Student's t distribution is the normal distribution (see Figure 1).

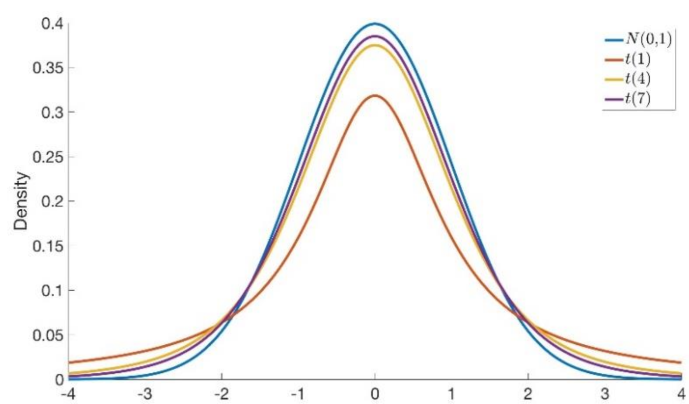

Figure 1. Graphical Representation of Normal Distribution and Student's t Distribution
(Note: key represents $t(n)$, where n is the sample size)

Theoretical Framework

A theoretical framework is necessary in order to analyze and describe how students understand a particular concept. The guiding theoretical framework for our larger study is APOS Theory (Asiala et al., 1996). APOS Theory is a framework which models an individual's mathematical conception using Actions, Processes, Objects, and Schema. An Action is an externally driven transformation of a mathematical object (or objects). An Action can be described as an individual needing an external cue to complete a task, such as a step-by-step example to follow. For our study, in the context of test statistic, an example of this would be a student calculates the test statistic by the correct formula (even with wrong distribution label), but cannot interpret the test statistic verbally or graphically. Another example, in the context of test statistic, would be a student who uses key words or phrases from the problem as external cues to decide which formula to use to calculate the test statistic.

Once Actions are repeated and reflected on, an individual can start to interiorize them to become a Process. A Process no longer requires step-by-step external cues. An individual is now able to internally imagine the steps in a transformation, without having to actually perform them for specific examples. In the context of test statistic, an example would be a student calculates test statistic by using the correct formula (even with wrong distribution label) and describes their calculations in general terms. Although the student can calculate the test statistic, they do not have to perform the steps in order to describe the calculations. Another example would be a student who interprets the test statistic verbally or graphically by describing how it corresponds to $\hat{p}$ or $\bar{x}$ or the distance from the sample value to the expected value ($\hat{p}$ to p or $\bar{x}$ to μ).

When an individual is then able to see the Process as a totality, is aware that transformations can be applied to it, then the Process has been encapsulated into an Object. In the context of test statistic, several examples of this are as follows: a student describes the test statistic as an input of a function that determines the p-value; student interprets test statistic graphically as determining the edge of the region whose area is the p-value; or student describes the test statistic as large or small in comparison to a "usual" value of a test statistic (not just describing the number as large or small in general). As defined by the textbook, a "usual" value of a test statistic refers to z-scores between -2 and 2 (Triola, 2014).

Schemas are "structures that contain the descriptions, organization, and exemplifications of the mental structures that an individual has constructed regarding a mathematical concept" (Arnon et al., 2014, p. 25). Schemas may also be included within another Schema. For example, the distribution schema plays a role in the development of the schema of test statistic. This report is devoted to providing examples of Action and Process conceptions of test statistic from a sample of student interviews conducted for a larger study.

Methodology

The focus of our study is on university students who are enrolled in an introductory statistics course based on the emporium model. The emporium model, originated at Virginia Tech, includes key components of "interactive computer software, personalized on-demand assistance, and mandatory student participation" (Twig, 2011, p. 26). For this particular institution, each week students were required to spend three academic hours in a computerized mathematics lab, as well as attend one academic hour class each week with an instructor. The time in the mathematics lab was spent actively learning using the mathematical software *MyStatLab* by Pearson. Students also read, viewed videos, and discussed material with peers, lab assistants, and instructors.

Relevant data was collected during Fall 2014 and Spring 2015. All students enrolled in six sections of an introductory statistics course (approximately 240 students) were invited to participate in a problem solving session and semi-structured interview pertaining to hypothesis testing. Twelve students volunteered to participate. During the problem solving sessions, each participant worked alone on two hypothesis test questions. They were allowed to use Excel when needed since the use of it was required as part of the class. The first question asked the student to conduct and interpret a hypothesis test for a single population proportion. The second question asked the student to conduct and interpret a hypothesis test for a single population mean. The questions were as follows:

1. In a recent poll of 750 randomly selected adults, 588 said that it is morally wrong to not report all income on tax returns. Use a 0.05 significance level to test the claim that 70% of adults say that it is morally wrong to not report all income on tax returns. Use the *P*-value method. Use the normal distribution as an approximation of the binomial distribution.
2. Assume that a simple random sample has been selected from a normally distributed population and test the given claim. In a manual on how to have a number one song, it is stated that a song must be no longer than 210 seconds. A simple random sample of 40 current hit songs results in a mean length of 231.8 seconds and a standard deviation of 53.5 seconds. Use a 0.05 significance level to test the claim that the sample is from a population of songs with a mean greater than 210 seconds.

Students had seen these exact questions with variable parameters on their homework and quizzes when using the *MyStatLab* software. Students also engaged in active learning associated with these concepts both in the lab and in class. Thus, students were expected to know how to conduct and interpret hypothesis tests for both questions, and in particular, they were expected to know to use the normal distribution to find the test statistic for Question 1 and the Student's t distribution to find the test statistic for Question 2. In other words, they were expected to know the procedure.

Immediately following the problem solving sessions, the students participated in semi-structured interviews. There were ten interviews, eight with one participant each and two with two participants each (12 students in total). During the semi-structured interviews, participants were asked to elaborate on their answers and thought processes. The interviews were conducted and divided among multiple members of the research team. To standardize the interviews, an interview protocol was developed beforehand. The relevant data for this paper consists of participants' written work, Microsoft Excel files, and transcribed discussion from the follow up interviews.

Data analysis took place after all interviews were conducted. The recordings of the interviews were distributed and transcribed by each of the six members of the research team. After transcriptions were completed, analysis was organized in a way so that each transcript was reviewed by two different pairs of researchers. The data was coded and analyzed according to APOS Theory. After codes were developed and agreed upon by each pair of researchers, the team came together for discussion as a whole. Six concepts of hypothesis testing emerged in participants' reasoning. This paper focuses on one of these six concepts, test statistic. The data and codes were then used to develop individual learning trajectories for each participant that merely served as a method to explore and organize the ways of understanding of each concept for this group of individuals. The focus of this paper will be on the individual learning trajectories for test statistic.

Results

In this section, we illustrate examples from the data analysis that are most relevant and indicative of the Action and Process conceptions of test statistic according to APOS Theory. Our results will focus on three students: Haley, Lana, and Steve. Each student was representative of different subgroups of the twelve learning trajectories, and exhibited different conceptions of test statistic.

Haley

Haley demonstrated evidence of an Action conception of test statistic. For both questions, Haley looked for indicator phrases to identify which test statistic formula to use. She identified that a problem about proportions implies that the test statistic will be a *z*-score. Haley also mentioned that if in a problem she is not given the population standard deviation, this indicates when she would use a *t*-score.

I: Okay, and um is this a t-score or a z-score?
H: This is a z… yeah this is a z-score.
I: And how did you know that?
H: Because we're using proportions so you just use z.
I: Okay, good. Um, and then when would you use a t-score?
H: When you don't know the.. like when you don't know the um… what is it? You don't know… when you don't know this [draws sigma on the paper].
I: Okay!
H: But like you know it for a sample! [laughs]
I: So this is.. so.. I know that this is referring to the standard deviation right?
H: Yeah.
I: So and you said if you know the sample… so I'm assuming you're saying this is not the sample standard deviation?
H: No, that's the population. So if you don't know the population standard deviation I should use t.

Haley appeared to base her ideas of which test statistic to use off of key words found in the problems. When calculating the test statistic, Haley again looked for indicator phrases in the problem to identify the values to plug in. She also goes on later in the interview to state that she has memorized the formulas for test statistics.

I: Okay, then for the test statistic… how did you figure out all those numbers and stuff?
H: Well, I took the [yawn] I took x bar minus mu and then I divided it by the standard deviation divided by the square root of n.
I: Okay and did you just find that formula on the sheet or did you have that one memorized?
H: I had it memorized.

As more evidence of a lack of full understanding of what a test statistic represents, for the second problem, she identified the given sample mean in addition to her test statistic in different places on her graph when in actuality the test statistic is representative of the sample mean.

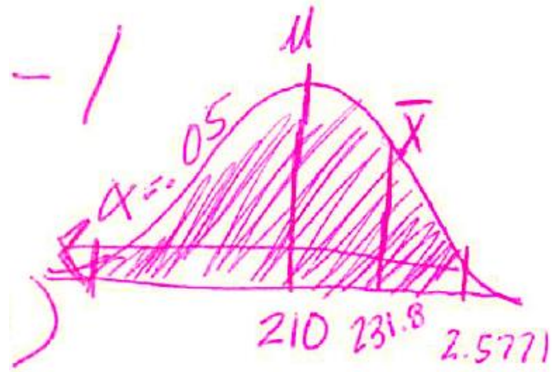

Figure 2. Haley's Graphical Representation of Question 2

Her memorization of formulas and what appears to be dependency on key words in the problem to identify which test statistic to use and what values to plug in, with no verbal explanation of the reasoning behind this, suggests Haley illustrates an Action conception of test statistic.

Lana

Lana exhibited evidence of a Process conception of test statistic. Lana, for Question 1, used the normal distribution to find the test statistic based on the fact that the problem was about proportions. After recognizing which test statistic to use, she described in general how to calculate the test statistic using the formula and she double checked all her work in Excel.

> L: And then I double checked by using the formula, the phat minus p over the square root of pq over n. I put that in Excel to double check and make sure that was right.

Lana was then prompted to explain the test statistic. She described, in words, what she imagined.

> L: I think that, I'm picturing the big curve, the bell curve, and I'm picturing the test statistic is where the point that falls on there … Okay, so this is the mean right in the middle, and the test statistic is one side of it, saying this is how far away from what they are saying is the mean, this is what the mean of this.

By reflecting on her previous steps and calculations, Lana appeared to interiorize the action of calculating test statistics. She internally imagined calculating or finding test statistics in relation to the mean, without having to actually perform any calculations. This suggests Lana exhibited a Process conception of test statistic. After her explanation, she drew a picture to illustrate her thinking (Figure 2) of a graphical representation of the normal distribution.

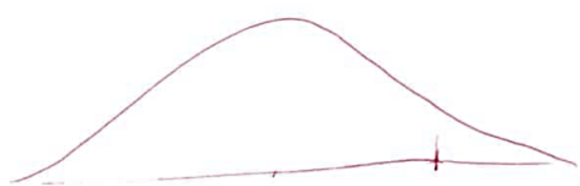

Figure 3. Lana's Graphical Representation of the Normal Distribution

In her written work, Lana initially used the normal distribution to find the test statistic for Question 2. During the interview she became worried when asked if the question was a *z*-test. She mentioned that she remembered from high school to use a *t*-score if the sample size is 30 or less. After prompting, she realized she should have used a *t*-score, however, she also immediately recognized that her *z*-score would "probably not" be very different from the *t*-score. She made the observation that t-scores and z-scores are "really close together". This is evidence of the role that distribution Schema plays in the development of the Schema of test statistic.

It appears that Lana illustrates a Process conception of test statistic because she pictured in her head a graphical interpretation of test statistic without relying on specific calculations, and also interpreted the test statistic as describing how far away the sample statistic is from the expected (population) value. It also appears that she possesses a distribution Schema that is in an early stage, as noted in her confusion between *z*-scores and *t*-scores. However, her understanding that a *z*-score and a *t*-score are "really close together" suggests that her distribution Schema is progressing and emerging.

Steve

Steve is included in the results as illustrative of a student whose analysis suggests discrepancies in his conceptual understanding of test statistic. For Question 1, Steve identified key words in the problem to recognize which test statistic to use. He explained, "I immediately thought of these two formulas, and at first I wasn't sure which one to use, and then I was like, oh wait, there's no x-bar or mu or standard deviation. So that makes it pretty easy." He used a system of elimination to decide which formula not to use. Even though he correctly identified the test statistic, he went on to say that this is "just a formula that I've learned like any other" and that he "doesn't understand why we use that formula, other than we just use it". He concluded his explanation stating that Question 1 used a *z*-value because the problem was of proportions, what appears is likely a memorized rule applied to the problem.

For Question 2, Steve mentioned that "it's basically the same problem", other than now being a question of means. Steve identified the distribution as normal based on the language in the problem, "a simple random sample has been selected from a 'normally distributed' population". He further explained that he would not know how to deal with a non-normally distributed population, that he could not recall learning anything other than a normal distribution, and that he did not know much about a Student's *t* distribution. Ironically, later in the interview, when asked if his answer was a *z*-value or *t*-value, he responded that it is "a t-value because you're testing means".

The excerpts above are suggestive of Action conception of test statistic. Steve appeared to rely on external cues based on key words identified in the problem and what appeared to be memorized rules of when to use a particular formula. However, when prompted by the interviewer to explain what a test statistic is, Steve elaborated as follows, "And also your test statistic is very large. I'm not totally sure what a test stat is, but it reminds me of z-scores, and I remember when you have a z-score that gets above 3. It starts to get pretty, pretty crazy. So 5 is huge, which is also the reason that you're getting a bunch of zeros or very close to 1 [for the p-value]." Although Steve's interpretation of z-scores seems fairly advanced in comparison to other students, it is not clear from his description whether he considers a *z*-score to be an example of the concept of test statistic or a similar concept that is distinct from the test statistic. The former would be suggestive of a Process conception of test statistic, while the latter would be suggestive of an Action conception of test statistic. Since these discrepancies exist, we suggest that Steve is emerging from the Action conception to the Process conception of understanding of test statistic.

Discussion and Concluding Remarks

Our results provide evidence of three students' understanding of test statistic, one who appears to exhibit an Action conception of test statistic, one who appears to exhibit a Process conception of test statistic, and one who appears to be emerging from an Action conception to a Process conception of test statistic. Consistent with Link (2002), many students used a procedural approach to hypothesis testing which included students plugging in correct values for a formula. In reference to test statistic, Haley looked for indicator phrases and key words in the problem to decide which test statistic formula to use and to decide which values to plug in, yet she did not have a full conceptual understanding of hypothesis testing. According to APOS Theory, she is illustrative of an Action conception of test statistic.

Another student, Lana, reflected on her calculations and appeared to interiorize the action of calculating test statistics by describing the test statistic in relation to the mean. However, for Question 2, Lana initially used the normal distribution to find the test statistic, rather than the Student's *t* distribution. In our study, we did not initially consider the role that the stage of distribution Schema would have in the development of the concept of test statistic. However, our results suggest that an individual can possess a Process conception of test statistic, while possessing only an early stage of Schema for distribution. Further research is suggested to explore the extent to which an individual's distribution Schema has in the development of the concept of test statistic.

Lastly, discrepancies in data analysis suggest Steve is emerging from an Action conception of test statistic to a Process conception of test statistic. Excerpts are suggestive that he was relying on key words and memorized formulas to decide which test statistic to use, evidence of Action conception of test statistic. However, Steve did verbally elaborate about *z*-scores, indicative of a possible Process conception. Nevertheless, inconsistency exists in the fact that Steve did not equate z-scores to the test statistic and instead suggested they remind him of each other. If Steve had a Process conception of test statistic, we would have expected him to note that test statistics are standardized values, which in this case *z*-scores are an example representative of test statistic as a whole.

As hypothesis testing is a key concept included in the majority of introductory statistics courses (Krishnan & Idris, 2015), and is arguably one of the most misunderstood statistical topics (Bantanero, 1994), it is important to continue research that investigates students' understanding and curriculum effectiveness of hypothesis testing. This paper, specifically focused on test statistic, a component of hypothesis testing, revealed students' understanding in two distinguished real world situations. By analyzing data according to APOS Theory, we have illustrated examples of Action conception, Process conception, and an example of a student who is emerging from Action conception to Process conception of test statistic. This knowledge can then be used to describe how students may develop an understanding of test statistic – an important concept within hypothesis testing and one that has not received much attention within the research community.

The Role of Visual Reasoning in Evaluating Statements about Real-Valued Functions: A Comparison of Two Advanced Calculus Students

Erika J. David
Arizona State University

Kyeong Hah Roh
Arizona State University

Morgan E. Sellers
Arizona State University

The purpose of this study is to examine the characteristics of students' visual reasoning in the context of evaluating statements about real-valued functions. We conducted clinical interviews with nine undergraduate students in which we asked them to evaluate several mathematical statements using graphs to explain their reasoning. In this paper, we focus on two Advanced Calculus students and the differences in their visual reasoning in these tasks. Our findings indicate that students' visual reasoning accounts for key differences in their understandings of mathematical statements. In this paper, we introduce a visual reasoning framework which emerged from our data. We also provide examples from the two students to highlight the use of the framework to characterize students' visual reasoning as value-thinking or location-thinking.

Key words: Visual Reasoning, Empirical Study, Graphical Interpretations, Undergraduate Students, Intermediate Value Theorem

Undergraduate Calculus courses, from elementary through advanced Calculus, are comprised of many definitions and theorems about real-valued functions. Often, these statements are accompanied by visual representations in the form of graphs of relevant functions. For example, the Intermediate Value Theorem (IVT) is one such statement commonly associated with a visual representation. The IVT can be stated as follows: "Suppose that f is a continuous function on $[a, b]$ with $f(a)\neq f(b)$. Then, for all real numbers N between $f(a)$ and $f(b)$, there exists a real number c in (a, b) such that $f(c)=N$." This theorem is often shown in Calculus textbooks with graphs to accompany the statement (e.g., Briggs, Cochran, & Gillett, 2011). For instance, a graph of a continuous function such as the one in Figure 1 (left) may be used to illustrate the IVT in the case of a monotone function. Additionally, a graph like Figure 1 (right) may be shown to demonstrate that for a given N value, the corresponding value of c need not be unique.

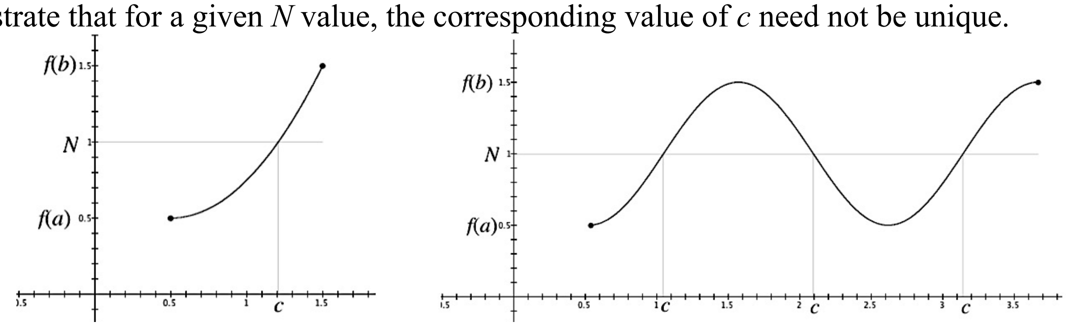

Figure 1. Possible graphical illustrations of the Intermediate Value Theorem (IVT)

Visual representations, such as the ones provided in Figure 1, are often included in textbooks to support students in understanding the given statement or theorem (e.g., Stewart, 2012). While research has called for the inclusion of such visual representations (Arcavi, 2003; Davis, 1993), few empirical studies have been conducted to look at students' visual reasoning about graphs of real-valued functions. Although several studies have looked at students' understanding of graphs as a whole (Monk, 1992; Moore & Thompson, 2015; Moore, 2016), it is not widely known what meanings students have for various aspects of graphs, such as the input, output, and points on graphs. While it is hoped that students focus on the details of graphs that highlight the intended concept, some students may construe other properties of a given graph rather than the intended ones. For instance, a student looking at Figure 1 may presume that the IVT refers to a single value of *N*, or that *N* can be selected from the entire range of the function. Thus, students' interpretations of the IVT, based on the information they perceived from the provided graphs, might hinder their subsequent mathematical activities, such as rigorous proofs.

The purpose of this study is to investigate the role of students' visual reasoning in understanding and evaluating mathematical statements from Calculus. In particular, this study focuses on the IVT and statements similar to the IVT. Through analyzing two advanced Calculus students' evaluations and interpretations of these statements, we address the following research questions: *What are characteristics of undergraduate students' visual reasoning about graphs related to statements from Calculus contexts?* Specifically,

a. *How do students interpret outputs of a function on a graph, points on a graph, and a graph as a whole?*
b. *How do students' visual reasoning affect their understanding and evaluation of the Intermediate Value Theorem and similar statements?*

Literature Review

Mathematics education research has included numerous studies and discussions of the role of visualization throughout mathematics teaching and learning (e.g., Arcavi, 2003; Bishop, 1980; Davis, 1993). Studies have both suggested and reported the success of various instructional interventions that utilize visualization in undergraduate mathematics contexts in various levels of Calculus (e.g., Tall, 2010; Thompson, Byerly, & Hatfield, 2013). Researchers have also examined students' understanding of mathematical concepts using visualization tools, including their understanding of graphs of functions (Kidron & Tall, 2015; Monk, 1992; Pinto & Tall, 2002). These studies provide evidence that visualization can be a powerful tool for students learning concepts in advanced mathematics.

Instructional Interventions Using Visualization

There have been calls throughout the literature to encourage and promote visual reasoning in mathematics instruction, as an essential part of mathematical activity (Arcavi, 2003; Davis, 1993). Several researchers have developed visual reasoning tasks that instructors can use to support students in understanding formal definitions of concepts in undergraduate mathematics (Kidron & Tall, 2015; Roh, 2010; Tall, 2010). Proposed instructional interventions, such as the ones noted above, show promise in supporting students' understanding (e.g., Cory & Garofalo, 2011; Kidron & Tall, 2015; Roh & Lee, 2017). However, visual representations and interventions that rely on them are not without limitations. Students may over-generalize from a single visual representation they view as "prototypical" (Harel & Sowder, 1998), focus on irrelevant details of them (Presmeg, 1986), or rely too heavily on self-generated visual representations (Alcock & Simpson, 2004). Arcavi (2003) accounts for some differences in what students gather from images, claiming that an individual's perceptions are "conceptually driven" (p. 234). Because visual representations may be interpreted differently by different onlookers or in different contexts, it is imperative to investigate what sense *students* make of visual representations of concepts that are commonly provided.

Students' Visual Reasoning about Graphs and Points

Several studies in mathematics and science education have documented students' creation, interpretation, and use of graphs (e.g., Padillo, McKenzie, & Shaw, 1986; Pinto & Tall, 2002). Some studies have classified students' conceptions of graphs as a whole, while others suggested models of students' understanding of points on a graph (Lakoff & Nunez, 2000; Moore & Thompson, 2015; Moore, 2016; Thompson & Carlson, 2017).

Moore and Thompson (2015) highlight a distinction in students' visual reasoning about graphs as a whole. In their study, some students whom they classified as engaged in *static shape-thinking* reasoned about graphs as though the graph itself was an object, such as a wire. In contrast, they describe students who engage in *emergent shape-thinking* as conceiving of a graph as a trace which emerges from the coordination of two varying quantities. Extending this work, Moore (2016) claims that students may attend to both visual properties of graphs and the relationships of the quantities represented, but one of the two will guide students' reasoning.

While most literature on students' visual reasoning focused on students' conception of graphs in their entirety, other researchers have attended to students' conception of points on a graph. Thompson and Carlson (2017) use the term *multiplicative object* to characterize student thinking about points as representing two values or quantities simultaneously in the form of a single object. Lakoff and Nunez (2000) offer a cognitive model for how individuals come to understand numbers as points on a number line, claiming this requires the use of what they call a *conceptual metaphor*, "an inference preserving cross-domain mapping" (p. 6). The idea of mapping numerical values to physical locations on a line preserves properties of values such as ordering. In two-dimensions, then, the conception of plotting a point relies on using this conceptual metaphor for each value of the pair represented, which may explain students' difficulties with interpreting points on graphs.

While these theoretical discussions can help distinguish certain aspects of student visual reasoning, we seek to investigate the ways students understand outputs and points on a graph at a more fine-grained level. In our effort to delve deeper into students' meanings for relevant aspects of graphs, we define the constructs *value-thinking* and *location-thinking*, as explained in the following theoretical framework section.

Theoretical Perspective and Visual Reasoning Framework

This study is grounded in a constructivist perspective. We adopt von Glasersfeld's (1995) view that students' knowledge consists of a set of action schemes that are increasingly viable given their experience. This perspective implies that we, as researchers, do not have direct access to students' knowledge and can only model their visual reasoning based upon what we can observe. Thus, our analysis reflects our best attempt at creating a hypothetical model of student visual reasoning grounded in evidence found in their words, gestures, and markings on graphs.

We adopt components of Arcavi's (2003) definition of visualization for this study:

> The ability, the process, and the product of creation, interpretation, use of and reflection upon pictures, images, diagrams, in our minds, on paper, or with technological tools, with the purpose of depicting and communicating information, thinking about and developing previously unknown ideas and advancing understandings (p. 217).

Arcavi (ibid) argues that visualization has a natural role in mathematics, and gives examples of visual representations such as graphs, or diagrams. While Arcavi's description of visualization is broad, in this study, we use the term *visual reasoning* to refer specifically to how students interpret, use, and reason about graphs of real-valued functions. We also use the terms "thinking" and "reasoning" interchangeably to describe students' mathematical activity in the context of graphs. In particular, we focus on how students perceive the elements that constitute graphs.

Our Visual Reasoning Framework

In this section, we describe the framework that we developed and employed to categorize students' visual reasoning. In particular, this framework is rooted in distinguishing students' visual reasoning about aspects of points on graphs.

Points in a two-dimensional Cartesian system are intended to represent the concurrence of the values of two quantities, conventionally notated as an ordered pair (x, y). This coordination of values x and y also has a spatial location in the Cartesian plane due to the geometric nature of a point in a plane as a coordination of two signed distances. To graph a point (x, y) in the Cartesian plane, one marks the spatial location that is a distance of x units from the origin along the x-axis (conventionally left or right) and a distance of y units from the origin along the y-axis (conventionally up or down). Thus, we see a point on a graph as dual-natured, simultaneously representing a pair of values, as well as a specified location in the space of the Cartesian plane.

These two properties of points in a Cartesian coordinate system, values and locations, are possible foci of a student's attention while reasoning about graphs. Accordingly, we developed our visual reasoning framework in terms of *value-thinking* and *location-thinking*. Students who primarily focus on the *values* represented by the coordinates of a point are said to engage in *value-thinking.* In contrast, *location-thinking* refers to reasoning that primarily attends to the spatial *location* of the point. We detail characteristics of both categories of visual reasoning in Table 1 by listing the meanings for three aspects of the graph for each category and observable behaviors indicative of these meanings. The three aspects of graphs in this framework are named from our perspective as researchers, whereas the meanings explicated under each type of visual reasoning are from the perspective of the student. To be clear, the distinction between these two ways of reasoning lies in the *place of the student's attention* when reasoning about graphs.

Table 1
Comparison of Characteristics of Value-Thinking and Location-Thinking

<table>
<tr><th colspan="2"></th><th colspan="2">Value-Thinking</th><th colspan="2">Location-Thinking</th></tr>
<tr><th colspan="2"></th><th>Visual Reasoning</th><th>Evidence</th><th>Visual Reasoning</th><th>Evidence</th></tr>

</table>

Value-thinking. By *value-thinking*, we mean visual reasoning that relies on the values represented by the coordinates of a given point on a graph. *Value-thinkers*, then, refer to those who engage in value-thinking. One of the key characteristics of value-thinking is distinguishing the output of a function from the corresponding point on a graph. Students who engage in value-thinking label points as ordered pairs (e.g., $(a, f(a))$) and speak about points as representing both input and output values simultaneously. When considering the output of a function, value-thinkers attend to the resulting value of the function from a given input value. Students focusing on values tend to label relevant output values on the output axis of graphs, and specifically speak about *values*. These actions are due to the student's attention to the corresponding values represented by a given point on a graph, which they consider to be a coordination of both an input and output value. Value-thinkers, then, treat graphs as a collection of ordered pairs that relate corresponding input and output values.

Location-thinking. By *location-thinking,* we mean visual reasoning that relies on the spatial locations of the points in the Cartesian plane. *Location-thinkers*, then, refer to those who engage in location-thinking. Location-thinkers focus on the location of the point, while the values of the coordinates are either in the background of their reasoning or absent from it. In contrast with value-thinking, one of the key characteristics of location-thinking is treating the output of the function as the location of the point on the graph of the function. Accordingly, location-thinkers often label points on the graph as outputs (e.g., $f(a)$) rather than ordered pairs and speak about points in terms of their location in the coordinate plane. While value-thinkers label outputs on the output axis, location-thinkers place the output label (e.g., $f(a)$) at the location of the point on the graph. Instead of speaking about output *values*, location-thinkers speak about *points on the graph* as the result of a value inputted to the function. Location-thinkers, then, treat graphs as a collection of locations in space associated with input values.

Use of Framework

The intent of our framework is to characterize students' visual reasoning with graphs of functions. In Figure 2, the two sets of labels on the same graph illustrate distinctive characteristics of value-thinking (left) and location-thinking (right), respectively.

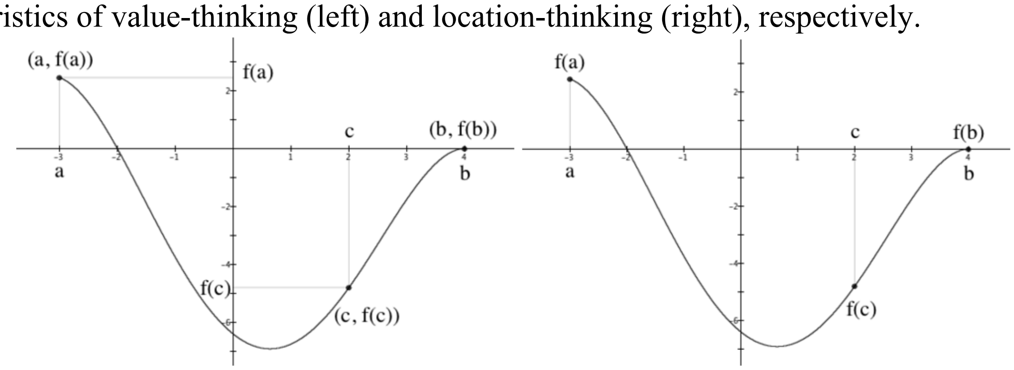

Figure 2. Sample labeling activity of a value thinker (left) vs. a location thinker (right)

In Figure 2 (left), input values are labeled on the input axis, and output values are labeled on the output axis. Furthermore, points on this graph are labeled as ordered pairs. In Figure 2 (right), while the input values are labeled on the input axis, the output values are not labeled on the output axis. In contrast to Figure 2 (left), points on the graph in Figure 2 (right) are labeled with only output notation, rather than as ordered pairs. Additionally, the placement of output labels differs between the two figures. For example, in Figure 2 (left), $f(c)$ is a label of a value on the output axis, whereas in Figure 2 (right), $f(c)$ is a label of a point at a particular spatial location.

This framework is intended to model students' visual reasoning through evidence found in the student's (repeated) *actions*, rather than their *abilities* to think in various ways. Thus, the classification of a student as a location-thinker does not imply that the student is unable to consider values of the output. On the contrary, it is likely that students may be classified as location-thinkers and may still at times refer to or find specific values of the output. Rather, location-thinkers focus on the location of the relevant points in their reasoning, as revealed through their words and actions. Accordingly, no single piece of evidence (e.g., one labeled point, one gesture) is viewed as enough to categorize a student's visual reasoning. We also recognize that the same student presented with different contexts may engage in value-thinking or location-thinking, depending on what he or she focuses on. We thus emphasize that the distinction between value-thinking and location-thinking is one of the placement of students' attention, rather than an exclusive way of thinking.

Visual Reasoning Framework in the IVT Context

In the context of the IVT and related statements, location-thinkers and value-thinkers likely interpret the phrase "N between $f(a)$ and $f(b)$" differently. Due to the differences in their meanings for outputs and points on a graph, value-thinkers interpret "N between $f(a)$ and $f(b)$" as referring to output *values* between the *values* of $f(a)$ and $f(b)$. This meaning stems from a conception of a point as a coordination of input and output values. In contrast, *location-thinkers* interpret "N between $f(a)$ and $f(b)$" as referring to *locations* between the *locations* of $f(a)$ (at $(a, f(a))$) and $f(b)$ (at $(b, f(b))$), an interpretation rooted in a conception of the location of points *themselves* as outputs of a function. Whether a student chooses to focus on the values or the locations of points in a graph influences how that student will interpret this phrase.

Methods

As part of a larger study, we conducted two-hour clinical interviews (Clement, 2000) with nine undergraduate students from a public southwestern university. We selected three undergraduates who had just completed one of the following three mathematical courses that may use the theorem: Calculus I, Introduction to Proof (also known as Transition-to-Proof), and Advanced Calculus. During each interview, one of the four members of our research team served as the interviewer with the other three acting as witnesses. All four researchers utilized laptops, whose screens the participant could not see, to communicate their current models of the participant's thinking and offer clarifying questions in real-time via group chat.

Interview Tasks

During the interview, the interviewer asked students to evaluate each of the four mathematical statements in Table 2 and to provide their justification. The second statement, the Intermediate Value Theorem (IVT), was the only true statement we presented. The remaining three statements (1, 3, and 4), all of which are false, were variations on the IVT with the quantifiers (for all, there exists) reordered or the variables (N, c) reversed. Table 2 contains the statements in the order presented to the students.

Table 2
Statements Presented to Participants, in Order

Statement 1	Suppose that f is a continuous function on $[a, b]$ such that $f(a)\neq f(b)$. Then, for all real numbers c in (a, b), there exists a real number N between $f(a)$ and $f(b)$ such that $f(c)=N$.
Statement 2 (IVT)	Suppose that f is a continuous function on $[a, b]$ such that $f(a)\neq f(b)$. Then, for all real numbers N between $f(a)$ and $f(b)$, there exists a real number c in (a, b) such that $f(c)=N$.
Statement 3	Suppose that f is a continuous function on $[a, b]$ such that $f(a)\neq f(b)$. Then, there exists a real number N between $f(a)$ and $f(b)$, such that for all real numbers c in (a, b), $f(c)=N$.
Statement 4	Suppose that f is a continuous function on $[a, b]$ such that $f(a)\neq f(b)$. Then, there exists a real number c in (a, b), such that for all real numbers N between $f(a)$ and $f(b)$, $f(c)=N$.

The interviewer later asked students to re-examine each statement along with six graphs we created, with the chance of changing their evaluation. The graphs, shown in Figure 3, were intended to represent a spectrum of possible functions and relevant counterexamples and included: a polynomial with extrema beyond the endpoints of the displayed function (Graph 1), a vertical line segment (Graph 2), a continuous sinusoidal function (Graph 3), a monotone increasing function (Graph 4), a constant function (Graph 5), and a function that is discontinuous on $[a, b]$ (Graph 6). Graphs 1, 3, and 4 were chosen to represent three cases of continuous functions where $f(a)\neq f(b)$. Graphs 2, 5, and 6 were chosen to represent graphs each of which does not meet one of the conditions of the four statements.

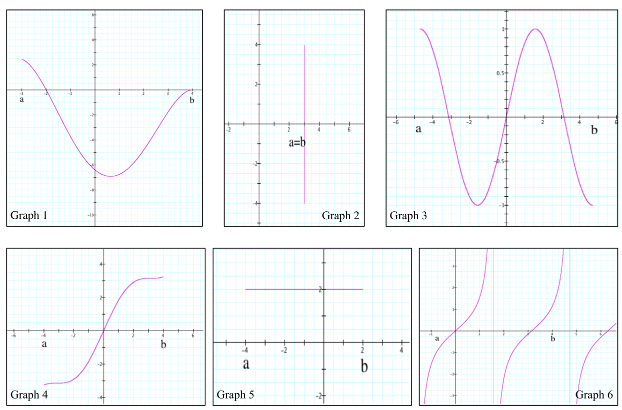

Figure 3. The six graphs we presented to the participants

The participants were also asked to explain how they interpreted various aspects of these graphs and to label relevant points and values on each graph where appropriate. As each participant explained his or her interpretations of the graphs, all four researchers developed models of the student's thinking in the moment. Where necessary, researchers proposed additional questions to confirm the current model of the student's thinking. If a student's responses to these questions did not confirm the model, the model was changed or refined to accommodate the student's response.

Data Analysis

Our data analysis was consistent with Corbin and Strauss' (2014) description of grounded theory, in which categories of student visual reasoning emerged from the data analysis. We began preliminary analysis during and immediately following each interview to note relevant findings. After all the interviews were conducted, we employed open coding (Corbin & Strauss, 2014), through which students' interpretation of the phrase "N between $f(a)$ and $f(b)$" emerged as highly relevant to their reasoning about graphs and subsequent evaluations of the given statements. We developed two codes, *value-thinking* and *location-thinking*, to broadly characterize our participants' visual reasoning about graphs. Finally, we refined these categories and re-coded the video interview data using axial coding (Corbin & Strauss, ibid). Through this process, we developed the theoretical framework described in the previous section (see Table 1) which emerged in our analysis. In the next section, we share our findings from this data analysis.

Results

The purpose of this study is to characterize students' visual reasoning with graphs related to statements from Calculus contexts. In particular, we examined students' interpretations of various aspects of graphs, as well as the effects of these interpretations on their understanding and evaluation of the IVT and three similar statements (see Table 2). We categorized the visual reasoning of each of the nine students we interviewed according to the theoretical framework (see Table 1) which emerged in the process of data analysis as previously described. In this paper, we report the cases of Nate and Jay, Advanced Calculus students from each category, in order to highlight the defining characteristics of each category of visual reasoning. We provide gestures, labeling on graphs, and verbal explanations of their interpretation of the graphs to describe details of each student's visual reasoning in terms of our theoretical framework (see Table 1).

Jay: A Value-Thinker

In this section, we describe characteristics of value-thinking in terms of Jay's meanings for outputs, points, and the phrase "N between $f(a)$ and $f(b)$" through examples from his visual reasoning. We present his verbal explanations along with his labeled graphs from two episodes of his interview to illustrate value-thinking.

Even before the interviewer provided him with graphs, Jay engaged in visual reasoning by creating his own graphical representations to explain his understanding of the statements. For instance, when the interviewer asked Jay to evaluate Statement 2 (IVT), he responded by saying that the statement was true, and drew a graph to explain his reasoning. Figure 4 shows Jay's hand-drawn graph.

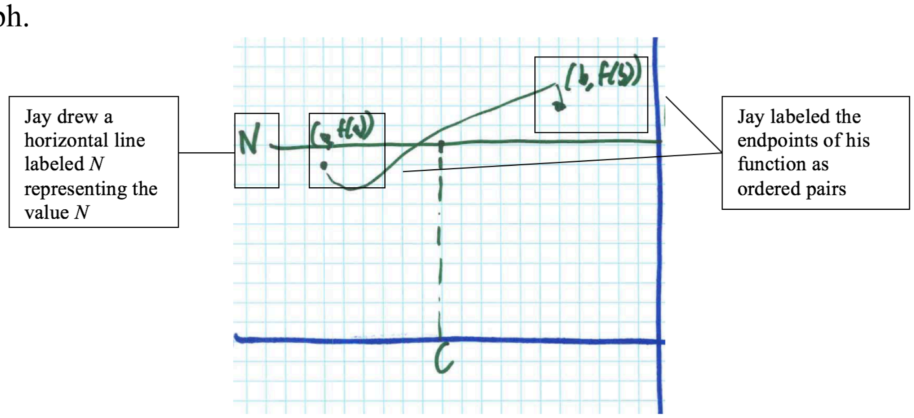

Figure 4. Jay's hand-drawn graph explaining why the IVT is true[1]

[1] Jay intended that c be placed at the intersection of the graph of the function and the horizontal line $y=N$.

In creating his graph in Figure 4, Jay first plotted two points to represent endpoints of a graph of a function, which he labeled as the ordered pairs, $(a, f(a))$ and $(b, f(b))$, respectively. Then, Jay drew a horizontal line, which he labeled 'N,' to represent a value of N between $f(a)$ and $f(b)$. Jay explained that, from his perspective, Statement 2 must be true because any graph of a continuous function that he could draw from $(a, f(a))$ to $(b, f(b))$ must cross the horizontal line (y=N) that he labeled N. He then labeled c on the x-axis and explained that if the function crossed the line y=N at the value c, then $f(c)$ equals N. Jay then drew a graph from $(a, f(a))$ to $(b, f(b))$ as an example of a continuous function that he was speaking of.

Outputs as values. Jay consistently treated outputs of the function as values. For instance, Jay drew a graph of a horizontal line y=N and claimed that where the function "cross[es] this line" is "where $f(c)$ is N." Jay's purpose in drawing this horizontal line was to identify a particular output value of the function, namely, N. We take both Jay's graph of the horizontal line y=N, and the way he used this line in his explanation as evidence that he was attending the value of outputs (similar to Figure 2 left). Confirming that he attended to the value of outputs of the function, Jay later explained that Statement 2 meant to him that continuous functions do not "skip over any *values* between $f(a)$ and $f(b)$." We thus take Jay's language and labeling on the graph as evidence of his consideration of *outputs of the function as values*, a characteristic of value-thinking as described in our visual reasoning framework (see Table 1).

Points as ordered pairs. Jay also labeled the endpoints of the graph as ordered pairs: $(a, f(a))$ and $(b, f(b))$. Additionally, he referred to the intersection point of a continuous function, f, and a horizontal line, y=N, as an ordered pair, $(c, f(c))$. Jay's labeling and description of points as ordered pairs indicate that he attended to both the values of the input and output represented at each point. We thus take Jay's consistent treatment of *points as ordered pairs* as evidence of value-thinking, as noted in Table 1.

In addition to considering outputs as values and points as ordered pairs, Jay's interpretation of the phrase "N between $f(a)$ and $f(b)$" in the later portion of the interview provides further evidence of Jay's value-thinking. We present a second episode from Jay's interview to highlight his meaning for this phrase.

Earlier in the interview, Jay had already evaluated all four statements correctly. Later, when the interviewer presented with graphs in Figure 3, Jay again explained his evaluation of the statements while looking at Graph 1. In particular, Jay used a curly brace along the y-axis to mark off what he took to be the relevant interval for possible N values between $f(a)$ and $f(b)$ (see Figure 5 for his work with Graph 1).

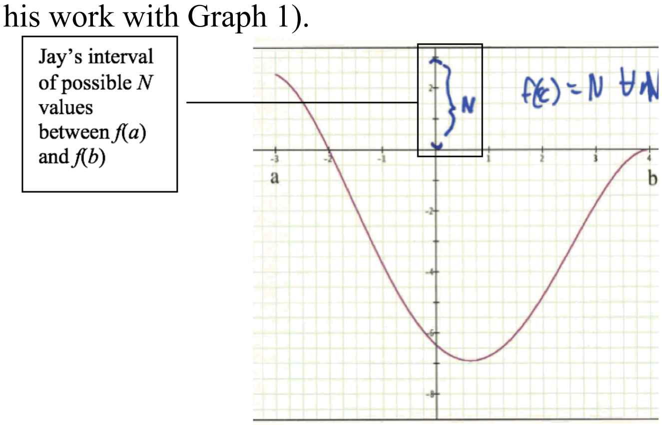

Figure 5. Jay's possible values of N on Graph 1

When explaining why he concluded that Statement 1was false, Jay referenced the interval for possible N values that he drew in Figure 5. In his explanation, he approximated this interval to be [0, 4] (Jay did not carefully attend to the scale of the y-axis), and explained that although 0 was an input value between a and b, i.e., in the interval (–3, 4) in Figure 5, its corresponding output $f(0)$, or –7, was not between $f(a)$ and $f(b)$, i.e., in the interval [0, 4]. The transcript below provides Jay's verbal explanation.

Jay	*Statement 1*	*Graph 1*
Interviewer: Can you use this graph to explain why the statement is false?		
Jay: This [Statement 1] is false in this case because it would say that in the open interval (a, b) (*points to a and b on x-axis*), okay, so for all numbers between these two numbers, –3 and 4, (*gestures along x-axis between –3 and 4*) there exists a real number between, and this is the important part, between 0 and 4 or 0 and 3, so between these two values, (*gestures on graph parallel to y-axis similar to interval he marked off above*) such that when I evaluate the function here (*gestures along x-axis between –3 and 4*), I get the value in here (*gestures to indicate interval on y-axis from f(a) to f(b)*). Okay…so if I am looking at $f(0)$, right? $f(0)$ is –7 which is outside of the interval of [0, 4], which means that there is no N between 0 and 4 such that… –7 which is... $f(c)$ is equal to N, that value between 0 and 4.		

N as a value "between f(a) and f(b)." As previously noted, Jay marked off what he took to be the interval of possible N values between $f(a)$ and $f(b)$ using a curly brace along the y-axis (see Figure 5). Using $f(0) = –7$ as an example in which the input value is between a and b, but the output value is not between $f(a)$ and $f(b)$, he determined Statement 1 to be false. We thus take Jay's interval of possible N values between $f(a)$ and $f(b)$ in Figure 5 as further evidence that he engaged in value-thinking, as explained in our Theoretical Framework.

Nate: A Location-Thinker

Unlike Jay and the other students whom we classified as value-thinkers, some students did not consider outputs as values, points as ordered pairs, or N as values "between $f(a)$ and $f(b)$." Instead, these students labeled *outputs at locations* on the graph rather than the y-axis, labeled *points as outputs* rather than ordered pairs, and considered N as a *spatial location* rather than a value. In this section, we present an illustrative episode from one such student, Nate, whose visual reasoning we categorized as *location-thinking*. To highlight the characteristics of *location-thinking,* we present his verbal explanations along with his gestures and graph labels to illustrate defining characteristics of location-thinking in terms of his meanings for outputs, points, and the phrase "N between $f(a)$ and $f(b)$."

In one portion of the interview, Nate explained why he evaluated Statement 1 as true using Graph 1. In contrast with value-thinkers who considered outputs of the function to be *values*, Nate considered both outputs of functions and points on graphs to be *locations* on graphs. Specifically, Nate first labeled the endpoints of the graph as $f(a)$ and $f(b)$, respectively. Then, Nate highlighted the x-axis with his pen, and explained that for every c on this axis, he could find an N on the curve that it maps to. He labeled several c's on the x-axis as he explained this. He also motioned from the x-axis vertically down to the graph when describing that c's were mapped to N's on the graph. Similarly, when describing N's, he swept along the entire graph of the function from what he marked as $f(a)$ to $f(b)$. His transcript in this portion of the interview is provided below and his labels on Graph 1 are shown in Figure 6.

Nate	*Statement 1*	*Graph 1*
Nate: So for all these c's (*sweeps pen along x-axis between a and b)* you can see that it mapped to a point on the curve. For every single c there is a point on the curve that it maps to…So after that *c, N* would be here (*marks c around 1 on x-axis, N at ordered pair location of (c, f(c))*. So it maps to that. And this c would be in here (*marks c around 2 on x-axis*). And this c would be like, N right here (*marks corresponding N's for each c on Graph 1*).		

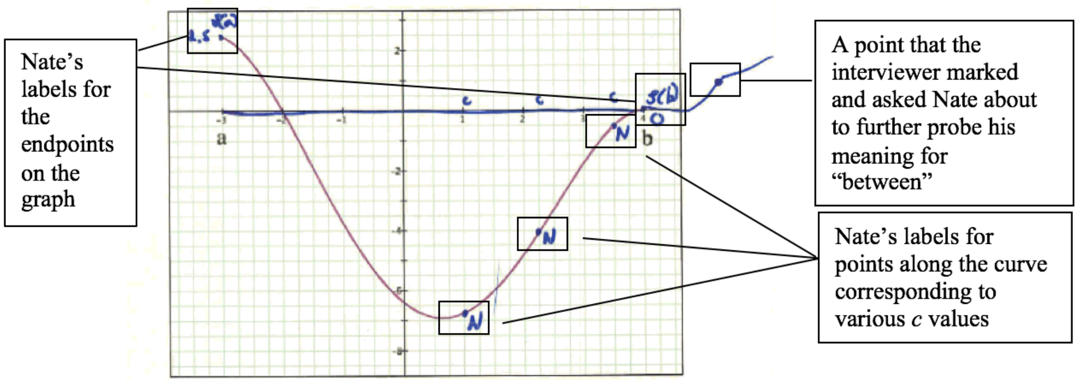

Figure 6. Nate's labeling on Graph 1 when he explained why he evaluated Statement 1 as true

Outputs as locations. Unlike the value-thinkers, who placed output labels on the y-axis, Nate, in Graph 1, used outputs, $f(a)$, $f(b)$, and N, to label points on the graph as shown in Figure 6. In fact, Nate consistently placed output labels at points on the graphs of the functions he worked with throughout the interview. His work on the graphs indicates that he considered these outputs to be locations on the graph, rather than values on the y-axis. Nate also spoke about inputs mapping to N's which he labeled on the graph. Thus, for Nate, outputs of the function were locations on the graph. We thus take Nate's gestures and graphical activity as evidence of his consideration of outputs of the function as locations, indicative of location-thinking as described in our visual reasoning framework (see Table 1).

Points as locations. We also take the placement of Nate's labels of $f(a)$, $f(b)$, and N at points as evidence that he attended to the different spatial locations of these points. Rather than label the points as an ordered pair of input and output values, Nate chose to label the endpoints as the output alone. For Nate, there was no difference between outputs of the function and points on the graph, as both referred to spatial locations on the graph. We thus conclude that Nate conceived of points as locations, an indication of location-thinking, as described in our framework.

When Nate explained his meaning for the phrase "N between $f(a)$ and $f(b)$,"his visual reasoning in terms of location-thinking was most prominent. The following exchange between Nate and the interviewer more clearly reveals his location-thinking. Nate labeled possible N's on the graph that were, from our perspective, not between $f(a)$ and $f(b)$, as the output values at these points were less than the value of $f(b)$. Noticing Nate's placement of N labels, the interviewer extended the graph to the right to further examine Nate's meaning for the phrase "N between $f(a)$ and $f(b)$" (see Figure 6). The interviewer picked a point on the extended graph, with an output value between the values of $f(a)$ and $f(b)$ and asked Nate if this output was between $f(a)$ and $f(b)$. In response, Nate hesitated and explained that there were two possible interpretations of the phrase "N between $f(a)$ and $f(b)$." The transcript below contains his explanation and Figure 6 contains his corresponding labels on Graph 1.

Nate	*Statement 1*	*Graph 1*
Interviewer: …Okay. Let's say we picked a point over here (*points to a point beyond endpoints of the graph, on portion of extended graph, the rightmost marked point on Figure 6*). Would we say that that output would be between $f(a)$ and $f(b)$?		
Nate: I would not say it's between $f(a)$ and $f(b)$. Even though the, yeah. This is the confusing part, where the actual numbers 2.5 and 0 (*marks the points 2.5, 0, boxed on Figure 6*). This would be, if you are looking at numbers 2.5, 0, this would be in between that interval. But it's in between that number interval. But it's not in between the functional interval in this case, so $f(a)$. The interval refers to all these points between $f(a)$ and $f(b)$ (*sweeps pen along the graph)*. All points of the function. That's what I am interpreting.		

N as a location "between f(a) and f(b)." The interviewer's prompt in the exchange above allowed Nate to consider more carefully his meaning for "N between $f(a)$ and $f(b)$." While Nate said the point that the interviewer plotted was not between $f(a)$ and $f(b)$, he acknowledged that the point was "in the number interval" between 2.5 and 0 (the values of $f(a)$ and $f(b)$). We take Nate's number interval to be referencing the interval of output values between 0 and 2.5, which he labeled on the endpoints of the graph. He clarified that the point was not "in the function interval," which we take as located on the graph of the function, since Nate swept along the graph as he described the function interval. Although Nate acknowledged the numerical interval, he considered his notion of the "function interval" as more relevant for interpreting the phrase "N between $f(a)$ and $f(b)$." We thus take Nate's interpretation of "between" in terms of the *location* of the points, rather than the values of the outputs, as indicative of *location-thinking*.

Conclusion

This study reveals that students' interpretations of outputs, points, and graphs differ based on their visual reasoning. Like Jay, the students whom we categorized as *value-thinkers* considered outputs as values, points as coordinates of input and output values, and N as a value. They consistently labeled outputs on the y-axis and points as ordered pairs. Additionally, they referred to the y-axis when speaking about possible values of N in the various statements. These characteristics of their visual reasoning are consistent with the characteristics of value-thinking described in our visual reasoning framework in Table 1. On the other hand, students like Nate whom we categorized as *location-thinkers* considered both outputs and points as locations on the graph of the function, and, consequently, N as a location between the endpoints of the graph. They consistently labeled outputs at points on the graph rather than label outputs on the y-axis or label points as ordered pairs. Additionally, they referred to the whole graph when speaking about possible values of N in the various statements. These characteristics of their visual reasoning are consistent with the characteristics of location-thinking described in our visual reasoning framework in Table 1.

Our analysis of the data in this study also reveals that students' visual reasoning impacts their understanding and evaluation of the statements. Five students including Jay were identified as value-thinkers and four students including Nate were identified as location-thinkers. Among the five value-thinkers, three students evaluated all four statements correctly as FTFF. In contrast, no location-thinker evaluated all four statements correctly.

The two students whose visual reasoning we reported in this paper share many similarities. Both Jay and Nate had recently completed Advanced Calculus and both showed evidence of having a proper understanding of multiple quantifiers and conditional structure. However, they evaluated Statement 1 differently. While Jay correctly evaluated this statement as false, Nate evaluated it as true. The role of visual reasoning, then, becomes central in explaining Nate's and Jay's opposite evaluations of Statement 1, since both students understood the quantifiers and conditional structure of the statement in the same way while their visual reasoning differed. In short, the sole reason Nate evaluated Statement 1 incorrectly was due to his location-thinking. Unlike value-thinking, which seemed to support students, location-thinking did not support students' understanding and evaluation of the statements.

Discussion

In summary, through probing students' understanding and evaluation of the IVT and related statements, along with several graphs, we discovered a significant distinction in how students interpreted these graphs. Location-thinkers confounded the output of a function with the location of the coordinate point. They thus interpreted the IVT and related statements differently from value-thinkers, who distinguished between output values and points that coordinated both an input and output value. We hypothesize that the differences in value-thinkers' and location-thinkers' visual reasoning may lead to differences in how these students understand other mathematical statements about real-valued functions.

Significance of findings & relation to literature

Through our analysis of student visual reasoning, we conclude that a subtle difference in place of a student's focus when reasoning about a graph has significant implications on mathematical ideas. As illustrated through the cases of Jay and Nate, different methods of visual reasoning contributed to different evaluations and understandings of a complex mathematical statement about real-valued functions, of which there are many in undergraduate mathematics courses.

Our results highlight and explain some important aspects of students' graphical activity not previously accounted for by current theories and studies on visual reasoning (Moore & Thompson, 2015; Moore, 2016). We view our findings as complimentary to Moore's (2016) work in classifying students' graphical reasoning through the source of their attention. In terms of Moore's (2016) constructs, students who were labeled as value-thinkers were seen as engaging in operative thought and emergent shape-thinking, as their visual perception of the graph was subordinate to their meanings for output value and they coordinated the values of the varying quantities. Location-thinkers, on the other hand, did not clearly fall into the alternate category of figurative thought, which Moore (2016) aligns with static shape-thinking. The visual cues from the graph did dominate their thinking in some aspects of the graph, such as the spatial location of the points, which informed their interpretation of "N between $f(a)$ and $f(b)$." Although location-thinkers engaged in figurative thought in this way, they did not conceive of the graph statically. Instead, these students conceived of graphs as emerging from the coordination of input values with the corresponding spatial locations of the points on the graph. This conception of a graph is neither captured by the construct of static shape thinking (not conceiving of the graph as a wire) nor emergent shape thinking, (not imagining the values of both the input and output represented simultaneously) as described by Moore and Thompson (2015). In this way, we consider our constructs of value-thinking and location-thinking as contributing to the existing body of literature in describing students' graphical activity. Thus, the use of our constructs of value-thinking and location-thinking could progress the depth of analysis in the field of student visual reasoning, especially with regard to ideas from Calculus.

Implications for curriculum and instruction

Our findings in this study provide insight into distinctions in students' visual reasoning, which instructors at both the high school and undergraduate level may find informative for understanding students' mathematical activity. In teaching concepts involving graphical representations, instructors' attention to the distinction between value-thinking and location-thinking may in turn provide students with opportunities to reflect on their conception of points and graphs. In the classroom, it may also be beneficial for instructors to be aware of the various ways in which students may interpret information from a visual representation.

While in our study, value-thinking helped students to understand the IVT and varied versions of the statement, in other contexts, such as Geometry, location-thinking may be preferable. Ideally, students should possess the ability to think in both ways, as well as the ability to discern when to use each. We also recognize that our findings indicate overcoming various perceptual cues found in graphs, beyond conceiving of the graph as a static shape, is a nontrivial achievement, even for advanced students. Teachers utilizing such representations may seek to support students in overcoming adherence to visual cues.

Our findings also have implications for curriculum and textbook design. Curriculum developers may consider including tasks designed to highlight the distinction in the two modes of visual reasoning. In the context of the IVT specifically, we note that the examples provided in Figure 1 do not readily provide students with the opportunity to reflect on the meaning of the phrase "N between $f(a)$ and $f(b)$" in the Calculus context as referring to values. Because the endpoints of the interval in Figure 1 coincide with the absolute minimum and maximum values of the function, students would arrive at the same conclusion, regardless of their mode of visual reasoning. Both curriculum developers and instructors may consider the use of graphs like our Graph 1, in which the function includes output values beyond the range of values between $f(a)$ and $f(b)$ to provide opportunities to distinguish students' visual reasoning. We hope that our findings raise awareness of the subtle yet significant details of students' visual reasoning and may thus inform decisions both in curriculum design and instruction.

Conceptual Understanding of Differential Calculus: A Comparative Study

Daria Gerasimova	Kathleen Matson	Robert Sachs	Margret Hjalmarson
George Mason University	George Mason University	George Mason University	George Mason University

The research community shares a concern for students' conceptual understanding of calculus and commonly advocates for student-centered approaches as a way to promote it. In this study, we investigated the effect of different instructional approaches on 151 undergraduate students' conceptual understanding of differential calculus in context-specific, natural settings. We collected data on the pre- and posttest of the Calculus Concept Inventory in three classes. In one class, most of the time was dedicated to conceptually oriented problem solving, another class implemented practice problems for students, and the third class was a traditional lecture class. The results showed that there was no difference in students' conceptual understanding of differential calculus controlling for their initial understanding. Thus, our findings do not support the research that advocates for student-centered instruction suggesting that the approaches' implementation and contextual differences may be sources of variation in their effectiveness.

Key words: Calculus, Conceptual Understanding, Active Learning, Instruction, Concept Inventory

Mastery of calculus, a desired and necessary student learning outcome (Sofronas et al., 2011), needs to include not only mastery of procedures but mastery of concepts, as well (Zerr, 2010). Multiple attempts have been made to identify instructional approaches that lead to greater conceptual understanding of STEM disciplines (Freeman et al., 2014; Prince, 2004) and specifically of calculus (Laursen, Hassi, Kogan, & Weston, 2014; Rasmussen, Kwon, Allen, Marrongelle, & Burtch, 2006), typically advocating for student-centered instruction. However, those calculus studies either used measures with limited evidence of validity and reliability or aggregated data across classrooms, potentially different in instruction implementation or contextual factors. With our ex post facto study, we aimed to overcome these limitations and investigate students' conceptual understanding of differential calculus (measured by a validated instrument) in three calculus classes with distinct instructional approaches taking contextual factors into account.

Literature Review

The education research community has been working on identifying instructional approaches effective for students' learning and specifically for their conceptual understanding of content for a long time (Prince, 2004). Many researchers have advocated for student-centered instruction as an effective one, typically contrasting it with the teacher-centered instruction. For example, in physics, one of the largest studies was conducted by Hake (1998) where he compared student conceptual understanding in interactive engagement classes and traditional classes. The results of that study suggested that students in the former classes had higher conceptual understanding than students in the latter.

In undergraduate mathematics, several studies exist that explored the influence of student-centered instruction - specifically inquiry-based learning (IBL) - on student conceptual understanding. One of such studies is a study of Laursen et al. (2014) where learning gains of students in IBL mathematics classes were compared to those of students in non-IBL mathematics classes. The results showed that students' cognitive gains in understanding and thinking, among others, were greater in IBL classes than in non-IBL. However, the measurement of learning gains in this study is important to note. The learning gains were self-reported by students, i.e., the gains were students' subjective perceptions of their learning. Perceived learning, though it has its advantages, might not always be an accurate estimation of actual learning.

Another relevant study was conducted by Rasmussen et al. (2006) where students conceptual understanding of differential equations was explored in IBL and traditional classes. The results also supported the effectiveness of IBL. However, several notes need to be made about the measurement of conceptual understanding in this study, as well. First, the validity evidence for the instrument used was limited (Kwon, Allen, & Rasmussen, 2005). Second, the measure was administered only as a posttest assessment (without a pretest) and only to volunteers after the final exam.

Both studies also used data that were aggregated across classrooms. While data aggregation has its pros in terms of increasing sample sizes and, therefore, increasing the power of statistical comparisons, it may have cons, as well. Our main concern is that by considering students from different classes as one sample, important class-level differences may be overlooked. These differences, may contribute to differences in learning outcomes between classes. Examples of such class-level differences may include different quality of teaching of different instructors or different implementation of the same teaching approach.

Due to the limitations of the studies of Laursen et al. (2014) and Rasmussen et al. (2006) discussed above, we decided to explore the effects of student-centered instruction on student conceptual understanding using a validated content instrument, administered during class time at the beginning and end of the semester. We specifically focused on differential calculus as (1) it is one of the fundamental college mathematics courses, and (2) the content measure for this material was already developed and validated. We also decided to consider each class individually to explore the effects of instructional approaches holistically. In this study, we examined two different student-centered instruction types and one traditional instruction type. The decision to study two different student-centered instruction types instead of one is consistent with the suggestions drawn from the meta-analysis of Freeman et al. (2014). This meta-analysis encouraged further research to focus on "second-generation research," which compares courses that differ in active learning implementation, rather than on "first-generation research," which compares active learning courses with traditional ones. The three studied classes are described in the next section.

Methods

Context

Course. The study was conducted in the three course sections of Calculus I, the first course in the calculus sequence. This mainstream course has the traditional material on limits, derivatives, the integral, and culminates in the fundamental theorem of calculus. All three sections met twice a week for a lecture with a professor (1 hour and 50 minutes each) and once a week for a recitation with a graduate teaching assistant (50 minutes). The study was conducted during the same academic year with the data collection in the first two classes done in the fall semester and in the third class in the spring semester.

Lectures. The lecture portion of the first class was taught in an active learning classroom with most of the class time dedicated to conceptually oriented problem solving (COPS) and whole class discussion (the COPS class). The ALT classroom has 8 round tables with 9 seats at each table (a total room capacity is 72). The room also contains flat screen displays (one per table), and whiteboards that cover the walls. In the COPS class, class periods typically started with resolving any questions or problems that students encountered doing homework or that remained from the last class period. The professor would ask students to write their concerns on a whiteboard, and then have a whole class discussion to address the concerns. Then, the professor would lecture for a short period of time (10-20 minutes), followed by student active work that would take the majority of the class time. The active work typically included student group work on worksheets that consisted of conceptually oriented problem sets. The groups were self-selected and included 4-5 students each. The students were also encouraged to work on whiteboards to show their solutions. During this part of the class, the professor and undergraduate learning assistants walked around the classroom and talked to students to monitor their progress and answer or pose questions. If a common question or misconception arose, the professor would often address it via a whole-class discussion. To wrap up the active work, the professor would ask students to do a gallery walk and/or would hold a whole class discussion. At the end of the class, students typically turned in their completed worksheets.

The lecture portion of the second class was taught in a traditional lecture hall and implemented practice problems (PP) during lectures (the PP class). Similar to the COPS class, this class also started with the professor answering student questions. Then, the professor would present new material and work through an example problem. Next, students were asked to solve a similar problem in groups (i.e., their neighbors) or individually, as they preferred. During this part of the class, the professor and learning assistants circulated around the classroom to monitor student progress and answer questions. After most students finished, the professor would write down the solution suggested by the students and then discuss it with the whole class.

The lecture portion of the third class was also taught in a lecture hall but utilized primarily direct instruction (DI), the DI class. This professor prepared handwritten notes of the material (typically, proofs) and projected them on the screen in class. He/she would talk through the projected notes and then show an example problem on the board. This professor also incorporated graded quizzes in class which usually consisted of true-false questions (typically conceptual) to check student understanding of the material. Answers to the quizzes were discussed during the following lecture. In this class, no group work was utilized.

Recitations. Recitations for the COPS and DI classes were taught by the same teaching assistant in a primarily lecture style. This teaching assistant would typically answer student questions, if any, conduct quizzes if required by the professor, and then explain the material and show solutions for example problems. Recitations for the PP class were taught in an active style with most of the class time dedicated to answering students' questions, addressing their concerns, and clarifying misconceptions.

Participants

The three professors who participated in the study were experienced mathematics faculty members with similar goals for Calculus I classes. All of them aimed for students to have a mastery of both concepts and procedures by the end of the course. In addition, all of them wanted students to be actively involved in class and ask questions. The teaching assistants – recitation instructors – were both graduate students studying mathematics. The recitation instructor for the PP class was an experienced teaching assistant; the recitation instructor for the

COPS and DI classes was a new teaching assistant at the university where the study was conducted, though he/she had teaching experience at a different institution.

A total of 151 undergraduate students participated in the study (49 in the COPS class, 64 in the PP class, and 38 in the DI class). The students were enrolled in the Calculus I course at a large, suburban public university located on the east coast of the U.S. Student demographic information is presented in Table 1. In the COPS class, most participants were sophomores; in the PP class, the majority were freshman; in the DI class, freshman and sophomore students were enrolled in about the same proportion. Students' GPAs (self-reported) in all classes varied greatly. In terms of gender, in the COPS class, about a half of students were male, while in the PP and DI classes, the majority of students were male. Students also varied in race and ethnicity. In all classes, about a half of students were White and about a quarter were Asian. Notably, the DI class had more African-American students than the other two classes. Lastly, in the PP class, students were, on average, 19 years old; in the COPS and DI classes, they were, on average, 20 years old.

Procedure

The Calculus Concept Inventory (CCI; Epstein, 2007), a measure of conceptual understanding of differential calculus, was administered in all three classes at the beginning and end of the semester during recitations. Additionally, at the end of the semester, students were also asked to complete a demographic form. Students received a small amount of extra credit for participating in the study. They also received their individual scores on the inventory. The instructors received only class average scores. After the semester was over, the instructors also participated in interviews, during which they were asked mainly about their teaching practices in the classes in question and their teaching philosophies.

Results

Data Exploration

We computed descriptive statistics of CCI scores for each class measured at each point of time (the beginning and end of the semester). The averages and standard deviations are presented in Table 2. First, we were interested in whether students in each class showed growth over time. To answer this research question, we conducted three dependent samples t-tests with a Bonferroni correction ($\alpha=0.017$). The results revealed a significant effect of Time for the PP class, $t(63)=3.303$, $p=0.002$, but not for the COPS class, $t(48)=2.165$, $p=0.035$, or for the DI class, $t(37)=2.371$, $p=0.023$.

Next, we wanted to know if students in the three classes differed in their conceptual understanding on the pre- and posttest. To answer this research question, we conducted two ANOVA tests with a Bonferroni correction ($\alpha=0.025$). The results showed a significant effect of Class for both the pretest ($F(2,148)=5.466$, $p=0.005$) and the posttest ($F(2,148)=5.700$, $p=0.004$). Multiple comparisons – Tukey HSD tests – revealed a significant difference between the PP and COPS classes ($p=0.013$ for the pretest; $p=0.012$ for the posttest) and between the PP and DI classes on the pretest only ($p=0.017$).

Table 2
Descriptive Statistics for CCI

	Mean (SD)			
	COPS (N=49)	**PP (N=64)**	**DI (N=38)**	**Total (N=151)**
Pretest	6.43 (3.03)	8.06 (3.18)	6.37 (2.56)	7.11 (3.08)
Posttest	7.33 (3.60)	9.28 (3.77)	7.37 (3.11)	8.17 (3.66)

Differences in Conceptual Understanding between Classes over Time

To determine whether there was a difference in student conceptual understanding of differential calculus between classes over time, we conducted a mixed design ANOVA with Time as a within subjects factor and Class as a between subjects factor (see Figure 1). The results indicated a main effect of Time ($F(1,148)=19.160$, $p=0.000$), i.e., students' conceptual understanding, averaged across classes, was higher at the end of the semester ($M=7.11$; $SD=3.08$) than at the beginning ($M=8.17$; $SD=3.66$). The results also showed a main effect of Class ($F(2,148)=6.811$, $p=0.001$). Multiple comparisons – Tukey HSD tests – revealed that students in the PP class had significantly higher conceptual understanding, averaged across time, than students in the COPS ($p=0.005$) or DI ($p=0.009$) classes. No interaction effect between Time and Class was found ($F(2,148)=0.187$, $p=0.830$). Thus, the changes in students' conceptual understanding in all three classes were not significantly different from each other.

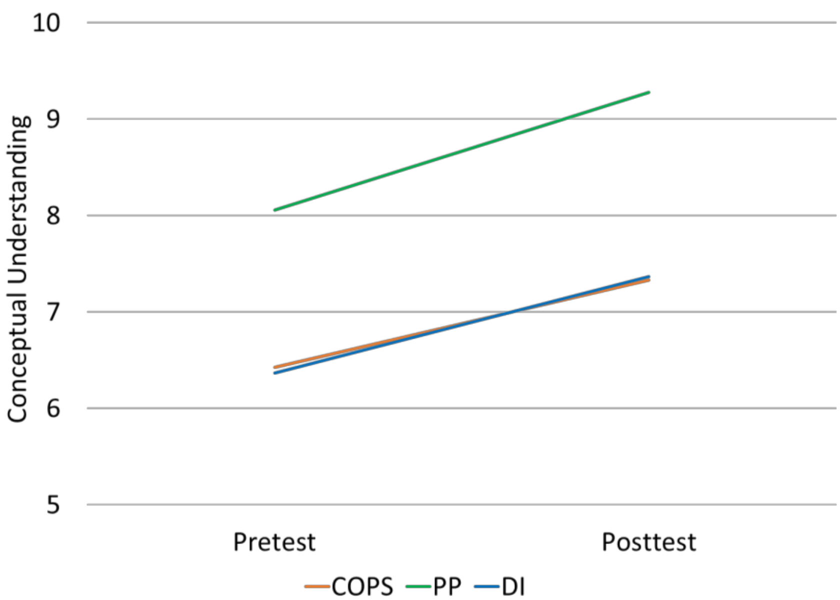

Figure 1. Pretest and posttest means for each class

Differences in Conceptual Understanding at the End of the Semester Controlling for Initial Understanding

To determine whether students differed in their conceptual understanding of differential calculus at the end of the semester controlling for their initial understanding, we conducted an ANCOVA test (see Figure 2). The results showed no difference between the classes in students' conceptual understanding at the end of the semester controlling for their initial understanding, $F(2,147)=1.065$, $p=0.347$. The adjusted means were as follows: 7.837 ($SE=0.398$) for the COPS class, 8.561 ($SE=0.353$) for the PP class, and 7.924 ($SE=0.452$) for the DI class.

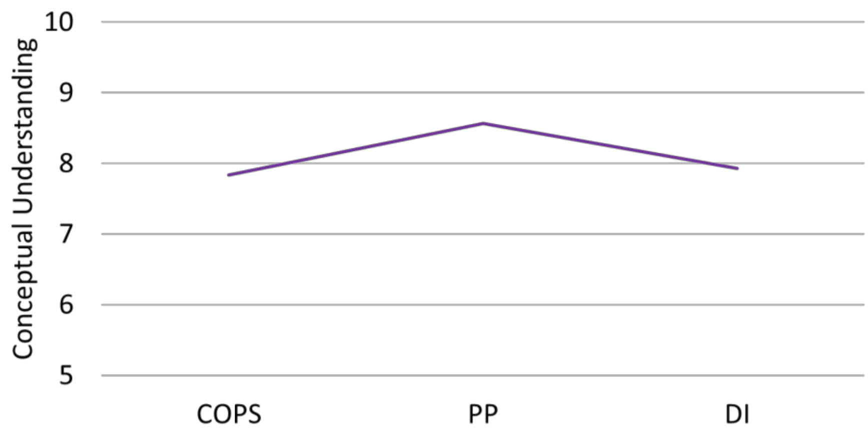

Figure 2. Adjusted posttest means for each class

Discussion

Our findings suggest that students' conceptual understanding of differential calculus is independent from the type of instruction when (1) conceptual understanding is measured by a validated, content instrument, and (2) the study is context-specific, i.e., when each class is considered individually instead of averaging across multiple classes. These nuances may explain why our results appeared to be different from the results of Laursen et al. (2014) and Rasmussen et al. (2006). In other words, implementation characteristics of a particular approach by a particular instructor in a particular course offering may lead to different levels of conceptual understanding and, therefore, need to be taken into account.

Among advantages of the study, we consider its ex post facto design, as no intervention was made. We aimed to explore the effects of teaching approaches in the most natural environment possible, and, therefore, chose to investigate the effects of the approaches typical to the instructors. Thus, this design provides a comprehensive picture of instruction implementation, where all elements of the instructional approaches are considered together. At the same time, a comprehensive picture of instruction has the disadvantage of making those elements with the most influence on the outcome challenging to identify. Therefore, future research should explore more context specific variations in approaches' implementation to determine potential commonalities between the effective ones. Another disadvantage of our ex post facto, context-specific design is a possibility for confounding variables to occur, as no control over the approaches is used. For example, the direct instruction in the recitations of the COPS class may have cancelled out the effect of conceptually oriented problem solving in the lecture periods. Finally, our study design substantially limits the generalizability of the findings.

ABSTRACT: *In the evaluation study presented in this paper, the authors compared the mathematical thinking of undergraduate students (as they responded to class work and interview prompts) who participated in an inquiry-based linear algebra course to a comparison group of students who participated in a traditional course.*

Key words: linear algebra, realistic mathematics education, inquiry based learning

The Problem

The literature on undergraduate mathematics shows that in traditional linear algebra classrooms students often memorize algorithmic methods that "work" even when not properly understood. Students develop understandings of matrix algebra and solving systems of linear equations using the Gaussian elimination, yet have problems with the more abstract notions of spanning set, linear independence and linear transformation (Stewart & Thomas, 2010). In the language of Sierpinska's modes of thinking (2000), the student dependent upon reducing a matrix to echelon form to determine whether vectors are linearly independent are thinking in *arithmetic mode*, whereas a student who is able to think more generally about objects as parts of a system, by applying a definition or theorem when appropriate, is thinking in *structural mode.* According to Bogomolny (2007), a notion of linear dependence as an object requires an understanding beyond the actual or intended procedures of row reduction toward an understanding of the structure of linear dependence relations as a set of vectors. While one mode of thinking is not given precedence over the other, and row-reduction and similar techniques are an important component of linear algebra, it is important for students to be able flexibly use an appropriate mode in a given context. According to Sierpinska (2000), despite a decade of innovations in the teaching of linear algebra "the students in our experiments could not understand the theory because they appeared to want to grasp it with a 'practical' rather than a 'theoretical' mind." (p. 211). Dubinsky's APOS theory (1994) has been used extensively since to characterize the ways in which students struggle with linear algebra concepts (eg. Stewart & Thomas 2010, 2009; Wawro, Rasmussen, Zandieh, Sweeney & Larson, 2012;). An inquiry based learning (IBL) course in linear algebra was designed based on the notion of mathematics as "mathematizing" (Freudenthal, 1991) in order to circumvent a purely arithmetic understanding of linear algebra concepts. This study compared the thinking of linear algebra students that participated in the IBL course to a comparison group of students who participated in a traditional course.

Theoretical Framework

Our framework is adapted from Stewart & Thomas (2009, 2010). Tall's three mathematical worlds (embodied, symbolic and formal) depict a progression in the development of mathematical thinking (Tall, 2004)) and coincide with the modes of reasoning purported in Sierpinska (2000). The *embodied world* uses physical attributes to build conceptions. Similarly the synthetic-geometric mode of thinking is one that is intuitive, practical and is used as a heuristic tool to aid thinking in the analytic modes. Tall's symbolic world is one in which symbolic representations of concepts are acted upon and manipulated. This corresponds to Sierpinska's *arithmetic mode* in which the appropriate use of formulas and techniques that allow one to solve problem concerning vectors and matrices are developed. The *symbolic world* is where Dubinsky's (1994) actions, processes and objects are constructed and symbolized.

According to APOS theory an action occurs as an instance of problem solution by the student—it is dependent upon a particular problem (Dubinsky & McDonald 2001). When this action is reflected upon, in such a way that the action can be imagined without being carried out, then the action has become a process. A process becomes an object when the student becomes aware of the totality of the process and is able to encapsulate it as a single entity or object. In Tall's formal world the properties of objects become formalized into axioms. This corresponds to Sierpinska's *structural mode* emphasizing connections between concepts and is concerned with vector spaces and linear transformations. The formal world with its emphasis on structural thinking is where objects become part of the learner's schemata. To illustrate consider Figure 1 below.

	Embodied World-Visual-Geometric Thinking	**Symbolic World - Arithmetic Thinking**	**Formal World – Structural Thinking**
Action	Can add multiples of two given vectors in R^2 or R^3 to visually determine whether a third is a linear combination of the given vectors.	Can test if a set of vectors is linear independent by constructing a matrix with the vectors as columns and row reducing it.	
Process	Can generalize this visualization process to two arbitrary vectors v_1, v_2, v_3 in R^2 or R^3.	Can think about the action above without actually carrying it out.	
Object	Can operate on this visualization of linear independent vectors (eg. transforming them via reflection, rotation, etc)	Understands process as above and can operate on the resulting matrix (eg. knows that if matrix has a pivot in every column then the original set of vectors is linear independent.	Shows set of given vectors is linear independent by definition by considering the vectors space that the vectors are in (eg. gives a dimensional argument)

Figure 1. Framework Using Three Worlds and APOS With Illustrations of Linear Independence.

Inquiry Based Learning Course

The IBL courses offered at this university are based on the premise that all of mathematics teaching and learning should consist of students mathematizing, as proposed in Realistic Mathematics Education (RME) (Freudenthal 1991, Gravemeijer, 1994, 1997). Within RME a learner comes to "know" by re-inventing mathematics, with the teacher as guide, as the learner responds to authentic problem contexts that are chosen to bring forth big ideas in mathematics (Schifter & Fosnot, 1993). Big ideas are the central, organizing ideas of mathematics—principles that define mathematical order such as linear independence, basis and linear transformation. The emergence of big ideas in learners occurs as a certain shift in mathematical thinking often evidenced by changes in strategy and model use. When learners participate in this kind of mathematical inquiry they are said to be mathematizing. According to Treffers (1997) *horizontal mathematizing* involves students in developing mathematical tools that help them to organize and solve a problem located in an embodied context that they can then generalize to use in other embodied contexts. *Vertical mathematizing* involves the forming of conjectures while working on problems that encourage finding shortcuts and discovering connections between concepts and strategies and then applying these discoveries (Treffers, 1987). Both types of mathematizing were incorporated into this course.

Horizontal mathematizing influenced the choice of course materials (Wawro, Rasmussen, Zandieh, Sweeney & Larson 2012), whereas the vertical counterpart influenced the structure of the centerpiece assignment in the course – the course wiki. In lieu of a textbook, students worked from a scaffolded sequence of tasks (the course notes) and recorded their findings in the form of a whole-class wiki, which ultimately served as their reference text. All of the Inquiry Oriented Linear Algebra task sequences were incorporated into the course notes (Inquiry-Oriented Instructional Materials website, n.d.). However, instead of presenting students with theorems, the students generated conjectures, which they recorded, revised and supported in the course wiki, which was intended to support student ownership of the material. Students could support conjectures with examples or proofs and this support was revised throughout the semester. These activities were intended to support students as they began to transition from embodied and symbolic thinking to structural thinking and participation in the formal world (Tall, 2004). Additionally, students build ``concept pages'' in the wiki, which included i) the definition of the concept, ii) information on and hyperlinks to key examples that illustrate applications of the concept and iii) additional information that provides intuition for the concept, information on the importance of the concept or explains the origins of the concept, including hyperlinks to relevant section and concept pages. All intended as opportunities for mathematizing.

Methods

During Fall 2014 data were collected from the linear algebra course as part of a larger research study to trace the efficacy of inquiry-based courses. Data were collected via examination questions and task-based interviews in order to compare the thinking of students in the inquiry and traditional classes. Two common final exam problems were given. Responses were collected and compared between student in the inquiry-based course (n=20) and a comparison group of student in the traditional course (n=20). Students in the comparison group were top course performers purposively sampled from those students who had expressed an interest in taking the inquiry-based course but who had not fit that course into their schedule. These students were enrolled in a traditional course with an experienced instructor.

Participants

In addition to the student responses described above, four students in the inquiry group and four students in the traditional group agreed to participate in an interview. The interviews were conducted during week 10 of the quarter and took between 30 and 40 minutes each.

Data

Final examination questions. Two common problems (see Figure 2 below) were placed on the final in both classes. In order to ensure that the items were accessible to the traditional students, Professor 1 who was teaching the traditional course shared his exam with Professor 2, the instructor for inquiry-based course, 3 days before the final was to take place. Professor 2 selected the two items from Professor 1's exam. Responses to these items were obtained from the course instructors. The data were used to compare students' ways of thinking about linear algebra concepts.

Problem 1a and b

3. Suppose the reduced row echelon form of a matrix A is $\begin{bmatrix} 1 & 2 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}$. How many solutions are there to $A\vec{x} = \vec{0}$? Does $A\vec{x} = \vec{b}$ always have a solution, or is it inconsistent for some vectors $\vec{b}$?

Problem 2

. Is $\begin{bmatrix} 0 & 0 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$ diagonalizable?

Figure 2. Common Final Exam Problems.

Task-based questions from interviews. Participants were asked to (1) describe their learning experiences in their linear algebra course, (2) express the big ideas in the linear algebra class, (3) talk about how they would solve two linear algebra problems that involved an understanding of span, linear independence, basis and linear transformation (figure 7 below).

Analysis and Results

Final exam question analysis. Student graded responses to final exam items and verbal and written/verbal responses to the task-based interview questions were coded in three ways: (1) Responses were categorized as correct/ incorrect; (2) Responses were open coded number based on the type of solution strategy used; (3) Strategies codes where grouped into themes using the framework in figure 1 as a guide.

Table 1. *Comparison of Errors Between Groups*

	Inquiry- Based Group (n=20)		Traditional Group (n=20)	
	# Computational errors	# Conceptual errors	# Computational errors	# Conceptual errors
Problem 1a	1	2	0	3
Problem 1b	0	1	1	4
Problem 2	3	3	6	3

While the number of errors in the groups were quite similar (slightly favoring the inquiry group) very different solution methods between the groups for problem 1a and 1b were observed. In problem 1a, the inquiry group most often found the kernel or the solution set to the homogeneous system to show that there are infinitely many solutions (9/17 with correct answers), whereas the majority of the traditional groups stated, "there was a free variable" (13/17 with correct answers).

Arithmetic thinking with connection to embodied world.	1. (15 pts) Suppose A is a 3×3 matrix with reduced row echelon form $\begin{bmatrix}1&2&0\\0&0&1\\0&0&0\end{bmatrix}\begin{bmatrix}x\\y\\z\end{bmatrix}=\vec{0}$ $x+2y=0$ $z=0$ $x=-2y$ $z=0$ $s\begin{bmatrix}-2\\1\\0\end{bmatrix}$ (a) How many solutions are there to $A\vec{x}=\vec{0}$? There are an infinite number of solutions to $A\vec{x}=\vec{0}$ such that $\vec{x}$ lies on the line defined by: $s\begin{bmatrix}-2\\1\\0\end{bmatrix}, s\in\mathbb{R}$
Arithmetic Mode of Thinking	(b) Does $A\vec{x}=\vec{b}$ always have a solution, or is it inconsistent for some vectors $\vec{b}\in\mathbb{R}^3$? If, after row reductions to RREF, the 3rd entry is no zero. (i.e 3rd row looks like: $0\,0\,0 \mid b \Rightarrow b \neq 0$) b/c there is no way for $0x+0y+0z=b$ to have a solutio
Structural Thinking/ connection to embodied world.	(b) Does $A\vec{x}=\vec{b}$ always have a solution, or is it inconsistent for some vectors $\vec{b}\in\mathbb{R}^3$? $A\vec{x}=\vec{b}$ does not always have a solution because the column space of A does not include all of $\mathbb{R}^3$ (the first and se columns are linearly dependent). As a result, any vector $\vec{b}$ does not lie on the x, y plane will not satisfy this equation.

Figure 3. One of the Common Final Exam Problems

The expectation in the inquiry-based class for the student to justify their answers may be responsible for this difference. For problem1b, most students across groups gave an example of a vector that made the non-homogeneous system inconsistent (comparison group 9/15, inquiry group 7/ 19), however 10 of the 19 inquiry based group for whom the problem was scored as correct and only 3 of the 14 in the comparison group gave an argument that took into consideration the fact that they were working with the augmented matrix rather than the matrix itself.

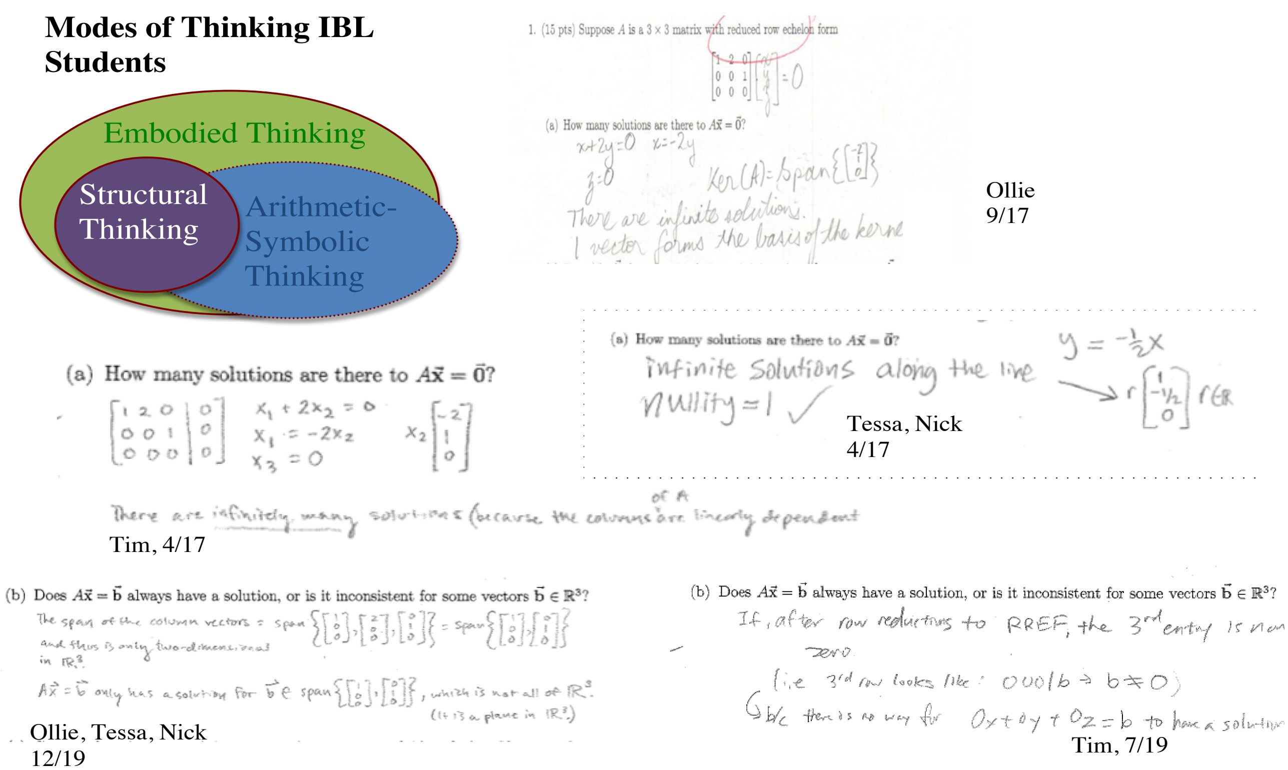

Figure 5. IBL Student Thinking

Using the framework to qualitatively classify student responses results indicate that in some instances 2 times as many students in the inquiry-based group were operating at both the *arithmetic* and *structural modes* (Exam question 1 part a: 7, 5) (Exam question 1 part b 10, 5 respectively). The solution methods were quite different between the groups with the inquiry-based group flexibly using two modes of reasoning--solving the system arithmetically followed by structural thinking to create the solution space while the traditional group used purely arithmetic modes of reasoning.

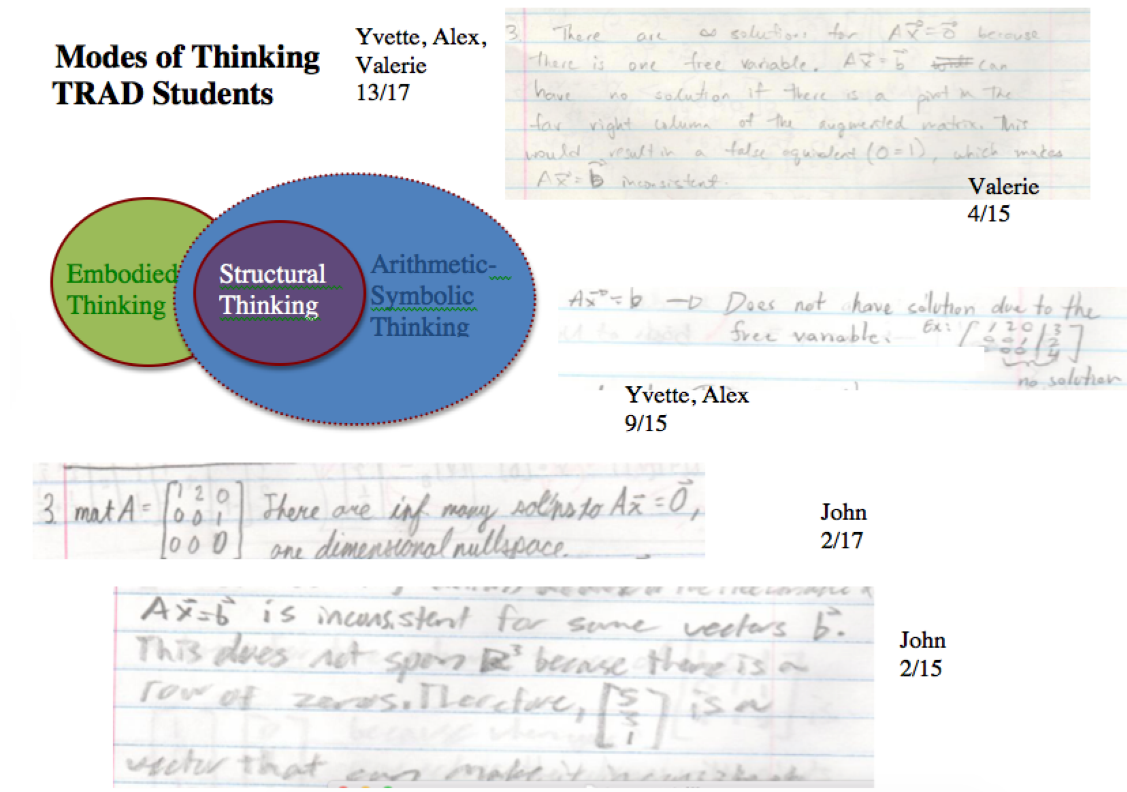

Figure 6. TRAD Student Thinking

Interview Analysis

In order to investigate students' modes of thinking in more depth, we interviewed eight students (four traditional and four students in the inquiry-based course). Table 2 below shows these interview participant demographics.

Table 2. *Interview Participant Demographics*

	Physics		Chemistry		Computer Science/Engineering	
	Male	Female	Male	Female	Male	Female
4AI (n=4)	2	1	1			
4A (n=4)	1				2	1

All participants were freshman, had comparable mathematics backgrounds and this course their first college math course. The purpose of the interviews was to further explore students' thinking about the linear algebra topics they were learning—in particular to explore their concept image (Tall & Vinner, 1991) of spanning set, linear independence, basis and transformation and their perspectives on the big ideas in linear algebra. Analysis of students' ideas about the big ideas in linear algebra is currently being analyzed to triangulate the findings from the common final items and the interview tasks. Table 3 below shows how these eight students' thinking on the final exam its were categorized.

Table 3. *Interview Participants' Thinking on Final Exam Items.*

Name	Part A		Part B	
	Strategy	Type of Thinking	Strategy	Type of Thinking
Alex (TRAD)	States free variable	Arithmetic Thinking/Process conception	Uses free variable	Cannot determine
John (TRAD)	Uses dimension of the null space	Structural reasoning	Columns don't span R^3	Structural reasoning
Yvette (TRAD)	States free variable	Arithmetic Thinking/Process conception	Uses free variable	Cannot determine
Valerie (TRAD)	States free variable	Arithmetic Thinking/Process conception	Gives a vector that doesn't have a solution	Arithmetic thinking
Nick (IBL)	Solves and presents solution set as a line	Geometric/Arithmetic	Span of LI column vectors does not span all of R^3	Structural reasoning
Ollie (IBL)	Uses dimension of the kernel	Structural reasoning	Span of LI column vectors does not span all of R^3	Structural reasoning
Tessa (IBL)	Solves and presents solution set as a line	Geometric/Arithmetic	Span of LI column vectors does not span all of R^3	Structural reasoning
Tim (IBL)	Uses columns are linearly independent	Structural reasoning	Gives a vector that doesn't have a solution	Arithmetic thinking

Figure 7 below depicts the strategies used by students on interview tasks and illustrates how the interview responses were coded similarly to the common final items and according to the three modes of thinking (Sierpinska, 2000). The first interview item was given to see if students had made connections between linear independence and spanning set. It was also used to see whether students were able to instantiate formal definitions and use them to form logical arguments. All four of the inquiry-based and two of the traditional group were able to instantiate and act upon their understanding of the connection between span and linear dependence to solve the problem. These students had an object conception of span and linear dependence and were operating in the formal word.

Interview Problem 1 *Suppose that Span {$v_1, v_2, v_3, \ldots\ldots, v_n$} = V and w is a vector in V.* *Is the set {$v_1, v_2, v_3, \ldots, v_n$, w} linearly independent (Justify your answer)?*	IBL Group (n=4)	TRAD Group (n=4)
<u>Structural Thinking.</u> Acts upon the definition of span to argue structurally that since w is in the spanning set then by definition it is a linear combination of a subset of the v_i and hence by definition of LI the set is not LI.	3 (Tim, Tessa, Ollie)	1 (Valerie)
<u>Geometric Thinking</u> Acts upon the definition of span and LI and thinks geometrically. When I think of span I think of where we can go if these v_1, v_2, ...v_n are means of transport. Span is all of the possible regions you can reach with these linear combinations. So now w is a vector in V and so is already reached by this set of vs – it doesn't really take me anywhere new so therefore the set is linearly dependent.	1 (Nick)	
<u>Erroneous Structural Thinking</u> Incorrectly acts upon the definition in the problem. Erroneously assumes that the space is n-dimensional and uses dimensional argument.		2 (Alex, John)
<u>Arithmetic Thinking</u> Thinks arithmetically, bypasses notion of span and thinks of LI as a process. "Row reduce" homogenous matrix or set up an augmented matrix.		1 (Yvette)

Interview problem 2:

Let $T : R^2 \to \mathbb{R}^3$

$$T\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x+y \\ 3x-y \\ 2x+4y \end{pmatrix}$$

Is it possible to find v_1, v_2, $v_3 \in \mathbb{R}^2$ such that $T(v_1)$, $T(v_2)$, $T(v_3)$ is a basis for $\mathbb{R}^3$?

<u>Geometric-Embodied/Structural Thinking.</u> Recognizes that the image of T is a two-dimensional subspace of R^3 hence not possible to find a basis for R^3.	Ollie, Tim	John
<u>Arithmetic-Structural Thinking</u> Starts to row reduce the matrix that defines the transformation to find the basis and concludes that no such basis can exist based on a dimensional argument.	Nick	
<u>Arithmetic Thinking</u> Say that it is possible by mapping the standard basis in R^2 via the transformation but does not complete the calculations.	Tessa	
<u>Arithmetic Thinking</u> Says that the basis exists and the way to find it is by row reducing the matrix that defines the transformation.		Valerie
Says it is possible but does not give reasoning.		Alex
Doesn't attempt the problem		Yvette

Figure 7. Coding Examples of Interview Questions

Even though this item was constructed to circumvent an approach that used matrix multiplication two of the traditional group demonstrated that they were dependent upon an action concept of linear dependence by saying that they would set up the vectors as columns in an *m x n* matrix and row reduce to see if the RREF was the identity matrix. This type of solution is dependent upon being given actual numbers and hence these students were not able to solve the problem (see Yvette example in Figure 8 below).

Suppose that Span $\{v_1, v_2, v_3, \ldots\ldots, v_n\} = V$ and w is a vector in V. Is the set $\{v_1, v_2, v_3, \ldots, v_n, w\}$ linearly independent (Justify your answer)?	
Category	**Example of student thinking**
Arithmetic thinking with process conception of linear independence.	"OK so for this one I would, wait ... [writes the vectors v_1, $v_2, \ldots, v_n$ as the columns of a m x n matrix]. I would just row reduce this and see if there are any free variables in the set. If there were then that would mean that the set were linearly dependent. If it were linearly independent there would be no free variables and there would be a pivot in every column." [Yvette]
Geometric thinking, using the "model for" in MCR (Wawro, Rasmussen, Zandieh, Sweeney & Larson, M. 2012)	When I think of span I think of where we can go if these v_1, v_2, ….v_ns are means of transport. Span is all of the possible regions you can reach with these linear combinations. So now w is a vector in V and so is already reached by this set of vs – it doesn't really take me anywhere new so therefore the set is linearly dependent.
Structural thinking but unable to "operationalize" the notation in the given definition.	The span of these vectors is this vector space and w is a vector in v, so is this set linearly independent? Well let's see, I am going to try to do a counter example if we have…so what I am going to do I know I have n vectors so I know that I can have at most n vectors in R^n, so if I added w to the set then that would exceed the number of vectors that I can have therefore this is not linearly independent." [John]
Structural thinking with object conception of linear independence.	The set containing w would be linearly dependent because if you have a span of all of these vectors and w is in that span then by definition you can add up some number of these, a linear combination of the vs, to get w [Tim, Tessa, Ollie, Valerie]

Figure 8. Examples of Student Thinking on Interview Item 1.

The remaining two students from the traditional group erroneously assumed that $V = R^n$ and incorrectly used the proposition proved in class that states there are at most n linearly independent vectors in a basis for R^n. These students appeared to be trying to operate in the formal world but possibly have not developed an object conception of linear dependence (see John example in Figure 8 above).

The second item, depicted in Figure 9 below, was used to understand whether students had formed an object conception of basis. Two of the inquiry students and one of the traditional students combined geometric and structural thinking (see John example). One of the inquiry students showed an object conception of basis by operating between the arithmetic-structural modes by reducing the matrix that defines the transformation to RREF and concluding that a basis does not exist as the matrix has 2 linearly independent columns (see Nicks example). Two traditional students showed erroneous arithmetic thinking by stating that such a basis did exist by reducing the transformation matrix to echelon form.

<table>
<tr><td colspan="2">Let $T : R^2 \to \mathbb{R}^3$
$$T\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x+y \\ 3x-y \\ 2x+4y \end{pmatrix}$$
Is it possible to find $v_1, v_2, v_3 \in \mathbb{R}^2$ such that $T(v_1), T(v_2), T(v_3)$ is a basis for $\mathbb{R}^3$?</td></tr>
<tr><td>Geometric Thinking</td><td>“I would have to say that you cannot because you are starting with a two dimensional space and this just transforms it to a plane. A plane cannot represent the whole space.” [John]</td></tr>
<tr><td>Thinking structurally across worlds</td><td>“It gives you a transformation and asks if it possible to find 3 vectors in R^2 such that the transformation in R^3 forms a basis for R^3. So if these three are a basis in R^3 then that means that they have to be independent. Now the transformations come from R^2 over here so one thing we can do is just try to find a matrix for the transformation. So just using these components work, this has to be 3,1 this has to be 3, -1 and this has to be 2, 4. Now the transformation acts on these vectors in R^2 we might have v_1, v_2 and v_3 and we want to check that $T(v_1)$, $T(v_2)$, $T(v_3)$ are independent, right?

If we get this to RREF, if we get the matrix associated with the transformation into RREF then that is going to end up being this matrix right here, because we only have 2 pivots because this…if you want to multiply a matrix and you are given three vectors here, v_1, v_2 and v_3, let’s make them into a matrix V. Actually lets call it [x_1, y_1; x_2, y_2; x_3, y_3] that gives us a 2 by 3 matrix and if we want the columns of this matrix to be independent then we are going to have 3 pivots but this matrix has only 2 pivots and this matrix at the best can only have 2 pivots because the pivots can never exceed the number of rows and columns. In matrix multiplication all you are doing is looking at linear combinations of rows and columns you can never have more than 2 pivots in the answer so this is impossible. “ [Nick]</td></tr>
</table>

Figure 9. Example Student Responses From Interview Item 2.

One student from the inquiry-based class started by applying the transformation to the standard basis in R^2 to get a basis for R^3. She convinced herself that this was a viable approach and that a basis did exist. One traditional student stated that such a basis could be found but did not give any rationale. The final traditional student did not attempt the problem.

Significance

Few studies have compared the understanding of students in inquiry-based versus traditional courses. We have presented data that suggests ways in which students in an inquiry-based linear algebra course have different understandings of concepts than students who have taken a traditional course. One reason that comparison studies are rare is due to the self-selection of students into non-traditional courses. This study circumvented the issue by forming the comparison group with students who self-selected into the non-traditional course but who could not take it due to schedule conflicts.

Data Cleaning in Mathematics Education Research: The Overlooked Methodological Step

Aleata Hubbard
WestEd

The results of educational research studies are only as accurate as the data used to produce them. Drawing on experiences conducting large-scale efficacy studies of classroom-based algebra interventions for community college and middle school students, I am developing practice-based data cleaning procedures to support scholars in conducting rigorous research. The poster identifies common sources of data errors in mathematics education research and offers a framework and related data cleaning process designed to address these errors.

Key words: Research methodology, Efficacy studies, Algebra

The results of educational research studies are only as accurate as the data used to produce them. Screening data for potential errors and ensuring anomalies do not influence analyses is an essential step of the research cycle (Wilkinson, 1999). Odom and Henson (2002) demonstrated how regression models of high school seniors' mathematics achievement varied depending on the level of screening applied to the publicly available High School and Beyond National Survey data set. As another example, Whalley (2011) analyzed the Panel Study of Income Dynamics data set to show how the choice of trimming procedures (i.e., methods for removing outliers) effected estimates of the relationship between education and labor income volatility. Educators and policy makers rely on study results to make decisions that influence the lives of many. It is important that scholars understand and apply appropriate methods for ensuring high quality data.

The process of identifying, resolving, and documenting data inconsistencies is called *data cleaning* (Rahm & Do, 2000). Despite the importance of data cleaning in rigorous research practice, most methodology courses only give cursory attention to the topic (Osborne, 2013). Therefore, scholars often acquire cleaning strategies heuristically, making it difficult for others to accurately judge or replicate studies (Leahey, Entwisle, & Einaudi, 2003). Furthermore, my conversations with scholars new to large-scale research suggest many underestimate the amount of time and resources required to properly clean data. Data collection and data preparation each can take about 20% of project time (Munson, 2012). Well-established standards for data cleaning could facilitate the integration of this topic into researcher training and support educational researchers in accurately planning their studies.

Drawing on my experiences conducting statewide and nationwide efficacy studies of mathematics interventions, I am developing practice-based data cleaning processes to support research in classroom settings. While data cleaning can be applied to many forms of data (e.g., interviews, observations, documents), I focus on quantitative data gathered from surveys, questionnaires, assessments, and demographic records. Specifically, I ask: (1) What are the sources of data errors and challenges in educational research studies conducted in authentic mathematics learning environments? (2) How can a data cleaning process be designed to consistently produce accurate, reliable, confidential, and timely datasets?

Methods

Two large-scale efficacy studies inform the framework presented here. *Study A* was a three-year, nationwide study of revisions to a popular mathematics curriculum involving over 10,000 middle school students and 180 mathematics teachers. Students completed between five and eight end-of-unit assessments on paper, two attitude surveys, and two mathematics assessments either on computers or on paper. Teachers completed weekly logs and two teaching knowledge assessments, all electronically. School districts provided demographic data and state test scores for participating students. *Study B* is a two-year statewide study of the use of a computerized interactive learning platform in community college elementary algebra courses. The first year of the college-level study involved approximately 400 students and 89 instructors across the state; the second year of the study is underway. In this study, all data is collected electronically. Students complete two mathematics assessments, a background questionnaire, an academic motivation questionnaire, and an end-of-semester survey. Log data of student interactions in a web-based activity and testing system are also collected. Instructors complete assessments of knowledge of technology in teaching and content knowledge for teaching, background questionnaires, and weekly logs.

An initial data cleaning process was created for Study A based on prior experiences with small-scale research and evaluation projects. Across the three years of Study A, the data team documented their data related challenges and associated resolutions, revising the Study A data cleaning process as they went along. The revised process was also compared against rigorous research standards in the What Works Clearinghouse Procedures and Standards Handbook (2016), ethnical research guidelines around privacy and confidentiality (OHRP, 1993), general data modeling rules from the field of computer science, and data management practices used in educational survey research (e.g., Schleicher & Saito, 2005) and in statistics (e.g., de Jonge & van der Loo, 2013). The modified data cleaning process is being implemented in Study B.

Researcher's Role and Background

Describing one's background and one's role in research allows readers to understand the perspective researchers bring to their work (Creswell, 2012). Drawing on my undergraduate training in computer science, I applied my knowledge of data modeling and databases to the framework described in this paper. My research training in learning sciences provided me with the domain knowledge needed to understand the contexts of Study A and Study B, to understand how data could be organized for useful analysis, and to identify anomalies that might signal problems at other stages of the research cycle.

I was involved in multiple aspects of Study A including participant management, data collection, data cleaning, data analysis, instrument creation, classroom observations, meetings with the research team, and professional development workshops for participating teachers. This level of involvement gave me a chance to confront data issues directly at many points across the study. For example, answering participant phone calls about the study provided insights into the ways teachers implemented study data collection tasks, which sometimes conflicted with researcher expectations (e.g., administering student assessments across multiple days). Working with researchers to conduct item-response theory (IRT) analyses and teams to score constructed response items highlighted the importance of distinguishing the reasons for which data were sometimes missing. My involvement in Study B was constrained to data management, working with a team to clean data files, and interacting with the project staff to stay abreast of study developments. This narrower role allowed me to focus more on the refinement of the data cleaning process.

Results

Data Errors and Challenges

Despite standardized procedures for administering and gathering data, data collection in large scale educational studies often result in a host of data cleaning errors that are, to some extent, unavoidable. Errors can include duplicated records, illegal values, missing values, or misspellings (Rahm & Do, 2000). In the studies described here, errors in the gathered data created the need to make decisions about issues such as handling duplicate records, the validity of an assessment completed on an incorrect form, and how to link records in a hierarchical research design when participant identifiers changed. Challenges in study implementation hindered the timely collection and cleaning of study data. Common sources of error and challenges in data cleaning for both studies are described below.

Variations in assessment administration. Schools and colleges differed in their schedules and access to computers. For example, many middle school class periods lasted 45 minutes while other schools operated on block schedules where class periods lasted 90 minutes. Some teachers with shorter class periods would administer paper-based assessments across two days, having students complete selected response items on the first day and constructed response items on the second day. The educational institutions within which Study A and Study B were conducted varied widely in their computer availability. Teachers with computers inside their classrooms easily administered online assessments for the study. However, teachers who had to reserve a computer lab often lost time in transitioning to the lab room or they held multiple administration sessions due to an insufficient number of computers for their students. A handful of teachers had no computer access and administered study assessments on paper. Lastly, some teachers requested Spanish versions of study assessments, which were only available on paper.

Understandably, teachers were responding to the realities of their school environments. However, some administration choices led to students completing part of an assessment on the wrong form or completing the assessment more than once. Differences in administration also complicated data cleaning processes. An assessment completed on paper, where students could write what they wanted, required different cleaning checks than the same assessment completed online, where computer-based forms restricted the possible answers permitted. Also, it became more difficult to account for test completion, both at the student level and the class level, when some items were received on paper and others online.

Participant mobility and late joiners. Some participants joined the studies after baseline data were collected and others changed institutions during the studies. This mobility was explained by various factors. First, families moved and in doing so placed their children into new school zones. Student mobility is common at the K-12 level in the U.S., particularly amongst students from urban areas, lower income families, or migrant, military, or immigrant families (Welsh, 2016). Student mobility occurred in Study A, particularly in schools near the U.S. border with Mexico that served large numbers of migrant families. Second, many community college instructors work across multiple institutions. In California, the location of Study B, 36% of associate faculty (e.g., part-time or adjunct instructors) teach at more than one institution in order to make a livable wage (Smith, 2013). While instructor mobility was not a significant issue to data collection for Study B, one participant unexpectedly taught the study-target course at different colleges each semester of the study. Third, research teams in both studies were confronted with low enrollment numbers and participant dropouts. Recruitment and retention of study participants in large-scale educational studies is challenging because it requires a long-term commitment from teachers who already have busy schedules (Gallagher, Roschelle, & Feng, 2014). This issue required (a) additional rounds of recruitment to obtain participant counts that allowed for sufficiently powered statistical analyses and (b) an extension of administration windows to allow for greater data collection. Lastly, a teacher strike that occurred during Study A delayed data collection for one district containing several consented participants.

Participant mobility resulted in some student participants in Study A moving between treatment and control groups and completing pre- and post-intervention assessments under different experimental conditions. In other instances, records at a given level of the study design appeared to be missing a link to records at the other levels of the study design. For example, when a teacher in Study B changed institutions, she was assigned a new participant identifier. During the cleaning process, data from students in her first semester course appeared unconnected to any teacher. Issues resulting from participant mobility introduced the need to (a) create new versions of data files that included late joiners and (b) make decisions about how to resolve participants linked to multiple classes, teachers, or schools.

Multiple participant names. Some participants became associated with multiple names and e-mail addresses and some had names that changed. In Study A, we often saw the name a student wrote on assessments differed from the name on the teacher's roster, which differed from the name provided by districts when collecting demographic information. In Study B, students used both school-provided and personal email addresses when completing study tasks. At the teacher level, names occasionally changed when participants changed marital status during the study.

As a consequence, participants sometimes appeared to have missing records because their data could not be matched to the legal name or school email address provided to the research team. Connecting individuals to the correct names and e-mails, a process called identity resolution in the field of computing, was time consuming and usually required direct communication with participants. Identity resolution was further complicated by the fact that some study participants had the same or similar names, sometimes within the same classroom.

External Vendor Systems. Assessment vendors (e.g., a company that hosts a website through which participants complete a test) and school districts were *external vendors* who provided participant data and hosted instruments in both studies. Over 65 school districts across 22 states provided demographic information and state standardized test scores for middle school student participants in Study A. Assessment providers host copyrighted instruments on their own websites and had specific rules regarding how paper versions of their assessments could be administered. Study A and Study B both used assessments offered through the University of California at San Diego's Mathematics Diagnostic Testing Project (MDTP).

External vendors typically used varied and conflicting conventions for data values. For example, in Study A, the ethnicity definitions across elementary school districts were wide-ranging. The category of Black or African American had values such as: 1, 4, Black/African American, Bl, and African Am. We decided to use standard categories provided by the National Center for Education Statistics[1] and transformed data values into these conventions. Confidentiality was also an issue because external vendors needed to identify participants but could not be provided with the identifiers used by our research team. If external vendors saw our research identifiers, they could easily identify specific participants in our publicly released datasets. This necessitated an additional set of interim identifiers to allow our data cleaning team to map data received from external vendors with our own participant records.

[1] Common Education Data Standards (CEDS) also provides a data dictionary for information related to pre-school through post-secondary educational environments that can be used to establish conventions for an educational research study.

Data Cleaning Process

My experiences with Study A highlighted the need to attend to data cleaning at all phases of the research cycle. I developed a list of tasks to accomplish during data planning, data collection, and data cleaning to minimize the issues likely to occur in educational data sets (see Table 1). My goal was not to eliminate issues from occurring, but rather, to create a reproducible process to improve the identification and handling of data errors in the cleaning process. Below I describe these tasks and their rationales.

Table 1

Data Cleaning Tasks

Task
Data Planning Phase
Create visually distinct instrument forms
Clarify data requirements and timeline with external vendors
Set administration windows and a last enrollment date
Determine decision rules for handling duplicate records
Develop codebooks for each instrument to describe variables and their possible values
Data Collection Phase
De-identify study data as early as possible in the data collection process
Collect details on how assessments were administered and any anomalies that occurred
Create three sets of identifiers for participants: one used by data collectors, one used by researchers, and one used by external vendors
Make sure identifiers do not depend on malleable participant characteristics
Verify administration dates on completed study instruments are valid
Data Cleaning Phase
Use tools that allow you to log and retrace your data cleaning steps
Establish a review process so data cleaning work can be checked by another person
Make a copy of your raw data file and only work with the copy
Check data files for missing and extra data columns
Apply codes to indicate types of missing data (e.g., not completed, not administered, optional)
Transform categorical values into pre-determined standard values
Check identifier columns for duplicate values
Flag records with errors
Indicate administration format in final data sets (e.g., completed on paper or online)

Data Planning Phase. In preparing to launch a study, research teams can facilitate future data cleaning by carefully planning the design of instrument forms, data collection timelines, decision rules for rejecting data, and instrument codebooks. Although these tasks are presented sequentially, in practice they can occur in any order and even concurrently. First, instrument forms should be visually distinct to help participants, administrators, and data collectors notice when an instrument was completed on the wrong form. This can be accomplished, for example, by using different colors, specifying instrument names and dates, and customizing templates to display the number of items and answer choices corresponding to the instrument form (see Figure 1). Second, research teams need to establish timelines for data collection and participant enrollment. This will require working with external vendors to understand the time and information they need to set up instruments or gather data. During this phase, research teams should familiarize themselves with the school calendars of study participants. For example, it would be extremely difficult for a middle school teacher to administer a study assessment during the week of state testing. Lastly, research teams need to consider the structure of their data and rules for rejecting data when issues occur. This can be accomplished by creating codebooks for each study instrument. Decisions for rejecting data may need to be made on a case-by-case base, but during the data planning phase research teams can consider the following question:

- When is it too late to accept data?
- How much of an instrument needs to be completed to be included in the dataset?
- How do we handle duplicate responses?

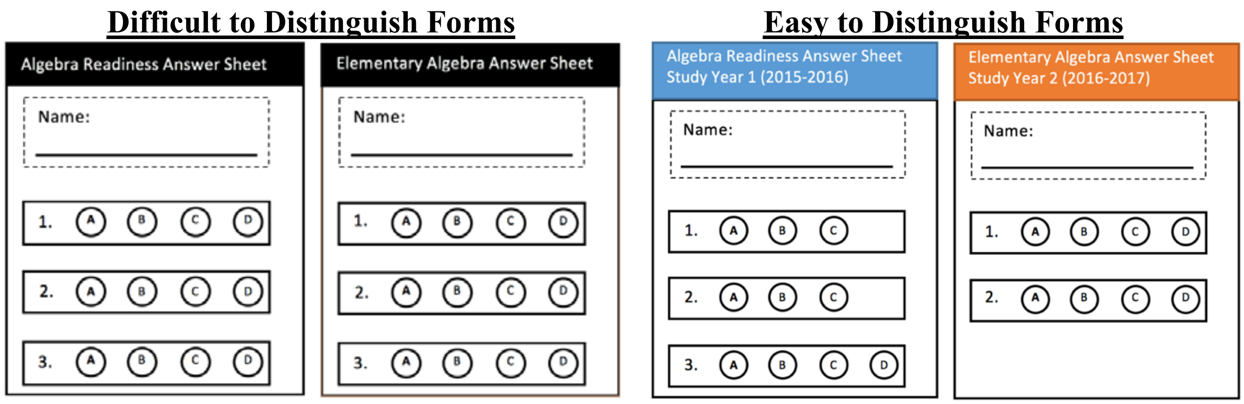

Figure 1. Sample Instrument Forms.

Data Collection Phase. Once a study has started, research teams can implement processes that make it easier to track data and to share real-time information with external vendors. First, de-identify study data as early as possible. The rationale behind this task is that people closer to participants will find it easier to identify who completed an instrument. When using paper instruments, we send teachers a list of barcode stickers that they distribute to specific students who then place the barcodes on their own assessments. These barcodes contain the student's study identifier and the instrument name which can be quickly entered into a tracking system using a barcode scanner. Second, research teams should collect information on instrument administration and any anomalies that occurred during administration. This can take the form of a feedback sheet administrators complete and send back with study data. When using online systems, this might require communicating with external vendors about any issues that appeared during administration (e.g., servers going down). Third, create unique identifiers for each study participant. Identifiers should not depend on characteristics that might change during a study. For example, a student identifier should not include the identifier of the student's teacher, because the student may change teachers or schools during the study. Also, if working with external vendors or external analysts, then an additional set of identifiers should be created to share with these audiences. Figure 2 provides an example of a data file shared with external vendors and analysts. Lastly, data collectors should also check administration dates to make sure they are within acceptable ranges. This can help identify anomalous data (e.g., students entering birthdates).

Original Data File

Internal_ID	Vendor_ID	Analyst_ID	Item_1	Item_2	Item_3
STU023	VSTU010	ASTU771	A	A	B
STU055	VSTU222	ASTU823	A	B	B
STU023	VSTU987	ASTU802	C	E	B

External Vendor Data File

Vendor_ID	Item_1	Item_2	Item_3
VSTU010	A	A	B
VSTU222	A	B	B
VSTU987	C	E	B

Analyst Data File

Analyst_ID	Item_1	Item_2	Item_3

ASTU823	A	B	B
ASTU802	C	E	B

Figure 2. Sample Data Files.

Data Cleaning Phase. After data has been collected, it should undergo a series of validation checks to identify and repair anomalies. Prior to beginning this process, data cleaners should identify a tool that will log steps used to transform data files into their final format. This will make it easier to reproduce files and to retrace steps in case errors are identified later. Our teams have worked with R (https://www.r-project.org/) and OpenRefine (http://openrefine.org). Second, data cleaners should establish a review process so that their work can be verified by another person. When working with many data files, it is easy to make simple mistakes (e.g., assigning a string value like 'treatment' the wrong numeric value). We implement this review process in two ways. First, we have each data cleaning script reviewed by someone who did not author the script. Second, we ask our participant managers and researchers to compare our file counts against their records to identify missing or extra participant records. Next, data cleaners should create copies of their raw data files and only work with the copies. This allows you to return to the original version if needed. To distinguish these files, we add the suffix *_raw* to our original files. Once data cleaners have setup these processes, they can begin working on the data cleaning checks listed in Table 1.

Figures 3 to 6 provide an example of data cleaning checks applied to a student questionnaire. First, the data file is compared against a codebook to identify any missing or extra data columns (Figure 3). Extra columns arise frequently in data files provided by external vendors or captured through online survey tools. Columns can go missing due to software failures or because they were simply overlooked. Second, missing data values are replaced with codes indicating the reason for their absence (Figure 4). I distinguish three types of missing data: data I expected to receive that was not provided, data I did not expect to receive, and data that were optional. Next, categorical values from an open-ended response item are transformed into a limited number of standard values (Figure 5). Demographic data often require mapping to standard values. Where possible, I use values common in educational work (e.g., NCES conventions) to support external researchers in comparing their own data against the data files I produce. Lastly, the unique identifier column is reviewed for duplicate values (Figure 6).

Check for missing and extra columns
By comparing the data file against the codebook, we see *Math Club* is missing and *School ID* was added. We need to work with data collectors to retrieve the missing Math Club information. The School ID column can be deleted.

School ID	Study ID	Grade	Grade 9 GPA	Grade 10 GPA	Elective
111-11-1111	STU01	9	2.0		Engineer
222-22-2222	STU01	9	3.2		Choir
333-33-3333	STU02		3.5	3.0	French

Codebook

Study ID	Unique ID
Grade	9-12
Grade 9 GPA	0.0 – 4.0
Grade 10 GPA	0.0 – 4.0
Elective	STEM Non-STEM
Math Club	Yes, No

Figure 3. Checking questionnaire data for missing and extra columns.

Apply codes to indicate types of missing data
The students in the first two rows are missing a Grade 10 GPA. Since they are in 9th grade, we expect their Grade 10 GPA values to be missing. We indicate missing values that are expected with 888888. The student in the last row is missing a value in the grade column, but we expect all students to have a grade level. We indicate missing values that are unexpected with 999999. Missing codes should stand out from other values in the same column.

Study ID	Grade	Grade 9 GPA	Grade 10 GPA	Elective	Math Club
STU01	9	2.0	888888	Engineer	Yes
STU01	9	3.2	888888	Choir	Yes
STU02	999999	3.5	3.0	French	No

Figure 4. Applying missing codes to questionnaire data.

Transform categorical values into standard values
According to the codebook, the *Elective* column should only contain the values of STEM or Non-STEM. We map fields such as engineering to STEM and other fields to Non-STEM.

Study ID	Grade	Grade 9 GPA	Grade 10 GPA	Elective	Math Club
STU01	9	2.0	888888	STEM	Yes
STU01	9	3.2	888888	Non-STEM	Yes
STU02	999999	3.5	3.0	Non-STEM	No

Figure 5. Transforming categorical values in questionnaire data.

Check identifier columns for duplicate values
The first two rows contain the same value in the *Study ID* column, but our codebook indicates this column should be unique. Looking back to our original data file, we see these students had different values in *School ID*. We would need to work with data collectors to identify if these records represent two different students. In the meantime, we add a column to flag that there is an error with these records.

Study ID	Grade	Grade 9 GPA	Grade 10 GPA	Elective	Math Club	Has Error
STU01	9	2.0	888888	STEM	Yes	1
STU01	9	3.2	888888	Non-STEM	Yes	1
STU02	999999	3.5	3.0	Non-STEM	No	0

Figure 6. Checking questionnaire data for duplicate values.

Communication Processes

Given the large scopes of Study A and Study B, data cleaning was completed by several individuals and required working with staff involved in other aspects of the projects. In Study B, for example, staff were divided into (a) a participant team responsible for recruitment and participant management, (b) a data management team responsible for data collection and cleaning, (c) a research team responsible for study design and analysis, and (d) a management team responsible for project planning and coordination. Working within and across teams to accomplish data cleaning work was not straightforward nor free from error.

As an example, several participating teachers were erroneously excluded from Study A data files because of differences between the participant team and the research team's understanding of *participant*. For the participant team, a 'participant' was someone who started study tasks and had communicated with the project staff at some point. However, for the research team, a 'participant' was any person who enrolled in the study and was randomized into a study condition, regardless of the number of study tasks completed. The error was uncovered when a research team member compared a data file record count against the randomization record count. As a bridge between participant teams and research teams, our data teams needed to navigate across different group norms and discourses to accomplish our work. Next, I briefly summarize the communication and collaboration processes I now use with other project staff to facilitate data cleaning tasks.

Prior to the data cleaning phase, I meet with both the research team and the participant team to discuss their study plans. For the research team, I review their list of data sources and prepare a low-tech sketch of each data file that includes a file name, data columns, and sample values (see Figure 7). Reviewing this sketch with the research team provides confirmation on the data files to be produced, helps to identify if additional files are needed (e.g., a master data file combining information from multiple files), and establishes a shared terminology. With the participant team, I gather information on recruitment deadlines, administration windows they have shared with participants, and school calendars, which inform data validity checks and the data cleaning timeline. During these conversations, I also attend to the ways in which the research team and the participant team discuss their work, being vigilant for possibly confounding terminology. After I meet with both teams, I produce an accounting spreadsheet listing each data file to be created and an estimated due date (see Figure 8).

Once data cleaning begins, I meet regularly with members of the research and participant teams to stay abreast of study progress that might impact data cleaning. For example, the participant team may decide to extend the administration window for a background questionnaire because a new class of students joined the study later than expected. Or, the research team may decide to include additional items on an attitude survey before the second administration of that instrument. These frequent meetings help to identify study plan changes that other project staff may not realize impact data cleaning procedures. When such changes occur, I record them in an appropriate documentation source such as the data accounting spreadsheet.

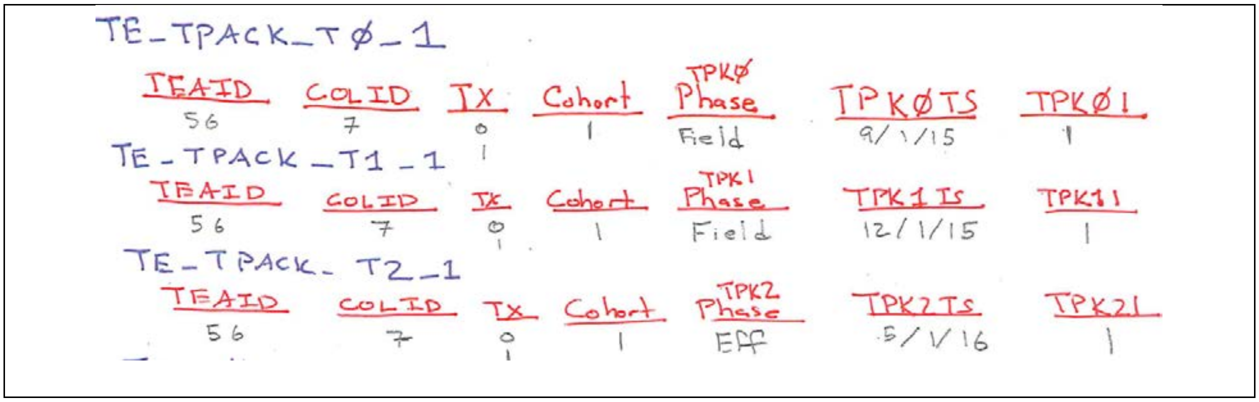

Figure 7. Low-tech sketch of a teacher (TE) assessment of teaching knowledge (TPACK). Teachers completed the assessment at the beginning (T0), middle (T1), and end (T2) of the school year.

Instrument	Pre/Post	Assigned to	Base File Name	Date Due	Status
TE_TPACK	Pre	Tammi	F.1.Tea.Tpk.0.V0	11/25/15	Finished
TE_TPACK	Mid	Tammi	F.1.Tea.Tpk.1.V0	01/15/16	Started
TE_TPACK	Post	Jean	F.1.Tea.Tpk.2.V0	06/30/16	Not started

Figure 8. Data accounting spreadsheet.

Discussion

While the topic of data cleaning may seem tangential to research in undergraduate mathematics education, I hope I have highlighted the critical role data cleaning plays in our research practices. The messiness of environments within which educational research studies are conducted necessitate attention to how we collect and prepare study data. The work presented here demonstrates that processes can be put in place to facilitate the efficient production of quality data sets. The data cleaning process, list of common data error sources, and communication processes offered here provide a framework for other researchers to evaluate their current data management strategies and to provide more comprehensive methods training for researchers.

For readers implementing the framework or embarking on their own data cleaning projects, I offer two recommendations. First, it is important to acknowledge that a comprehensive data cleaning process cannot be created a priori. Studies evolve, participants change, and unexpected events occur. It is impossible to predict all of these variations before a study begins. Implementing an initial data cleaning process that is flexible can help you plan for common errors while giving you the space to adopt procedures as needed in the future. Second, documentation of decisions, processes, and data files is essential. Recording such information helps with accountability and communicating across teams during the data cleaning phase. Documentation also helps researchers recall their procedures and reproduce their work months (even years) after studies have finished and data cleaning decisions are distant memories.

Lastly, some readers may wonder if the procedures presented here apply beyond large-scale, quantitative studies. I argue that all research data needs to undergo some level of cleaning before analysis. While the specific checks of the framework may not apply to all studies (e.g., duplicate records may not be an issue in a case study with one participant), its underlying ideas are relevant to other types of research. In the qualitative research I conduct, my data undergo condensation or "the process of selecting, focusing, simplifying, abstracting, and/or transforming the data that appear in the full corpus (body) of written-up field notes, interview transcripts, documents, and other empirical materials" (Miles & Huberman, 2013, p. 12). I still review my transformed qualitative data to ensure all records are accounted for and no erroneous values exist (e.g., a participant being mistakenly labeled as a teacher instead of a student). At the heart of data cleaning is the acknowledgement that data errors can occur in our studies and that rigorous research practices involve correcting them before analysis.

Acknowledgements

I would like to thank Bryan Matlen and Shandy Hauk for encouraging the writing of this paper and their reviews of my earlier drafts. I would also like to thank Yvonne Kao, Katie D'Silva, Kimkinyona Cully, Eunice Chow, Danielle Oberbeck, and Mykael Thompson for their collaborations on the Study A and Study B data teams.

Mathematicians' Evaluations of the Language of Mathematical Proof Writing at the Undergraduate Level in Three Different Pedagogical Contexts

Kristen Lew
Arizona State University

Juan Pablo Mejía-Ramos
Rutgers University

This paper presents the findings from a survey used to investigate how mathematicians perceive the genre of mathematical proof writing at the undergraduate level. Mathematicians were asked whether proof excerpts were unconventional in three contexts: undergraduate textbooks, what instructors write on the blackboard in undergraduate courses, and how students write in these courses. There are four main findings. First, participants found some potential breaches unconventional regardless of the context in which they occur. Second, mathematicians perceived the linguistic conventions in blackboard proofs and student-produced proofs differently in some cases. Third, textbook authors are expected to adhere to stricter norms than instructors and students when writing proofs. Fourth, there were potential breaches that the literature suggests were unconventional, which were not evaluated as unconventional by the mathematicians.

Key words: Mathematical language, Proof, Mathematics textbooks, Mathematics lectures

Introduction

Research has shown that undergraduate mathematics students have difficulties when constructing (Weber, 2001), reading (Conradie & Frith, 2000), and validating (Selden & Selden, 2003) mathematical proofs. Among several reasons for why undergraduate students struggle with constructing mathematical proofs, Moore (1994) included unfamiliarity with the language of mathematical proof writing. However, there is a dearth of empirical research in the field of mathematics education on the language of mathematical proof writing at the undergraduate level. In particular, how undergraduate mathematics students and mathematicians understand and use the technical language of mathematical proof writing is largely unknown to the field.

In Lew & Mejía-Ramos (2016), we conducted semi-structured clinical interviews with mathematicians and undergraduate students, asking them to identify and discuss potential breaches of mathematical language conventions in student-produced proofs. The findings of this study showed that mathematicians and undergraduate students disagreed on the extent to which one should attend to English grammar, the introduction of new mathematical objects, and the context in which the proof was constructed. While these interviews provided a clearer picture of how some mathematicians and undergraduate students perceived the language of proof writing at the undergraduate level, the present study investigated how a larger sample of mathematicians evaluated parts of the same proofs used in Lew & Mejía-Ramos (2016) via an online survey.

This quantitative approach lends a different perspective on how mathematicians understand this technical language and further informs researchers' and mathematics instructors' understanding of mathematicians' expectations regarding the presentation of proofs at the undergraduate level. In turn, such understandings could enable the design of interventions and curriculum to help undergraduate students in their transition to advanced mathematics courses.

One of the main findings from Lew & Mejía-Ramos (2016) was that the participating mathematicians focused on the context in which the proof was written when evaluating the exposition of a mathematical proof. As such, this consideration of context frames the present study, which investigates the extent to which the findings from Lew & Mejía-Ramos (2016) generalize to a larger sample. In particular, we investigate the following two questions:

1. To what extent do mathematicians differentiate between the contexts of textbook proofs, blackboard proofs, and student-produced proofs when evaluating the exposition of a mathematical proof?
2. To what extent do mathematicians agree among themselves on what the linguistic conventions of mathematical proof writing are in each one of these three contexts?

Related Literature and Theoretical Perspective

There is little systematic, empirical work on the language of mathematical proof writing. In one of the few systematic studies of published mathematical proofs, Konior (1993) studied over 700 mathematical proofs written in academic textbooks and mathematical monographs. He identified a common structure that authors used to frame the arguments of a proof, which included highlighting the "plan of procedure" of the proof and using cues to direct the reader through the parts of a proof. In another study, Burton and Morgan (2000) analyzed the writing of mathematicians in 53 published research papers, and found that the norms discussed in professional writing guides (e.g. Gillman, 1987; Krantz, 1998) were often broken by mathematicians (e.g. using of the word "we" to include the reader and avoid the use of passive voice), especially by those who were highly regarded in the field. Selden and Selden (2014) described seven conjectured features of the style in which mathematicians write proofs (e.g., statements of entire definitions are not included within written proofs) and reported having interviewed an undisclosed number of mathematicians who identified these features in their own published papers. While these studies begin to further our understanding of proof writing at the professional level, research on the language of proof writing at the undergraduate level is scarce.

As referred above, a number of mathematicians (e.g. Gillman, 1987; Krantz, 1997) have written texts describing how to properly and effectively use the language of mathematics for professional purposes such as published journal articles, dissertations, and books. Common suggestions for proof writing included: (1) making the logical structure evident in the exposition of the proof, (2) avoiding statements using too many symbols and mathematical notation, (3) being consistent with respect to both notation and word choice, (4) aiming to be concise while still using full and correct sentences, 5) using correct grammar when considering symbols as words and mathematical expressions as phrases, and 6) avoiding using a passive voice. A number of mathematicians and a mathematics educator have written similar guides for undergraduate students, three of which (Vivaldi, 2014; Alcock, 2013; Houston, 2009) have sections addressing the language of mathematical proof writing specifically. While there is overlap in the suggestions given in writing guides for mathematicians and students, the suggestions for students focused on issues of mathematical grammar and clarity, including: 1) using correct words to describe mathematical objects, 2) using connecting words and phrases, 3) avoiding using unclear referents, 4) defining symbols and notation used in a proof, 5) using symbols and notation commonly used in practice, and 6) revising their mathematical writing.

Since the suggestions provided in guides for mathematicians and students were written based on the authors' own assumptions and personal experiences with mathematical writing, further work is necessary to investigate the extent to which these expectations of advanced mathematical proof writing are shared by mathematicians. This study serves as a first step toward this goal.

Linguistic Conventions of Proof Writing in Different Contexts

As a particular type of mathematical text, we see mathematical proof as a genre of mathematical writing. Mathematician Armand Borel (1983) equated mathematical proofs to the genre of poetry in natural language, saying, “our poems are written in a highly specialized language, the mathematical language […], unfortunately, these poems can only be understood in the original” (p .15). Borel emphasized not only that the language of mathematics is distinct from the vernacular, but also that one *must* be knowledgeable in the language of mathematics in order to understand mathematical proofs. In this work, we assume that the genre of proof is defined by both the formal properties and linguistic structures of this type of mathematical text, as well as the communicative purposes of using these texts in particular contexts. This view of genre is consistent with the genre theory literature (Hyland, 2002). Our consideration of proofs in this light is in the pursuit of helping students to understand the linguistic conventions and other characteristics of the genre, as others have done in other genres and discourses (Hyon, 1996).

In our study of mathematical proof writing, we sought to identify the different linguistic conventions of this genre. Understanding conventions as rationally justifiable customs of practice to which members of that practice are expected to conform to (Jackman, 1998), we take linguistic conventions to be rationally justifiable customs of linguistic communication. Existing literature (e.g. Gillman, 1987; Krantz, 1998) has suggested possible conventions of writing proofs for professional contexts, such as correctly situating notation within a sentence according to proper grammar and structuring the proof to guide a reader through the argument.

Meanwhile, it is important to consider how the context of the proof might affect how these conventions are followed as suggested by the mathematicians in Lew & Mejía-Ramos’s (2016) study. In particular, we investigate how mathematicians believe conventions of proof writing vary in the contexts of undergraduate textbooks, and in two classroom contexts: the way proofs are written on the board in class and the ways in which proofs are written by students. The regard of this variation of context within the genre of proof allows this work to highlight similarities and differences in the contexts created by mathematical discourse, as Bondi (1999) identified in her study of research papers, textbooks, and newspaper articles in economic discourse.

Researchers in higher education (Becher, 1987), linguistics (Hyland, 2004), and composition (Bizzell, 1982; Batholomae, 1985) have highlighted that different disciplines have characteristic discourse practices. Berkenkotter, Huckin, and Ackerman (1988) explained “students entering academic disciplines must learn the genres and conventions that members of the disciplinary community employ. Without this knowledge, [Bizzell and Batholomae] contend, students remain locked outside of the community’s discourse” (p. 10). We extend this necessity to acquire specialized literacy to undergraduate students of advanced mathematics, who—we argue—must understand the conventions of mathematical discourse, including the genre of proof in contexts that pervade their study. Given the fundamental role of proof in mathematical practice (e.g. Thurston, 1994) and Borel’s (1983) sentiment above, understanding the language in which proofs are written is of utmost importance for advanced undergraduate mathematics students.

In the present study, we investigate the conventions of mathematical proof writing from the perspective of mathematicians—the most prevalent instructors and examiners of undergraduate students’ proof writing. This investigation was motivated by the mathematicians’ focus on the context in which the proof was constructed in Lew & Mejía-Ramos (2016). The mathematicians in that study discussed the importance of knowing in what course the student was enrolled, where the proof was written (in a textbook, on the board, in a graded assignment), and what type of assessment the proof was a part of (in a homework assignment, or a timed exam setting). As a result of these discussions with mathematicians in Lew & Mejía-Ramos (2016), the current study examines how three different proof contexts (textbook, blackboard, and student-produced) affect mathematicians’ evaluations of potential breaches of mathematical language.

Methods

Following the methods of data collection employed by Inglis and Mejía-Ramos (2009), this study uses an online survey in order to maximize the sample size of mathematicians. Using an online survey to conduct research presents some practical difficulties including the possibility of individual participants submitting multiple responses. Meanwhile, using the steps described by Reips (2000), Gosling et al. (2004), and Krantz and Dalal (2000) showed that online studies can produce results consistent with more traditional methods of research. Moreover, mathematics education publications have used these methods of web-based research (see Inglis, Mejía-Ramos, Weber, & Alcock, 2013; Lai, Weber, & Mejía-Ramos, 2012; Mejía-Ramos & Weber, 2014).

Participants

Participants were recruited from 25 of the top mathematics departments in the United States through email solicitation through their department secretaries. In total, 128 mathematicians (75 PhD students, 16 Postdoctoral fellows, and 37 faculty members) participated in the survey.

Design of the Study

The survey website included fourteen pages asking participants to make evaluations regarding the language used in partial proofs (that were truncated to discourage participants from focusing on the logical validity of the purported proof being evaluated, and to instead focus the evaluation on the use of mathematical language). For an example survey page, see the Appendix. The tasks of the survey were designed based on the design and analysis of Lew & Mejía-Ramos (2016). We chose four of the seven partial proofs from Lew & Mejía-Ramos (2016) to include in the survey as shown in Table 1. Partial proofs were chosen to maximize the number of types of potential breaches of mathematical language included and to include proof excerpts for which mathematicians and students disagreed in Lew & Mejía-Ramos (2016). Each of the proofs in the survey included three or four types of potential breaches of mathematical language.

Potential breaches of the language of mathematical proof writing

Each of the potential breaches of mathematical language included in the survey is briefly described in Table 1. The table includes the highlighted portions of the partial proofs for each of the potential breaches along with the verbatim explanations provided. The explanations are based on the mathematicians' discussions of the same potential breaches and proofs in Lew & Mejía-Ramos (2016). These potential breaches of mathematical proof writing are at the core of both this study and the study presented in Lew & Mejía-Ramos (2016). These breaches were identified as common, potentially unconventional uses of mathematical language found in student-produced proofs from 149 exams at the introduction to proof level (Lew & Mejía-Ramos, 2015). The breaches were categorized based on suggestions from the mathematical writing guides discussed above, our personal experiences with undergraduate proof writing, and existing literature discussing the genre of mathematical proof writing (Selden & Selden, 2003).

The fourteen potential breaches of the language of mathematical proof writing considered in this study are provided in Table 1. More specifically, Table 1 shows each of the four partial proofs marked for all of the potential breaches of the language of mathematical proof writing included in the survey. Below each of the partial proofs, proof excerpts are given with the marked potential breach and the explanation provided in the survey for why one might believe the potential breach is unconventional. In each page of the survey presenting a potential breach of the language of mathematical proof writing, the entire partial proof appeared marked with only one of the potential breaches (for an example, see the Appendix).

Table 1. Example potential breach and explanation presented in the survey by partial proof.

Survey Tasks

For each of the potential breaches presented, participants were provided an explanation of why a colleague might believe the corresponding proof excerpt was written in an unconventional manner. Participants were asked if they agreed this proof excerpt was indeed unconventional for the stated reason, and to what extent it affected the quality of the proof. These questions were asked for the context of a textbook proof, and for both classroom contexts: a blackboard proof and a student-produced proof. Finally, mathematicians were asked if they would make a note or deduct points for this use of language in a homework assignment and an exam. An example survey page is provided in the Appendix. The four proofs were presented in a randomized order.

Analysis

The analysis for this study investigated how the mathematicians answered the various aspects of the survey–in particular, whether they agreed the potential breaches were unconventional in each of the three contexts (textbook proofs, blackboard profs, and student-produced proofs), whether they agreed on the extent to which these potential breaches affected the quality of the proof in each of the three contexts, whether they believed points would be deducted or a note would be made in a student-produced proof, and the extent to which participants viewed these contexts differently. The findings from the study are summarized in Tables 2, 3, and 4.

Table 2 focuses on the mathematicians responses indicating if they agreed that the proof excerpt was unconventional for the reason provided in each context. In order to evaluate if the proportions of agreement that a potential breach was unconventional indicated a high level of agreement within the samples, we considered 75% of the sample to be the threshold. Similarly, we considered 25% of the sample to be the threshold of a high level of agreement that a potential breach was not unconventional within the samples. As such, we conducted Chi-squared tests for equality of proportions checking for proportions $p=0.25$ and 0.75 with a level of significance of $\alpha=0.05/42$. The results of these Chi-squared tests are indicated with ++ and - - as described below Table 2. The proportions of agreement were categorized in the following ways: high agreement that the use is unconventional (significantly different from and greater than 75%), high agreement that the use is not unconventional (significantly different from and less than 25%), or inconclusive (not shown to have high agreement within the sample).

Table 3 provides pairwise comparisons of the responses across the three contexts. To investigate if the mathematicians evaluated the three different contexts differently when evaluating if the potential breaches were unconventional of mathematical language, we conducted pairwise Cochran Q tests comparing how the participants responded in the following contexts: textbook proofs vs. blackboard proofs, textbook proofs vs. student-produced proofs, and blackboard proofs vs. student-produced proofs. These tests were also evaluated with a level of significance of $\alpha=0.05/42$ and are indicated in Table 3 with * as described below Table 3.

Table 4 presents the mathematicians' expectations of how a student-constructed proof would be assessed in classroom assignments. We conducted Stuart-Maxwell Tests with a level of significance $\alpha=0.05/28$ to evaluate if the mathematicians evaluated the contexts of proofs written in homework assignments and proofs written in an in-class exam differently. Categories in which mathematicians graded the contexts differently are indicted in bold as described below Table 4.

Results

To what extent does context affect mathematicians' evaluations of proof writing?

As shown in Table 3, the pairwise Cochran Q tests indicate that context did play a role in participants' evaluations of whether or not these potential breaches were unconventional for the reasons provided. Indeed, for twelve of the fourteen potential breaches, mathematicians' level of agreement differed significantly depending on the context of the evaluation. Overall, the comparison between participants' level of agreement in the textbook context and the classroom contexts yielded a different outcome to the corresponding comparison between the two classroom contexts.

Table 4. Reponses by mathematicians of their expectations of how a student-constructed proof would be assessed in classroom assignments.

The context of textbook proofs

For twelve of the fourteen breaches presented in the survey, a significantly higher percentage of mathematicians agreed that the potential breach was unconventional in the context of textbook proofs than in either the context of blackboard proofs or student-produced proofs. In other words, a large majority of the potential breaches were more commonly judged to be unconventional in the context of textbooks than the classroom contexts. For instance, 85% of participants agreed that using an unspecified variable with an existential quantifier in the way shown in Partial Proof 4 (which contains the line "$\exists y$ s.t. $(x,y) \in S^{-1}$ and $(y,x) \in S$") was unconventional in the textbook context, given that the introduction of the variable y should specify the set to which it belongs. However, only 55% and 54% of mathematicians agreed that this constituted an unconventional use of mathematical language (for the reason provided) in the contexts of blackboard proofs and student-produced proofs, respectively.

Contexts of blackboard proofs and student-produced proofs

In contrast to the prevalent differences in agreement levels between the textbook and classroom contexts, when comparing the contexts of blackboard proofs and student-produced proofs, the corresponding agreement levels were significantly different in only three of the fourteen potential breaches. In particular, the Cochran-Q tests indicated that the mathematicians judged the proof excerpts that lacked punctuation and capitalization, mixed mathematical notation and text, and lacked verbal connectives differently in the contexts of blackboard proofs and student-produced proofs. Moreover, for each of these three potential breaches, a significantly larger percentage of mathematicians found the potential breach to be unconventional in the context of student-produced proofs than in the context of blackboard proofs. For instance, 28% of participants agreed that mixing mathematical notation and text in the way done in the last line of Partial Proof 2 (i.e. "Note that their greatest common divisor = 1.") was unconventional in the blackboard context given that the equal symbol should not be used to connect a verbal statement and a number. However, 45% of mathematicians agreed this constituted an unconventional use of mathematical language (for the reason provided) in the context of student-produced proofs.

When the context of the proof may not matter

The responses from mathematicians were not significantly different across contexts for two of the potential breaches: using non-statements and overusing variable names. Furthermore, mathematician widely agreed that these potential breaches were unconventional, with agreement levels between 93% and 100% across contexts. In other words, the only two potential breaches for which context did not make a difference were potential breaches that were widely considered to be unconventional. For instance, 100% of participants agreed that using non-statements in the way shown in the first line of Partial Proof 1 (i.e. "Suppose f is onto B and $g \circ f$.") was unconventional in the textbook and the blackboard contexts, given that "suppose $g \circ f$" is an incomplete/meaningless statement. In the student-proof context, 98% of mathematicians evaluated this use of language as unconventional for the reason provided.

Summary

This analysis revealed that mathematicians evaluated a large majority of the potential breaches differently depending on the context, failing to differentiate between the three given contexts in only two of the fourteen potential breaches. These results are consistent with the findings from Lew & Mejía-Ramos's (2016) interview study, in which mathematicians focused on the context in which the proof was written when evaluating the exposition of a mathematical proof. Furthermore, we found most of these differences were accounted by the fact that potential breaches were more commonly judged to be unconventional in the context of textbooks than in the classroom contexts, which makes sense given the extensive editorial work devoted to improving the presentation of mathematics (including proofs) in this context. Finally, we found that the only two potential breaches for which context did not make a difference, were potential breaches that were widely considered to be unconventional. Participants' evaluations of these two types of potential breaches provide evidence of *the existence* of uses of mathematical language that are widely perceived to be unconventional, regardless of context.

In contrast to comparisons to the textbook context, comparisons between the evaluations in the contexts of blackboard proofs and student-produced proofs were *not* found to be significantly different in eleven of the fourteen potential breaches. Furthermore, for the three remaining breaches, a significantly larger percentage of mathematicians found the potential breach to be unconventional in the context of student-produced proofs than in the blackboard proofs. Taken together, these findings may suggest mathematicians generally do not see a difference between the contexts of blackboard proofs and student-produced proofs when it comes to the language of proof writing, but when they do differentiate between these contexts, mathematicians may hold students' proofs to higher linguistic standards than the proofs they themselves write on the blackboard in class. This suggests, in certain respects, that the formality of a blackboard proof is less important to mathematicians than that of a student-produced proof. This is particularly interesting as mathematicians most often present proofs to their students on the blackboard. As such, these results suggest the most common way in which mathematicians present proofs to their students is less formal than the way they might expect their students to produce proofs.

To what extent do mathematicians agree among themselves in these contexts?

Figure 5 shows the percentage of mathematicians who agreed the potential breaches were unconventional for the reason provided in each context. Lines connect the agreement percentages for evaluation in the same context and the shaded sections indicate percentages significantly different and greater than 75% or significantly different and less than 25%. The un-shaded, center section of the graph presents the results of the participants' surveys, which did not show high levels of agreement according to the Chi-squared tests for equality of proportions. In this section, we first discuss the types of potential breaches for which the mathematicians' responses showed high level of agreement. Then, we provide a post hoc analysis of the types of potential breaches for which responses did not show this high agreement.

Types of potential breaches for which the mathematicians' responses showed high agreement

As shown on Figure 5, (significantly) more than 75% of mathematicians found eight of the fourteen types of potential breaches (using non-statements, overusing variable names, lacking punctuation and capitalization, mixing mathematical notation and text, lacking verbal connectives, using formal propositional language, using unclear referents, and using an unspecified variable with an existential quantifier) to be unconventional in the context of textbook proofs for the reasons presented in the survey. Moreover, there was a high level of agreement among mathematicians that the proof excerpts exhibiting the use of non-statements or overuse of variable names were also unconventional in each of the other two contexts.

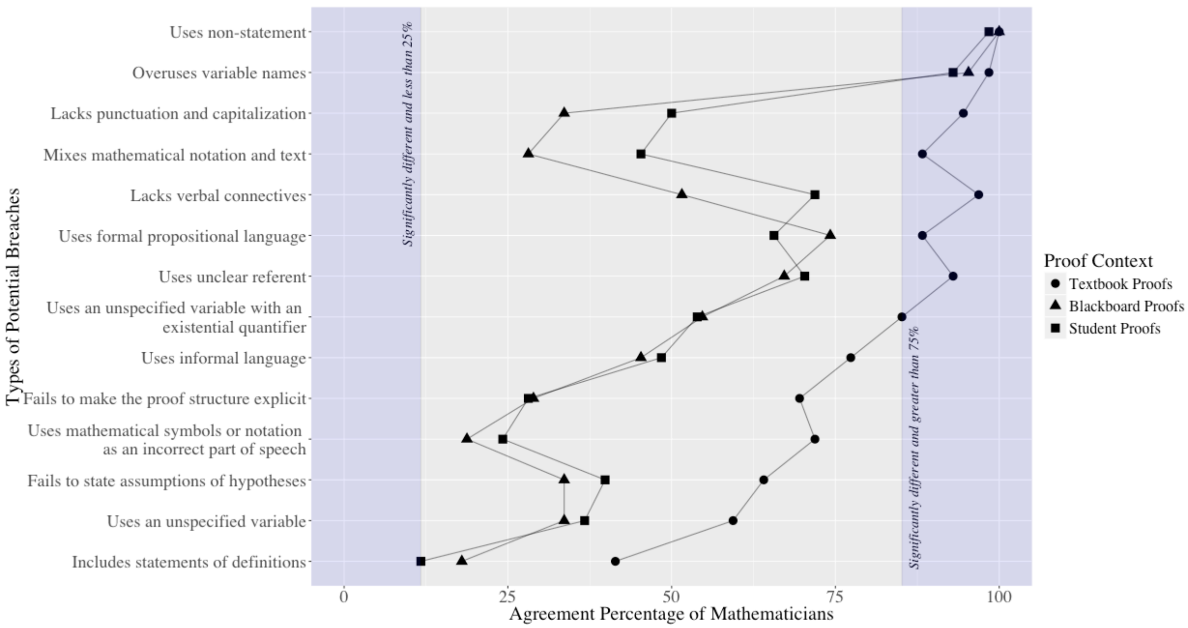

Figure 5. The mathematicians' agreement percentage of agreement for each potential breach in each of the three contexts.

These findings indicate that these eight potential breaches of the conventions of mathematical language are indeed unconventional in the context of textbook proofs for the reasons provided in the survey and that overusing variable names and the use of non-statements are also unconventional in classroom contexts. Figure 5 also shows there was high agreement amongst the mathematicians that the inclusion of statements of definition was not unconventional in the context of a student-produced proof. Moreover, fewer than 42% of mathematicians agreed that the inclusion of statements of definitions was unconventional in any of the contexts considered. We note that this is in contrast to claims made by Selden and Selden (2014) that mathematicians do not include the statements of entire definitions within their written proofs. Thus, it may not be the case that the features of proof writing described by Selden and Selden (2014) extend to different contexts of proofs written by mathematicians (including textbook and blackboard proofs), or to the contexts of student-produced proofs.

When the mathematicians' responses did not show high agreement

For 29 of the 42 judgments made by mathematicians (fourteen potential breaches in three contexts) the agreement percentages were inconclusive, i.e. percentages were not significantly different from and higher that 75%, or significantly different from and lower than 25%. Figure 5 further shows that for five of the potential breaches, there was no high agreement among mathematicians in *any of the three contexts*, and that when we restrict the analysis to only the classroom contexts, the results did not show high agreement for up to eleven of the fourteen types of potential breaches. Finally, Figure 5 further highlights that a number of these agreement percentages are close to 50%. In particular, eight of the 42 judgments had percentage agreements between 40% and 60%, including two judgments in the context of textbook proofs.

Summary

Mathematicians displayed a high level of agreement (as defined above) in 13 out of the 42 evaluations they were asked to make in this survey (fourteen potential breaches in each of three contexts), with 8 of them about potential breaches in the textbook context. This provides evidence that the language used in some of the partial proofs they evaluated indeed breached the conventions of proof writing in those contexts. However, beyond failing to provide confirmation that the remaining 29 proof passages were indeed breaches of linguistic conventions in proof writing, these findings suggest that the disagreement among mathematicians may be higher in the classroom contexts, and that for some specific types of potential breaches the disagreement amongst mathematicians may be particularly extreme, even in the context of textbook proofs.

These findings suggest a possible lack of clarity from the mathematicians of what a student-produced proof should look like. If it were the case that mathematicians do not have a shared understanding of how mathematical language should be used in student-produced proofs, it would then be unsurprising if undergraduate students similarly lacked clear understandings of undergraduate proof writing. A lack of a shared understanding between mathematicians and students would indicate a need for a discussion among mathematicians and students on the expositional expectations of students' proofs in introduction to proof courses.

Conclusion

This paper reported on the results of a survey asking mathematicians to agree or disagree that potential breaches of the language of mathematical proof writing in different contexts were unconventional for reasons provided in the survey. As such, this study identified breaches of linguistic conventions, in the sense of Jackman (1998), based on the participants' assessments of rational justifications of potential linguistic customs in mathematics. There are four main findings from this survey: First, there are some potential breaches of mathematical language that are unconventional regardless of the context in which they occur. Second, while we only found a few instances in which mathematicians differentiated between the contexts of blackboard proofs and student-produced proofs, when they did mathematicians held students' proofs to higher linguistic standards than the proofs they themselves write on the blackboard in class. Third, textbook authors are expected to adhere to stricter writing norms than mathematics instructors and undergraduate students when writing proofs. Fourth, the participants' responses indicated there are some potential breaches of mathematical language that the literature (Selden & Selden, 2003) might suggest are unconventional, which the participants agreed were not unconventional.

The findings of this report highlight some potential breaches of mathematical language that mathematicians agree are unconventional in the context of published proofs and provide insight on how mathematicians consider the language of mathematical proof writing in the classroom context at the introduction to proof level. In particular, the results regarding the linguistic conventions of mathematical proof writing in classroom contexts suggest that it is unclear what a student-produced proof is expected to look like. The mathematicians' responses did not indicate significantly high levels of agreement for eleven of the fourteen types of potential breaches in the student context, which may indicate the possibility that there is no standard universal understanding or expectation among mathematicians of how students should write proofs.

Moreover, despite findings indicating that mathematicians may not have a shared understanding of linguistic conventions of student-produced proofs, results do suggest the way mathematicians present proofs in their introduction to proof courses is less formal than the manner in which they may expect their students to produce proofs. However, research studies on note taking indicate that students are less likely to recall details of a lecture that were not included in their notes (Kiewra, 2002) and are more likely to record what is written on the blackboard (Johnstone & Su, 1994). Thus, one would expect students to model their proof writing based on how their professors write proofs in class. As a result, this paper's finding that mathematicians may not present proofs in class in a manner that represents their linguistic expectations of their students' proofs is certainly troubling.

Discussions amongst mathematicians, especially those who teach introduction to proof courses, concerning their expectations for the writing of mathematical proofs by their students would be a useful step towards a shared understanding of linguistic conventions of proof writing in the context of student-produced proofs. Meanwhile, if there is not currently a consensus among mathematicians of how their students in introduction to proof courses should be writing their proofs, then a natural question is, how are the instructors of these courses presenting mathematical proof writing to their students?

One possible avenue for future research entails considering mathematical proofs, which are written by mathematicians for their students to read outside of class time such as homework solutions, and how students perceive the differences between the exposition of the proofs they produced in their own homework and the exposition of their professor's solution.

Appendix: Survey Page Example

Please keep in mind this study is particularly focused on the mathematical writing of the proof. While it is natural to focus on the validity of the logical argument of the proof, this is not the goal of this study.

Also, keep in mind the three different contexts of undergraduate proof writing:

1. A ***textbook proof*** is a proof that is written in the way that proofs in undergraduate textbooks are normally written.
2. A ***blackboard proof*** is a proof that is written in the way that proofs normally appear on the blackboard in an undergraduate proof-based course taught by a mathematician.
3. A ***student produced proof*** is a proof that is written in the way that you expect that a mathematician would prefer an ideal undergraduate student to write mathematical proofs.

Consider the following task and subsequent partial proof:

Let A be a set. Prove: If S is a relation on A, then the relation $R = S \circ S^{-1}$ is symmetric.

let $x, z \in A$ s.t.

$(x,z) \in R$

$R = S \circ S^{-1}$

$(x,z) \in S \circ S^{-1}$

$\exists y$ s.t. $(x,y) \in S^{-1}$ and $(y,z) \in S$

$(y,z) \in S \therefore (z,y) \in S^{-1}$

$(x,y) \in S^{-1} \therefore (y,x) \in S$

	A mathematician suggested that this is unconventional mathematical writing because ***the writer should use verbal connectives (e.g. therefore, then, since) to indicate the flow of the argument to the reader.*** Would you agree or disagree in the following contexts?		To what extent does this use of mathematical language lower the quality of the exposition of the partial proof in the following contexts? *(Please select "N/A" if you do not find this writing to be unconventional.)*			
	Agree	Disagree	Significantly	Moderately	Not at all	N/A
Textbook Proofs	○	○	○	○	○	○
Blackboard Proofs	○	○	○	○	○	○
Student Produced Proofs	○	○	○	○	○	○

In an introduction to proof course, would you take points off for this type of unconventional use of mathematical language in the following contexts?

	I would take points off (and perhaps make a note).	I would make a note, but not take points off.	I would not take points off or make any note to the student.

Spatial Training and Calculus Ability: Investigating Impacts on Student Performance and Cognitive Style

Emily Cilli-Turner
University of Washington Tacoma

Lindsay McCunn
University of Washington Tacoma

Despite concerted efforts on the part of educational policy makers, women are still underrepresented in the STEM fields. Researchers have shown that calculus plays a major role in this gender disparity since it requires spatial skills to success -- skills that women tend to utilize differently compared to men. However, previous studies have shown that spatial ability is malleable and spatial skills can be improved with training. This pilot study employed a form of spatial training in a third-term calculus course and measured the effects of this training on students' calculus ability, spatial rotation ability, and cognitive style. Associations between cognitive style and task performance were also measured. Preliminary results indicate that spatial training did not significantly impact student performance on a calculus skills assessment or a test of mental rotations, but effects on students' cognitive style were present.

Key words: spatial training, calculus skills, cognitive learning style

Introduction & Literature Review

A concentrated effort is being made to achieve greater diversity in students graduating with bachelor's degrees in Science, Technology, Engineering and Mathematics (STEM) (Stieff & Uttal, 2015). Unfortunately, the demographics of STEM graduates have been stagnant in recent years (Stieff & Uttal, 2015) and women are often underrepresented in STEM fields in North America and Europe (Nimmesgern, 2016; Schlenker, 2015). Indeed, those women who do undertake studies in the STEM fields seem to have a higher probability of *not* working in STEM occupations after graduation compared to men (OECD, 2012).

While there are a number of psychosocial reasons for the underrepresentation of women in STEM fields (e.g., Nimmesgern, 2016; Saucerman & Vasquez, 2014; Skolnik, 2015), one often-cited reason is that females may have less developed spatial abilities than males (as per Ferrini-Mundy, 1987), and perform spatial tasks differently than males starting as young as four years of age (Levine et al., 1999; Voyer, Voyer, & Bryden, 1995). Gender has also been found to associate with the accuracy and organization of spatial learning (Gãrling et al., 1981; Kirasic, Allen, & Siegel, 1984) often (but not always) in favor of males (Acredolo, 1988; Brown et al., 1998; Cutmore et al., 2000; Gifford, 2007; Lehnung et al., 2003; Ward et al., 1986; Webley & Whalley, 1987). Although a number of studies have found insignificant differences between the performances of men and women on various spatial tasks, these results seem to depend on the type of task and the age of the study (see Casey, 2013). However, in general, men have been found to consistently perform better than women on spatial perception and mental rotation tasks (Linn & Petersen, 1985).

Although the body of literature on spatial ability indicates that this skill is an important facet of general intelligence (Johnson & Bouchard, 2005), and that spatial ability can be used as a key performance indicator for success in the STEM fields (National Science Board, 2010), more must be done to understand these relationships with respect to gender. Recently, the association between spatial ability and success in the STEM fields have been outlined in a landmark longitudinal study (titled 'Project Talent') following the lives of high school students from the

1950s to the present day (Wai, Lubinski, & Benbow, 2009). The study indicates that those who score highly on spatial tests are more likely to enjoy the STEM fields and gravitate toward STEM careers over and above the effects of mathematical and verbal ability (Wai, Lubinski, & Benbow, 2009). A previous study done by the same authors found that mathematically-talented participants who chose careers in math and science also excelled in object-based skills earlier in life (Lubinsky & Benbow, 2006).

One way to approach closing the gender gap in the STEM fields is to utilize the encouraging evidence that one can train to improve spatial ability exists (Newcombe, 2010; Stieff & Uttal, 2015; Uttal, 2009). Spatial training refers to the explicit teaching of spatial skills, often through the use of mental rotation tasks. At this time, the body of literature concerning the benefits of spatial training is not conclusive on whether an increase in spatial ability has a direct effect on performance in the STEM fields. Although studies done with students enrolled in engineering courses have found an association between spatial training and academic performance, as well as a closing of the gender gap (Sorby et al., 2013), few studies have been done to correlate spatial training and mathematics performance. One thirty-year old study by Ferrini-Mundy (1987) required undergraduate students to complete spatial training exercises during a calculus course but did not find significant increases in calculus performance (although female students were better able to visualize solids of revolution than male students post-training). Other research has found that while spatial training can reduce the gender gap in performance on spatial tasks, it fails to eliminate it (Uttal, 2009). Thus, a call has been made in the spatial cognition literature to extend this line of enquiry and test the potential for spatial training to close the gender gap in the STEM fields by investigating mediating variables and extending periods of spatial training (Casey, 2013).

One correlate to spatial and mathematical ability may be the psychological construct of cognitive style. Cognitive style represents consistency in an individual's manner of cognitive functioning (i.e., information acquisition and processing) (Harvard Mental Imagery and Human-Computer Interaction Lab, 2013). Kozhevnikov, Kosslyn, and Shephard (2005) have investigated cognitive styles that describe individuals' preferences to, or self-assessments of, the use of object, spatial, or verbal modes of information processing. Because the human visual system distinctly processes properties about objects (color, shape) and space (location and spatial relations), they used this neuropsychological evidence to propose the Object-Spatial-Verbal theoretical model of cognitive style. The model outlines three independent dimensions (object imagery, spatial imagery, and verbalization) to propose that object visualizers prefer to construct vivid, concrete, and detailed images of individual objects, while spatial imagers schematically represent spatial relations of objects and spatial transformations. Verbalizers prefer to process and represent information verbally and rely on non-visual strategies (Kozhevnikov, Kosslyn, & Shephard, 2005). In their examination of the three types of cognitive styles, Kozhevnikov, Kosslyn, and Shephard (2005) found that verbalizers performed at an intermediate level on imagery tasks (not at the low level one might expect), and that object visualizers "encode and process images holistically as a single perceptual unit, while spatial visualizers generate and process images analytically, part-by-part" (p. 710).

It seems that individuals often prefer to use one style over another (Kozhevnikov et al., 2005) and that one's preference for one of the three styles directly relates to performance on either mathematical, object imagery ability, or spatial ability tests (MM Virtual Design, 2016). Therefore, cognitive styles may assist math educators to tailor content, assignments, and visualization tools to students' individual differences in cognitive style. Further, information presented in ways that satisfy all cognitive styles could augment student engagement with information presented in the classroom and, perhaps, encourage students' willingness to contribute and collaborate with others, regardless of gender. But, presumably, learning and performance based on visual information presented in a manner congruent to one's cognitive style would be more consistent and effective and, perhaps, help close the gender gap in STEM.

Women tend to report higher object imagery ratings (Blajenkova et al. 2006) and have a negligible advantage in verbal ability (Hyde & Linn, 1988). Casey (2013) pointed out that one reason why large gender differences are often found for mental rotation tasks is because verbal strategies are less effective in solving them than holistic mental rotation approaches used more often by men. Thus, measuring cognitive style in association with spatial ability and an understanding of calculus may afford information about whether those with predominant verbal cognitive styles are women, as well as whether their performance in calculus improves with spatial training. Since success in calculus often predicts success in STEM fields (and calculus involves spatial reasoning), it may be that congruence between cognitive style and material presented or assigned in calculus courses can increase learning and retention (as suggested by Blajenkova & Kozhevnikov, 2008) and, perhaps, increase confidence – a psychological factor that may also help to close the gender gap in STEM fields

Study aims

This pilot study aimed to augment the body of literature regarding the usefulness of spatial training in undergraduate mathematics and answer the following three research questions: (1) What are the impacts of spatial training on undergraduate students' performance in a calculus course? (2) Are differences present in the effects of spatial training between male and female students? (3) What are the impacts of spatial training on students' cognitive style and does cognitive style predict success in the course?

Because academic success in at least one term of calculus is often required in undergraduate STEM programs, calculus courses can serve as "gatekeepers" for STEM fields (Bressoud et al., 2009). If our study reveals that spatial training is beneficial to performance in a calculus course, math educators may have reason to recommend a spatial training module be added to courses that require students to think abstractly. Indeed, if results reveal this training to be particularly effective for female students, an argument may exist that spatial training be studied further with respect to gender differences. Finally, if cognitive styles change over the course of a term to be more spatial as students receive spatial training, or if one style predicts success in the course over another style, it may be reasonable to include an assessment of cognitive style at the start of STEM courses in order for instructors to tailor the delivery of information to students depending on the predominant style of the group (or to assist individual students with styles that are more or less likely to respond to spatial requirements of a course). Overall, connecting research on cognitive styles with spatial training methodology may help educators to diversify the pool of students studying STEM at the undergraduate level while bolstering the success of those who enter into the STEM fields with a non-spatial cognitive style.

Methods

Context

The study took place in the summer quarter of 2016 (June to August) with student participants enrolled in TMATH 126 (Calculus with Analytic Geometry III) at a mid-sized state-funded university in the United States. TMATH 126 covers calculus of sequences and series, vectors and parametric equations and properties of three-dimensional surfaces, as well as integration techniques and approximation, applications of integration and differential equations. Because we assessed introductory-level calculus knowledge, students in TMATH 126 could be expected to understand items in the knowledge assessment we used in both studies.

Participants

Participants were undergraduate students who had already completed two quarters of calculus and, thus, had some prior knowledge of the subject. Seventeen students (8 males, 9 females) attended class for both rounds of data collection but all but one took part in the study (n = 16; 8 males, 8 females, mean age = 21 years). Five students (31% of the sample) reported to be concurrently taking a differential equations course during the summer term, while 11 participants (69% of the sample) reported that they were not receiving other forms of math training at the time of the study). These students also reported that they expected to work an average of 12 hours a week (SD = 5.00) on studying TMATH 126 course material.

Materials

The Calculus Concept Inventory. The Calculus Concept Inventory (CCI) was designed by Epstein (2013) to evaluate how students think about the fundamental concepts in calculus and was used in the present study to gather a baseline of students' knowledge of calculus as well as to determine the effects of spatial training on conceptual knowledge of calculus at the end of the term. The CCI contains 22 questions about limits and differential calculus only, many of which are visual and require an interpretation of a graph. The use of the CCI was deliberate: we did not want to measure mastery of concepts learned in the current course but to measure instead whether spatial training could impact understanding of previously-learned visual topics.

The Purdue Spatial Visualization Test: Rotations. To test students' spatial ability, a shortened version (15 items) of the Purdue Spatial Visualization Test: Rotations (PSVT:R) (Guay, 1977) was also administered. The PSVT:R is a multiple choice test that, per shape, asks students to choose from 5 possibilities a shape that is equivalently rotated as a given shape. This test established each student's baseline spatial ability to assess improvement throughout the quarter and to determine whether spatial training had any effect on students' cognitive style.

Object-Spatial Imagery and Verbal Questionnaire. The Object-Spatial Imagery and Verbal Questionnaire (OSIVQ) developed by Blazhenkova and Kozhevnikov (2009) (but copyrighted jointly by MM Virtual Design, LLC and Rutgers University) was administered to determine students' predominant cognitive style. The OSIVQ is a "self-report questionnaire designed to distinguish between three different types of people: 1) object imagers who prefer to construct vivid, concrete and detailed images of individual objects (e.g., visual artists), 2) spatial imagers who prefer to use imagery to schematically represent spatial relations among objects and to perform complex spatial transformations (e.g., scientists), and 3) verbalizers who prefer to use verbal-analytical tools to solve cognitive tasks (e.g., philosophers and linguists)" (MM Virtual Design, 2016, paragraph 1). The OSIVQ consists of 45 questions (an equal number concerning object imagery, spatial imagery ability, and verbal ability) to assess object imagers, spatial imagers, and verbalizers and takes approximately 10 minutes. Each item asked on a 5-point Likert scale ranging from "totally disagree" (1) to "totally agree" (5). Four items (one spatial, three verbal) from the OSIVQ required reverse coding.

Spatial training. All participants received spatial training during the term consisting of the administration and discussion of several tests of spatial ability, such as those described in Wai et al. (2009). In addition, exercises from a spatial training workbook developed by Sorby et al. (2013) was used with permission. Students completed an average of 15 minutes of spatial training during each day of class. Exercises in the workbook ranged from assessments of what a given shape would look like when rotated around a given axis, to asking students to draw an object from different angles using different cross-sections, to showing a 2-D expression of an object when asking students to draw an analogous 3-D object. During spatial training, students were asked to discuss the exercises in small groups and come to a consensus on the correct answer before answers were discussed among the class at large.

Procedure

Participants completed all tasks in the assigned TMATH 126 classroom for both rounds of data collection. The four tasks were offered to participants in the following order: consent form; OSIVQ; Visualization and Rotation Purdue Spatial Visualization Test; Calculus Concept Inventory. Thus, the tasks were not completed simultaneously: only when a task was completed was the next task offered to a participant by one of the researchers. Each participant was asked to create a unique codename for him or herself to include on the front page of each task in order afford direct measurement of change in task performance over time. No calculators or other electronic devices were used during task completion. Each participant was dismissed from the classroom after he or she had completed all tasks.

Results

Data from the CCI was analyzed to determine students normalized gain on the assessment using the formula $g = \frac{posttest - pretest}{100 - pretest}$. Calculating normalized gain was appropriate because it takes into account the amount of improvement possible for each student. This is important because students may have widely variable spatial abilities upon entry into the course. Each student's score was tallied on both the pre-test and post-test and a paired-samples *t*-test was performed to determine significant improvements in calculus knowledge. No significant improvement was revealed over the term ($p > .05$).

Although male participants' average scores were higher on the CCI than women at the start of term ($M = 9.63$, $SD = 4.47$ and $M = 7.75$, $SD = 7.75$, respectively), they were not significantly higher ($p > .05$). This result was also borne out at the end of term whereby male students' average scores on the CCI were insignificantly higher than female students' scores ($M = 10.25$, $SD = 2.09$ and $M = 8.25$, $SD = 1.40$, respectively).

To determine an association between students' spatial ability and mathematical ability, a correlation coefficient for a student's final grade in Calculus III and their final PSVT:R score was calculated. This correlation ($r = 0.4283$) was not significant ($p > .05$). Additionally, a paired-samples *t*-test did not determine a significant improvement in students' rotational ability during the term ($p > .05$). Consistent with previous studies (Levine et al., 1999; Voyer, Voyer, & Bryden, 1995), male participants' average scores were higher on the PSVT:R than women at the start of term ($M = 9.87$, $SD = 4.29$ and $M = 9.75$, $SD = 2.05$, respectively), and at the end of the term ($M = 10.5$, $SD = 1.45$ and $M = 9.25$, $SD = 1.24$, respectively). However, these differences were not significant ($p > .05$). And, similar to results pertaining to performance on the CCI, a paired-samples *t*-test did not determine a significant improvement in students' rotation ability during the term ($p > .05$).

Table 1:
Descriptive Statistics for Test Variables Per Gender Type

Variable	Gender	Mean	Standard Deviation
		Round 1	*Round 1*
CCI (scored out of 22)	Male	9.63	4.47
	Female	7.75	3.45
PSVT:R (scored out of 15)	Male	9.88	4.29
	Female	9.75	2.05
OSIVQ: Spatial (scored out of 75)	Male	49.75	2.74
	Female	46.13	3.44
OSIVQ: Object (scored out of 75)	Male	47.00	2.67
	Female	50.13	2.26
OSIVQ: Verbal (scored out of 75)	Male	42.75	1.40
	Female	39.50	1.58
		Round 2	*Round 2*
CCI (scored out of 22)	Male	10.25	2.09
	Female	8.25	1.40
PSVT:R (scored out of 15)	Male	10.5	1.45
	Female	9.25	1.24
OSIVQ: Spatial (scored out of 75)	Male	54.00	2.19
	Female	47.50	3.70
OSIVQ: Object (scored out of 75)	Male	52.38	3.42
	Female	49.25	2.04
OSIVQ: Verbal (scored out of 75)	Male	45.38	0.80
	Female	40.13	1.42

Similar to scores on the CCI, male participants' average scores were higher on the PSVT:R than women at the start of term ($M = 9.87$, $SD = 4.29$ and $M = 9.75$, $SD = 2.05$, respectively), and at the end of the term ($M = 10.5$, $SD = 1.45$ and $M = 9.25$, $SD = 1.24$, respectively). However, these differences were not significant ($p > .05$).

On average, more students at the start of the term self-identified as object learners ($M = 48.56$, $SD = 7.00$) than they did as spatial learners ($M = 47.94$, $SD = 8.69$) or verbal learners ($M = 41.13$, $SD = 4.41$). Indeed, scores on the object sub-scale were significantly higher than on the verbal sub-scale, $t(15) = 3.97$, $p = .001$. In addition, scores on the spatial sub-scale were significantly higher than those on the verbal sub-scale, $t(15) = -2.98$, $p < .01$. No significant differences were found between scores on the spatial and object subscales ($p > .05$).

After 10 weeks, the object style remained the predominant style for the class as a whole ($M = 50.81$, $SD = 7.87$) and, similar to the start of term, the second-most common style among the class was spatial ($M = 50.75$, $SD = 8.96$), followed by verbal ($M = 42.75$, $SD = 4.16$). Similar to the start of the term, these differences were significant: students self-scored significantly higher on the object style sub-scale compared to the verbal style subscale, $t(15) = 3.57$, $p < .01$. They also self-scored significantly higher on the spatial sub-scale compared to the verbal subscale, $t(15) = 3.55$, $p < .01$. Again, no significant differences were found between scores on the spatial and object subscales ($p > .05$).

Although mean scores on each of the three sub-scales increased over the term, paired-samples *t*-tests revealed only one significant difference between subscale scores over time. Students did not self-score significantly better or worse on the object or verbal subscales over time (all *p*s > .05). However, they did self-score significantly higher on the spatial sub-scale at the end of the term after receiving spatial training, $t(15) = -2.59$, $p < .05$.

At the start of the term, the men in the sample identified most, on average, as spatial learners (*M* = 49.75, *SD* = 2.74) and least as verbal learners (*M* = 42.75, *SD* = 1.40). This was also the case at the end of the term (see Table 1). In contrast, the highest average score among the three cognitive styles for women was on the object sub-scale (*M* = 50.13, *SD* = 2.26) while the lowest was on the verbal subscale (*M* = 39.50, *SD* = 1.58) and remained so at the end of term.

Although participants' general perceptions of dominant cognitive styles remained stable over 10 weeks, each gender's scores increased on each sub-scale except that women's scores on the object style sub-scale decreased slightly (but insignificantly, $p > .05$) over time.

After the first round of data collection, independent samples t-tests revealed no significant differences between male and female participants' scores on the three OSIVQ sub-scales (all *p*s $> .05$). However, at the end of the term, a significant difference between men and women's scores on the verbal sub-scale of the OSIVQ was revealed, $t(14) = 3.22$, $p < .01$.

Finally, scores on the spatial sub-scale of the OSIVQ did not correlate significantly with high scores on the PSVT:R at the start of the term ($p > .05$) but did so at the end of term ($r = .62$, $p = .01$). No other significant correlations were revealed between scores on the PSVT:R and other sub-scales of the OSIVQ, nor were there any significant associations between scores on the OSIVQ sub-scales and the CCI at the start or end of the term.

Discussion & Future Work

This pilot study revealed that students who self-identified more as object or spatial learners than verbal learners did so significantly more so after spatial training. In particular, a strong identification as a spatial learner linearly associated with mental rotation ability after spatial training. However, spatial training alone did not significantly impact the calculus or mental rotation abilities of undergraduate students. The results of this research informed an adjustment to the methods when a second study was undertaken with a second-term calculus course in 2016. Since the present study was done during a summer term, only a total of 18 classes occurred, with approximately 15 minutes of spatial training done per class -- this may not have been sufficient for students to be influenced by the training because less than half of the items in the workbook were completed during the term.

In general, the second study further explores our research questions in a Calculus II course ($n = 14$), as well as in a section of Calculus II that was not engaged in spatial training to serve as a control group ($n = 9$). The type of data collected was the same as the pilot study except that students were required in the second study to complete some spatial training modules independently and then bring their responses to the classroom to discuss with their peers in order to allow more time for an effect. Another difference between the present study and second iteration concerns the PSVT:R assessment. In the pilot study, 15 items were chosen ranging in difficulty from easy to medium. This range did not determine a reliable baseline in the pilot study because several students obtained a perfect score on this instrument pre- and post-spatial training. Therefore, in the second study, 15 items were chosen where 5 were categorized within the PSVT:R as "easy," 5 as "medium," and 5 as "difficult." No participant in the second study scored perfectly on the pre-test of the PSVT:R. Other results from the second study are currently being analyzed.

We believe that continuing this interdisciplinary line of enquiry is compelling for math educators and cognitive psychologists in better understanding how best to present calculus to students and assess their knowledge over time. Some evidence exists that object visualizers experience difficulties in interpreting science graphs as abstract schematic representations because they interpret them more literally, as though it were a picture (e.g., Heagarty & Kozhevnikov, 1999; Kozhevnikov et al., 2002). Perhaps students with particular cognitive style preferences can be offered opportunities in the classroom to pair physical events (or words) with graphical representations moving in real time to explore connections between how they perceive the world, as Kozhevnikov & Thornton, 2006, suggest. We hope that understanding more about how cognitive styles associate with spatial training and success in mathematics courses will advance pedagogical principles and practices and, ultimately, help to close the gender gap in STEM fields.

Exploring Student Conceptions of Binary Operation

Kathleen M. Melhuish
Texas State University

Joshua B. Fagan
Texas State University

Students' conceptions about binary operations often reflect a lifetime of situated learning about concepts such as arithmetic operations and functions in their K-12 years. This prior knowledge base bleeds into their experience of binary operation in abstract algebra, leading students to have differing and incomplete notions of what constitutes a binary operation. We present a qualitative study in which we classify students' conceptions of binary operation in terms of variation theory and concept image and definition. These frameworks helped us to focus on critical and noncritical aspects of binary operation found in student reasoning. Our results indicate that students' enacted objects about binary operation fall into one of three domains (i.e. function meaning, arithmetic meaning, and structural meaning) and often depend on task context. Additionally, students' reasoning reflected a set of critical aspects that diverge from the conventional critical aspects of binary operation.

Key words: Abstract Algebra, Binary Operation, Conceptual Understanding

Binary operations are woven into mathematics from early elementary school and throughout the K-20 spectrum. However, binary operation is not defined abstractly until advanced mathematics courses such as abstract algebra. Despite the role that operations play in both familiar structures such as our base ten number system, and non-routine and abstract settings of group, ring and field, little attention has been paid to binary operation directly. This is reflected both in its treatment in abstract algebra textbooks (e.g. Fraleigh, 2003, Gallian 2012), and the body of mathematics education literature (Melhuish, 2015). In fact, during a recent survey with abstract algebra instructors, binary operation was deemed one of the most important topics in introductory group theory, yet identified as one of the least difficult topics in the course (Melhuish & Fasteen, 2016). This divergent sentiment may account for the lack of specific attention to binary operations as an abstract concept.

However, as part of a large study exploring student conceptions in introductory group theory, we found that student conceptions of binary operations had the potential to interfere with their performance on tasks related to a number of essential topics in group theory (Melhuish & Fasteen, 2016). We developed a survey centered on binary operation to empirically explore whether abstract algebra students have alternate or incomplete views on binary operation. In this paper, we report on student conceptions of binary operation through three lenses: function, arithmetic, and structure. We also leverage ideas from variation theory to dissect enacted objects of learning, specifically focusing our analysis on which critical aspects students appeared to attend to during their engagements in the tasks. We conclude with some discussion of how variations related to binary operation in typical classrooms may align with students' understanding (or lack thereof) of binary operation.

Theoretical Framing

There are a number of ways to make sense of concept understanding in advanced mathematics. In this study, we merge the construct of concept image/concept definition (Tall & Vinner, 1981) with elements of the variation theory of learning (Marton & Booth, 1997). Our underlying assumption is that a given theory of learning can meaningfully inform the analysis of student understanding at a point in time. The concept image and definition framework provides a parsing of concept understanding into definitions and surrounding cognitive structures associated with a given concept. A concept has a conventional definition in the mathematics community, but also personal definition for each student. Concept images capture both this personal definition, and all associations such as metaphors, examples, applications, and representations of a concept. Tall and Vinner's work is especially powerful in its ability to capture a lack of coherence that often exist between and within student concept images and definitions.

Variation Theory (Marton & Booth, 1997; Watson & Mason, 2006) can provide one lens for making sense of concept images and definitions by both focusing on contrasting elements across a particular construct as well as bringing to light analogous features that may also exist (Watson, 2017). This is done by leveraging the underlying assumption in variation theory that, "nothing is one thing only, and each thing has many features" (Lueng, 2017, p. 68). Variation frames aspects of an object as either critical aspects, features an object possesses that are shared across all instantiations (e.g. the sum the interior angles of an n-gon is $(n-2) * 180$ for all n-gons), while others features, permissible variations, may be unique to a specific instantiation or subclass of object when compared to others (e.g. the sum of the interior angles of a triangle is 180). For instance, variation theory could be used to explore how a child is taught about oranges in the context of apples. Through contrasting oranges and apples, students may attend to what aspects of orange are critical to "orange-ness" versus what aspects are shared amongst the two fruits. In this way, variation draws attention to critical aspects through *contrast*, that is by comparing examples and non-examples, students can attend to the features that are critical to the concept by seeing them vary in the non-examples.

Beyond contrast, variation also allows generalizing via attending to sameness, or features that are shared with elements contained in a student's prior knowledge. Gu (1994) identifies the use of examples, standard and non-standard, and non-examples as *conceptual variation.* To return to our orange example, by experiencing varying types of oranges such as common oranges and bitter oranges, students may apprehend commonalities such as texture and color to determine critical aspects of "orange-ness" and remove noncritical features such as a requirement for sweetness. Other metaphors have been aptly used to explain variation theory: seeing the forest through the trees (Leung, 2017, p. 68) in the sense of being able to separate features and have a holistic treatment of a topic, and putting a puzzle together (Marton & Booth, 1997) where essential features, or *critical aspects* are pieced together to build an accurate conception of the whole concept.

In order to meaningfully leverage a theory of learning (variation), and theory of understanding (concept image and definition), we use variation theory's construct of *enacted object of learning* (Marton & Pang, 2006). The enacted object refers to what is at the forefront of a student's awareness when engaged in a task, including the critical aspects they attend to. Additionally, the *lived object of learning* refers to the critical aspects students are aware of after leaving a learning environment. In a survey situation, students enact an object of learning that reflects their lived object of learning. In this way, to make sense of snapshot understanding, we can identify what *critical aspects* appear to be part of the student's concept image or object of learning. See Figure 1. A students' concept image can be parsed in terms of critical and noncritical aspects brought to the forefront by students when engaged in survey tasks. We also adapt Bussey, Orgill, & Crippen's (2013) view that a students' lived object of learning is not just a result of exposure to variation in class, but also combines with *prior knowledge* in order to develop their larger conception.

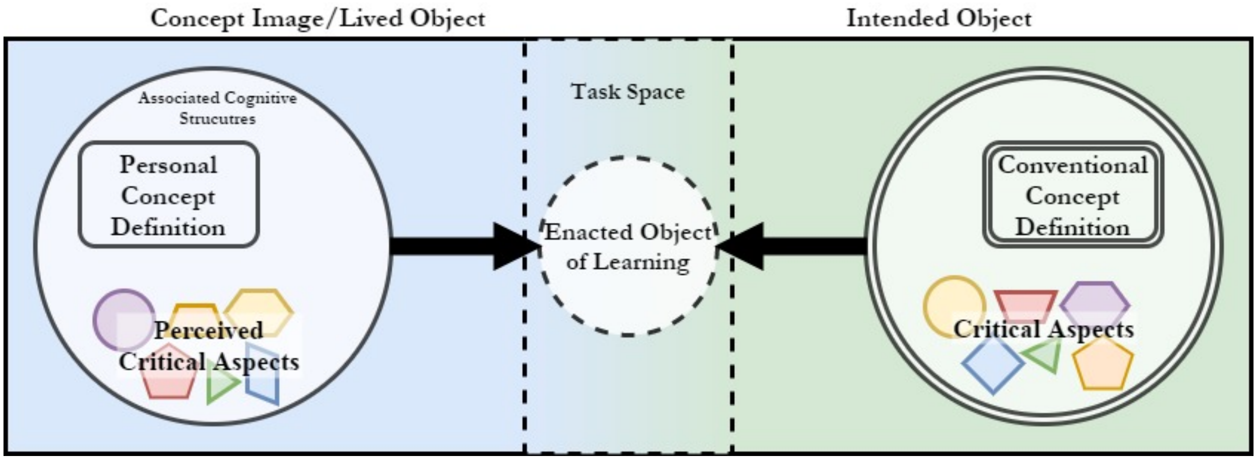

Figure 1. The relationship between a students' concept image, the intended object and the enacted object of learning within the task space.

Prior Research on Student Conceptions of Binary Operation

Binary operation is often a key underlying component of educational studies in abstract algebra, although its role is often left implicit. Group, ring and field are defined via the way binary operation(s) provide structure on a relevant set. Binary operation played an essential role in Larsen's (2009) student-driven reinvention of the group structure (Larsen, 2009) and Simpson and Stehlíková's (2006) work having a student apprehend the structure of a commutative ring. Informally, a binary operation can be thought of as a rule for combining two elements of a set to produce a single element (from the same set). Addition is a binary operation on the set of integers because the sum of any two integers is another integer. Formally, binary operations are typically defined as:

A *binary operation* $*$ on a set S is a function mapping $S \times S$ into S.

In this way, binary operation brings together two concepts that may have been seen as disjoint in prior situations: operations and functions. In the operation literature, functions may be treated as special cases of operation (e.g. Slavit, 1998), or alternately, binary operations may be treated as special cases of functions (e.g. Dubinsky, Dautermann, Leron, & Zazkis, 1994).

A majority of the literature on operation falls into the former category with focus on arithmetic operations (with the occasional use of function as an operation example.) Slavit (1998) posits one such framework: *operation sense*. He discussed operation sense in a series of stages built around familiarity with standard arithmetic operations in terms of underlying models, symbolic notation, their relationships to other operations, properties they may possess, and their meaning independent of concrete inputs. However, this framework is built in terms of operations that are not arbitrarily defined but rather represent a standard process. For example, a process of combining groups underlies the operation of addition. One of the driving components behind operation sense is the operation's duality as both a process and object. Gray and Tall (1994) use the construct of *procept* to explain the process and concept associated with a given operation symbol. For instance, an expression such as "$3 + 2$" represents both the process of adding 3 and 2, as well as the resulting sum. This literature is emblematic of the larger field of research on operations in that it remains contextualized with specific examples of operations.

When attending to binary operations as a special case of functions, student conceptions around functions may play an additional role in their understanding. A large body of literature exists highlighting the many complexities of the function concept and students have been documented with many alternate and incomplete understandings through the K-20 spectrum (Oehrtman, Carlson, & Thompson, 2008). For example, students may prefer a certain representation such as a written, symbolic rule (Breidenbach, Dubsinky, Hawks, & Nicols, 1992; Vinner & Dreyfus, 1989). From a variation standpoint, this may reflect students overgeneralizing standard examples where a general rule is often an aspect. Additionally, students have frequently proceduralized functions such as evaluating $f(x+a)$ as being equal to $f(x)+a$ (Carlson, 1998). This highlights the complexity involved in making sense of what constitutes the inputs and outputs of a function. The input and output language (and to an extent input/output machine metaphor) often provides the basis for conceptualizing function (Tall, McGowen, & DeMarois, 2000). Frequently, much of the difficulty with functions is attributed to the process/object duality of functions (e.g. Dubinsky & Wilson, 2013). Functions can be conceptualized as the *action* of mapping individual inputs to outputs, the more general *process* of mapping from domain to range, or as an *object* itself to be operated and compared with other functions. As with operations research, function research generally does not breach binary operation specifically, but tends to remain in the more familiar K-12 context of inputs that are singular elements rather than two inputs (or equivalently ordered pairs of inputs).

In terms of the abstract concept of binary operation, the literature does provide some framework options. Brown, DeVries, Dubinsky, and Thomas (1997) presented a genetic decomposition of binary operation where students may have an action conception (explicitly combining two inputs to arrive at an output), a process conception (a general process for combining inputs to arrive at outputs), or an object conception (seeing binary operations as things that can be acted on as objects themselves). Novotná, Stehliková, and Hoch (2006) provided a structure sense framework capturing the transition from familiar to unfamiliar operations. They divided understanding of binary operations into four levels: *Recognise a binary operation in familiar structures; Recognise a binary operation in non-familiar structures; See elements of the set as objects to be manipulated, and understand the closure property; and See similarities and differences of the forms of defining the operations (formula, table, other).* Rather than considering stages of mental constructions in terms of process/object reification, the focus was on apprehending structure. Ehmke, Peasonen, and Haapasalo (2001) presented a framework leveraging different representations to distinguish students with procedural and conceptual understandings. They identified students as having procedure-based understanding of binary operation if they could match binary operations if presented in different representations. The next level is procedure-oriented where students could also create different representations when prompted. The highest level is conceptual where students could not only move between representations, but also determine if a given relation was a binary operation. The variation theory-informed approach in this paper aims to complement these process frameworks with a more nuanced view of exactly what critical aspects/noncritical aspects of binary operation may be influencing student conceptions.

Some of these attributes have been broached in the misconception literature in other subjects. Mevarech (1983) found statistics students overgeneralized properties (noncritical aspects) such as associativity onto binary operations. Zaslavsky and Peled (1996) had pre-service and in-service teachers generate examples of binary operations resulting in a number of issues that can be attributed to critical aspects. For example, some of the participants defined a unary operation which may indicate that an operation defined on two elements may not be a critical aspect of these students' conceptions of binary operation.

The study presented below serves a follow-up to initial results from the Group Theory Concept Assessment (GTCA), formerly, Group Concept Inventory (Melhuish & Fasteen, 2016). We conjectured that student conceptions of binary operation accounted for performance on questions targeting subgroups, the associative property, and groups themselves. Of 486 students asked if a binary operation could be defined on the set $\{1,2,4\}$ in a way to form a group, only 23% responded correctly that "an operation can be defined on any three element set to form a group." We conjectured that the students were limiting their view of acceptable binary operation to those with a familiar symbolic name. In a question targeting subgroups, students were asked whether the set $\{\overline{1},\overline{2},\overline{3}\}$ forms a subgroup in $\mathbb{Z}_6$ (adapted from Dubinsky, et al., 1994; Hazzan & Leron, 1996). A little over a third of the 429 students who responded, indicated that the set forms a subgroup by claiming that $\mathbb{Z}_3$ is a group itself. Although $\mathbb{Z}_3$ has a different operation, the students appeared unaware of this fact possibly owing to students possessing a view of binary operations that only allowed them to attend to the similarities in $(+ \bmod 3)$ and $(+ \bmod 6)$ (i.e. the additive structure) and unaware of the contrasting restrictions placed by the moduli. In a third question, students were asked if the binary operation defined as $a \diamond b = 1/2\,(a+b)$ was associative. A sizable number of students (17% of 432) treated $1/2$, a, and b as the inputs claiming the operation was not associative because: $1/2\,(a+b) \neq (1/2\,a) + b$. These students appeared to have issues identifying what exactly was the binary operation as they attempted to attend to some sort of artificial structural feature that they felt was shared amongst all binary operators.. In each of these cases, conceptual issues with binary operations appeared to be a logical cause for the students' reasoning. In this paper, we directly unpack conceptual understandings associated with binary operation in terms of *meanings* and *critical aspects*.

Methods

The surveys analyzed below were given to two introductory, undergraduate-level, modern algebra classes (n=12, n=8 respectively) at a large, public university. The surveys were created to cover a variety of binary operations in terms of standard examples, non-standard examples, and non-examples. We selected four activity domains that research has shown are tightly linked to understanding of mathematical concepts:

1. *Is or is not.* Determining if a given instantiation is an example of a concept (e.g. Ehmke, Peasonen, and Happasalo, 2011)
2. *Same or different.* Determining if two instantiations are mathematical the same (e.g. Novotná, Stehliková, and Hoch, 2006)
3. *Properties.* Determining what properties an example may or may not have. (e.g. Dubinsky, et al., 1994)
4. *Generating.* Creating an example meeting some criteria (e.g. Zazkis, & Leiken, 2007)

The survey consisted of questions corresponding to each of the above categories. In each case, the student was also prompted to explain their reasoning. A set of sample tasks can be seen in Table 1. Additionally, four think aloud interviews were conducted in order to test the robustness of survey interpretations. The interviews were semi-structured to allow for the interviewer to follow the student reasoning in an organic manner.

Table 1

Sample Survey Tasks

Determine if the following define a binary operation on the given set. Explain why or why not. • Addition mod 3 on the set $\{0, 1, 2\}$ • $\diamond(a) = \sqrt[3]{a}$ on $\mathbb{R}$ (the set of real numbers) • $\diamond(a) = a^2$ on $\mathbb{R}$
Determine if the following binary operations are the same. Explain why or why not. • **Op 1:** Division on $\mathbb{R}$, **Op 2:** Multiplication on $\mathbb{R}$
Consider the operation $\diamond$ on the set of real numbers defined as follows $a \diamond b = \frac{1}{2}(a + b)$ Is this operation associative? Why or Why not?
Is it possible to define a binary operation on the set $\{1,2,4\}$ such that the set and operation form a group? Why or why not?

Analysis

The surveys were analyzed through a content analysis heavily informed by phenomenographic methods. Phenomenographic studies attempt to study *meaning* through the interaction between an individual and a task (Trigwell, 2006). The assumption is that students experience different phenomena in a variety of ways. One use of this type of study is to "investigate the range of different ways that students experience technical concepts" (Reed, 2006, p. 1). The focus is often on the range of ways students ascribe meaning to ideas. The analysis is not about classifying students into categories, but rather classifying their reasoning based on ways of experiencing binary operation in the given tasks. Similarly, the classification of student reasoning is not meant to ascribe hierarchical values to different forms of thinking, but to report the qualitatively different ways in which students thought about binary operations themselves.

From this vantage point, the data was analyzed in two manners to attend to our focal aspects of concept image: (1) Global: overarching understanding of binary operation and (2) Local: properties treated as critical aspects of binary operations. In phenomographic tradition student responses were stripped from individual surveys and interviews to put attention on the reported reasoning in tasks rather than analyze an individuals' responses as a whole. In the next section, we outline three ways of thinking about binary operation and various critical and noncritical aspects were found across surveys.

Results and Discussion

At the global level, we identified three meanings associated with binary operation: *function meaning, arithmetic meaning,* and *structural meaning.* We begin by explaining each type of meaning. We then explore the enacted objects of learning via looking at aspects of binary operation treated as critical throughout the range of tasks. At each point, we also reflect on the connections between these aspects and relevant meanings for binary operation.

Function Meaning for Binary Operation

We define a *function meaning* as one that leverages notions of function when attributing meaning and engaging in tasks related to binary operation. From the parent study (Melhuish, 2015), this type of definition has been articulated by a number of students both formally and informally. One undergraduate student described binary operation (on $\mathbb{Q}$) as, “you have some operation that goes from $\mathbb{Q}\times\mathbb{Q}$ to $\mathbb{Q}$” explicitly focusing on the ordered pair domain. Other students provided more informal definitions such as, "[A binary operation] takes two elements as input and outputs a single element but it has to be defined on the entire... on all possible pairs in $\mathbb{Q}$ or in your group.”

This type of definition aligns with what definition is found in standard undergraduate textbooks for introductory abstract algebra (e.g. Fraleigh, 2003, Gallian 2012). With a function treatment of binary operation, various properties associated with prior knowledge of function may be paired with the specific binary operation case such as those of being well-defined, range-domains, or one-to-one. Similarly, function language such as “input” and “outputs” often become part of the vernacular around binary operation.

Arithmetic Meaning for Binary Operation

We define an *arithmetic meaning* for binary operation as a focus on a binary operation as a way to combine two elements to produce a third. For example, one student stated that an operation was, “a binary operation does something to two elements from a set and that what it does to those two at the very end is still in that set.” This meaning more prominently connects to prior knowledge of operations such as arithmetic operations. An operation such as addition is thought of as a way to sum two numbers to produce an third. Rather than conceptualizing adding the numbers 2 and 3 as inputs with an output of 5, students are likely to think of combining 2 and 3 to arrive at 5. This language aligns with the literature where operation is often framed as often abstracting and formalizing some process to arrive at a result such as combining groups as the process behind addition.

Structural Meaning for Binary Operation

We define *structural meaning* for binary operation as meaning ascribed at a more global level where binary operation can be thought of a general pattern or way that elements interact without necessarily attending to the role of either input/output or combining two elements to arrive at a third. Structural meaning manifested in reasoning that looked holistically at operations often identifying familiar traits. This type of treatment tended to emerge in tasks prompting students to determine if two binary operations are the same. In fact, students applying a structural meaning may not even look at the inputs at all, but rather focus on the set of outputs or even the general utility of an operation. The meaning language surrounding binary operation often contained “pattern” or that the tables “behave the same.” The term structural was selected because (1) students leveraging this type of meaning where generally not attending to individual element interactions, and (2) they may be leaning on prior class knowledge on “structural properties” and their intimate relationship to binary operations.

At this point, we want to caution that these meanings a) are not always mutually exclusive in a given enacted object of learning, b) may internally have varying levels of sophistication, and c) are not necessarily consistent and coherent amongst individuals as they engage in tasks. In fact, of the interviewed students, most used all three meanings at different points when engaging in these tasks. In terms of sophistication, a number of frameworks exist to capture sophistication of function understanding. For example, if a student has a schema understanding (in the sense of Dubinsky & Wilson, 2013) of the binary operation function, they can likely approach majority of the tasks with high sophistication via treating a binary operation as a function object, process, or action at appropriate times. However, a robust understanding of binary operation using an arithmetic approach can also allow for successful treatment of binary operation tasks. As we know from the Concept Image / Definition (Tall & Vinner, 1981) literature, students' degree of sophistication with one meaning or definition may or may not align with other aspects. In this way, the purpose of the below analysis is to attend explicitly to critical aspects of binary operation appearing in students' enacted object of learning throughout the survey tasks.

In the next section we briefly outline the most prevalent aspects of binary operation found in the students' reasoning amongst surveys. The aspects can be found in the Table 2.

Table 2

Critical Aspects in Students' Concept Images

Aspect	Description	Critical/Noncritical
Closure	A binary operation is closed on the set	Critical Aspect
Two Elements	A binary operation is defined on two elements	Critical Aspect
Defined Element-wise	A binary operation is determined by where each pair of elements map	Critical Aspect
General Rule	A binary operation has a familiar, general name	Noncritical Aspect
Element-Operator-Element	A binary operation is of the form $a * b$	Noncritical Aspect

Critical Aspects of Binary Operation

We begin by exploring three critical aspects of binary operation reflected in students' enacted objects of learning. These are aspects of binary operation that are generally part of the intended object of learning and reflect the conventional approach to binary operation. We share the degree to which they were found in students' reasoning.

Closure. The most commonly addressed critical aspect of binary operation enacted was closure. In fact, reasoning about closure emerged during the *Is or Is Not* questions almost universally. Only one survey was absent of reasoning about closure. For example, when asked if x^2 was a binary operation on the set of real numbers, a typical student response was: "yes, because any $a \in \mathbb{R}$ squared will still be in $\mathbb{R}$." A number of tasks included functions that were not binary operations, but rather unary operations. These tasks may lead to students leveraging a function meaning focused on a single input and output to explore closure. For example, one student shared the following sentiment while exploring this prompt, "One input could only give you one unique output." This language reflects a function meaning for binary operation.

Two elements. The critical aspect of binary operation that was often not seen in the enacted objects of learning was that of an operation being defined on two elements, or on an ordered pair. This aspect was addressed only twice amongst the responses to $\sqrt[3]{x}$ and x^2 being binary operations respectively. As seen in the closure section above, the focus was exclusively on returning to the same set without attention to the type of input (or equivalently the domain of the function). The students who did attend to this critical aspect used language reflecting an arithmetic meaning using "two things" rather than "ordered pair" or input/output language. During a follow-up interview, one student reflected, "Do we need two things? Probably, because the word binary…Initially I was thinking closure, then I was like, wait should there be two things?" This student originally attended only to closure, but revised his thinking in light of the intentional variation between unary and binary operations in the tasks. His enacted object of learning was influenced by the particular tasks illustrating an example of a critical aspect moving from the background to forefront of his concept image.

Defined element-wise. When students were asked to determine if two binary operations were the same, their reasoning often varied depending on the task. For example, when students were provided with a table of elements and a list of elements defined element-by-element (see Figure 2), they were able to check each individual pair of inputs to determine if the outputs match. This approach likely reflects an arithmetic meaning for operation.

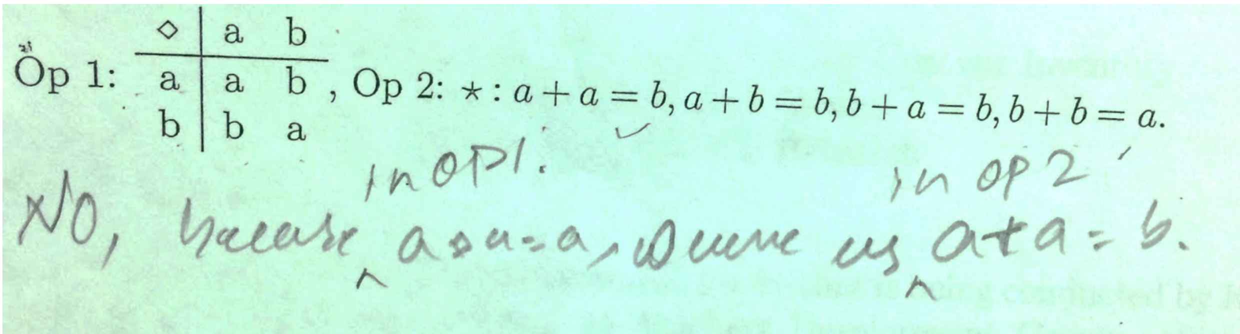

Figure 2. Student identifying two operations as different based upon an element-wise conception of binary operation.

However, when asked about the operations in the Cayley tables in Figure 3, different reasoning emerged reflecting a different enacted object. Student reasoning often included language like the "same pattern" or alternately they were the same type of operation, "addition." The differing number of elements and differing outputs for the same inputs were not treated as problematic in much of the student reasoning. In this task, the students did not seem to attend to where the elements map as a critical aspect of binary operation. This patterning approach aligns with a more structural meaning for binary operation. Rather than looking at combining individual elements, or thinking about the function mapping, the students looked holistically at the binary operations.

Op 1:

$\diamond$	0	1	2
0	0	1	2
1	1	2	0
2	2	0	1

, Op 2:

$\star$	0	1	2	3	4	5
0	0	1	2	3	4	5
1	1	2	3	4	5	0
2	2	3	4	5	0	1
3	3	4	5	0	1	2
4	4	5	0	1	2	3
5	5	0	1	2	3	4

Figure 3. $\mathbb{Z}_3$ and $\mathbb{Z}_6$ presented as Cayley Tables

This also occurred when asked if multiplication and division on the real numbers were the same operation. This occurred validly (such as stating one is associative and the other is not) and invalidly such as explaining that the operations were the same because, "basically to undo division, you apply multiplication" or that division could be rewritten as multiplication: "Yes because a/b is the same as $a * 1/b$." This structural approach likely encapsulates a number of ways of making sense of sameness in mathematics from identifying families (such as the operations in Figure 3 being types of "addition") or related operations (such as multiplication and division which are inverses). We do not want to imply that addressing patterns holistically may limit approaching this family of tasks. A high level of sophistication around this idea may be reflected in identifying structural or essential sameness in the sense of isomorphism (e.g. Weber & Alcock, 2004, Leron, Hazzan, & Zazkis, 1995). In fact, treating operation as a structure on sets is a fundamental goal in abstract algebra. To adopt APOS-language, seeing operations as structures rather than just processes or actions is necessary for an object conception. However, differing tasks illustrated a variety of student reasoning related to a structural meaning with both accurate and inaccurate approaches.

Noncritical Aspects of Binary Operation

While students treated intended critical aspects of binary operation to varying degrees, students' reasoning reflected a number of noncritical aspects as well.

Element-operator-element. Student responses reflected a struggle with identifying the binary operation in a situation where the binary operation did not appear as "element operator element" (E-O-E). The treatment of E-O-E format emerged in a number of tasks. When asked if $a \diamond b = 1/2\,(a+b)$ is associative, many student responses contained: $1/2\,(a+b) \neq (1/2\,a) + b$. In follow-up interviews, one student explained, "I don't know what is the binary rule." This particular student explained she lacked confidence in her response because she was not sure what the binary operation was. Her enacted binary object did not align with the object found in the task. Another student providing a similar response was asked to explain what this binary operation was and identified the "$a + b$" portion of the expression. In this sense, the student was focusing on the portion of the operation that appeared in E-O-E format. She had some cognitive dissonance when attempting to apply her definition of the associative property of: $a * (b * c) = (a * b) * c$ to explore whether the midpoint binary operation in fact met this requirement. When the interviewer asked what operation the $*$ represented between the b and c, the student responded, "the plus sign." The student responses to this prompt tended to link to the arithmetic meaning of binary operation, however, with perhaps a lower level of sophistication where the idea of combining two inputs is necessarily linked to a rule in the E-O-E format. This noncritical aspect was also seen in other tasks including the previously discussed task prompting students to determine if x^2 is a binary operation. Several student responses explained that x^2 could be written as "$x * x$" and therefore was a binary operation. They converted from a non-E-O-E form to an E-O-E form.

A general rule. In addition to binary operations typically represented in the E-O-E format, most binary operations have general names. When asked to generate a binary operation that forms a group on an atypical set $\{1,2,4\}$, a majority of students provided examples where they checked known operations such as modular arithmetic operations. The responses in this study were consistent with our previous finding (Melhuish & Fasteen, 2016), where students reasoned by checking a list of known operations. This desire for a general rule was further found in other tasks such as determining if the operation defined element-wise was a binary operation. A task of this sort was found in Figure 4.

$$1+1=1, 2+2=1, 1+2=2, 2+1=2 \text{ on the set } \{1,2\}$$

Figure 4. This task prompted students to determine if the operation defined element-wise was a binary operation.

This task was frequently left blank. When interviewing a student who did so, she explained, "I was just- I don't know. What are they trying to get at?" She explained she had not seen this binary operation and was attempting to define a general rule without success. She noted, "I guess because it didn't specifically say mod something- it blew me away because of that." A general rule appeared to be a critical aspect of her enacted object. This attention to a general rule reflects the similar desire for functions to have a general rule in the literature on student conceptions of function (Breidenbach, Dubsinky, Hawks, & Nicols, 1992). The interview subject primarily used language reflecting a structural meaning such as searching for a "pattern." However, her enacted object may be linked to her function knowledge (that of a general rule being a critical aspect), her arithmetic knowledge (a set of named, general rules), or more generally a desire to reduce abstraction level (Hazzan, 1999) to familiar operations.

Other properties. The list of critical aspects and permissible variations of binary operation does not present an exhaustive list of features attended to in students' enacted objects. Rather, they provide an outline of some of the most prevalent aspects found in responses to the survey tasks. In Figure 5, we provide a list of additional aspects of binary operation that were found in student reasoning. In the blue are critical aspects explicitly found in definitions. In red are critical aspects implicit in the binary operation definition. In purple are noncritical aspects of binary operation found in student reasoning. Additional noncritical aspects are related to functions (one-to-one), and groups (associative property, and group structure). Binary operations that impose a group structure are the typical examples in abstract algebra, and therefore their critical aspects may be adopted to the students' lived binary operation object.

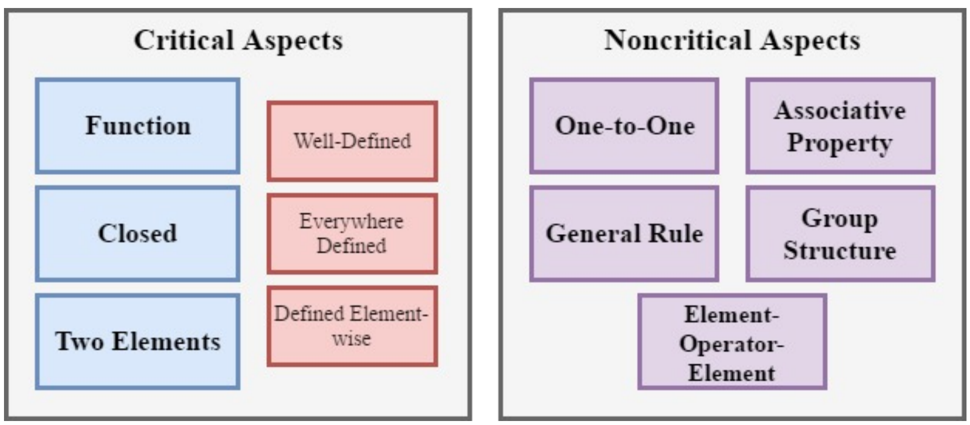

Figure 5. Critical and noncritical aspects of binary operation found in students' survey responses.

A Reflection on Variation as Attended to By Students

As a final point of discussion, we connect the available student reasoning, student interview responses, and the intended curriculum. During the four interviews, the students reflected on their experiences in class indicating that these tasks were atypical. Furthermore, they shared the binary operations they knew which covered a set of standard examples: arithmetic operations, modular arithmetic, and function composition. These exemplars are unsurprising as they are leveraged heavily in abstract algebra curriculums (Melhuish, 2015). One student explained:

> The things that we were shown in modern algebra were pretty basic examples of what a binary operation does. It almost seems like we are going to explore this to the extent that helps us in other topics and just move on to more interesting topics.

In the case of each of these standard examples, most of the noncritical aspects (such as E-O-E, general rules) exist. In this sense, it is not surprising that students may not be delineating these aspects as non-essential. In both their class and their textbook (Gallian, 2012), the only type of non-examples addressed have two elements, and but lacked closure. These non-examples did not allow for contrast between unary and binary operations. The types of variation students are exposed to may prevent them from becoming focally aware of other aspects that can cause a given relation to not meet the requirements of binary operation (such as the need for two elements) or overgeneralize noncritical aspects (such as E-O-E format).

All of the interviewed students also reflected that majority of their binary operation exposure was in the group context, i.e. one of the “more interesting topics” referenced above. In this sense, most binary operations examples are well-behaved, frequently with a general named rule, and often embodying additional properties such as the associative property. One student articulated the struggle to make sense of the relationship between binary operations and some properties explaining, “I know when it was introduced to me commutative and associative were very important. I didn’t really understand the connection between them.” He went on to share his uncertainty about whether they were required or optional properties of binary operation. Another student explicitly noted a noncritical aspect as always being part of the treatment of binary operation in her class. She explained that in their notes, binary operations always looked of the E-O-E form with the usage of “something like a star and circle” whenever discussing or introducing binary operations. This consistent feature was part of her lived object of learning, and was retained through her enacted object when approaching various binary operation-related tasks.

Two of the students, unprompted, expressed direct concerns about understanding what constituted a binary operation. One student reflected, “I don’t know what is and is not the fine details of [binary operation.]” She went on to explain that she felt they were supposed to apprehend the meaning of binary operation from examples, but was unsure of the point, struggling to sort critical aspects and noncritical aspects (our language). Furthermore, she explained, “You tend to focus on one little thing that stands out and you miss another one.” Her discussed metacognition on her learning process reflects the underlying premise of learning in variation theory: becoming aware of focal features through contrast and comparison.

Conclusion

By addressing meaning and critical aspects of student conceptions of binary operation, we were able to illustrate some of the many complexities associated with a topic that is often considered straightforward. Students reasoning reflected different meanings, and leveraged different aspects of binary operation depending on task and student. The aspects and meanings used varied in a ways illustrating incoherence in students’ concept images.

The results complement earlier work looking at action, process, and object conceptions of binary operation. As illustrated in Zandieh’s (2000) work with derivatives, these conceptual levels do not necessarily map in a hierarchical way. In our study we found reasoning at the structural level often treated binary operations at the object or process level without attention to the element (or action level). However, without de-encapsulating, the responses to the tasks tended have mathematical inaccuracies. In terms of the structure sense approach to binary operation, many of the tasks corresponded to levels of recognizing familiar and unfamiliar operations, and working with properties. The levels of recognizing familiar and unfamiliar binary operations broadly addresses a complete conceptualization when many students may have partial conceptualizations with some but not all critical components needed to address whether an instantiation is a binary operation. For example, students could attend to unfamiliar binary operations in terms of closure, but could not rule out non-examples that were unary and not binary. They could engage with tasks that presented unfamiliar binary operations when the form was E-O-E, but not always with differing presentations. We see our results as providing some nuance to more hierarchical frameworks by exploring a range of properties, representations, and example-types.

In order to situate these results in the larger sphere of variation, we may want to reflect on the examples and non-examples students are exposed to in their curriculum and classes. Studies have started looking at dimensions of variability available for students in abstract algebra classes in terms of groups and rings (Cook & Fukawa-Connelly, 2015; Fukawa-Connelly & Newton, 2014). Pairing such studies with student responses can provide a powerful impetus towards consciously varying examples and non-examples to best bring attention to structural attributes. In terms of binary operation, majority of textbooks focus explicitly on certain features such as the critical aspect of closure, and the permissible variations such as the associative property commutative property. If students are never exposed to instantiations that are unary or ternary, they may not assimilate particular critical aspects of binary operation. Without an awareness of these features, students may have a weakened foundation for making sense of group theory where binary operation plays a universal and critical role.

Overall, students appeared to draw on new learnings and variations, but also prior knowledge of functions and operations when approaching these prompts. Understanding binary operation requires a coordination of a new abstract notion of binary operation with the previous understanding of functions and familiar operations. The use of a meaning and critical aspects lens appeared to be a fruitful way to dissect student reasoning, concept image, and more particularly enacted objects of learning. Students provided a number of surprising responses such as seeing multiplication and division as the same operation or identifying a function like cuberoot as a binary operation. By dissecting various critical aspects, it became clear that even after the completion of an abstract algebra class, student concept images around binary operation may not be robust. This directly challenges the expert assertions that binary operation is a trivial topic (Melhuish & Fasteen, 2016). Furthermore, in our 2016 paper, we conjectured that students may have some underlying conceptual issues with binary operation that may account for performance on tasks aimed to explore their understanding of various topics such as subgroup and the associative property. This study confirmed that incomplete conceptions of binary operation not only exist amongst this population, but were prevalent across our sample. Additionally, the student responses in our small in-depth study were consistent with the responses in the larger, representative study. While, generalizability of these results is limited because of our sample size, we garner some strength of validity based on points of intersection with the prior study (e.g. Melhuish, 2105; Melhuish & Fasteen, 2016). As instructors and researchers in advanced mathematics, we caution overlooking binary operation conceptions and the essential role they play in any number of advanced classes.

Opportunities to Learn from Teaching:
A Case Study of Two Graduate Teaching Assistants

Erica Miller	Nathan Wakefield	Yvonne Lai
University of Nebraska-Lincoln	University of Nebraska-Lincoln	University of Nebraska-Lincoln

Pass rates in US first-year undergraduate mathematics courses are abysmally low. However, recent studies have found that there are doctoral programs that have improved pass rates by focusing on improving instruction. In particular, these exemplary programs focus on interpreting student thinking and that this instructional shift creates a more positive experience for undergraduate students. To scale up this result, it is important to understand how instructors connect student thinking to teaching actions. The purpose of this case study is to examine how two graduate student teaching assistants developed the ability to connect student work to hypotheses about student thinking and then link these hypotheses to teaching actions. For this analysis, the researchers introduce a framework that has potential to help providers of professional development identify how to strengthen graduate students' opportunities to learn from teaching, as well identify variations in graduate students' use of undergraduate student thinking to inform teaching actions.

Key words: Post-Secondary Professional Development, Graduate Teaching Assistants, Student Thinking, First-Year Course Instruction

Future faculty members often have their first teaching experiences when they are graduate students. Assigning graduate teaching assistants (GTAs) to their first course as primary instructor – meaning, the GTA is the person most responsible for teaching the material – is something that mathematics departments should not take lightly. Many universities entrust mathematics departments with the responsibility of teaching a substantial number of freshman students and, in many cases, the first college mathematics course that undergraduate students take is taught by a graduate student. As the economy depends more and more on science, technology, engineering, and mathematics, mathematics departments must recognize that the courses they teach can be seen as 'gatekeepers' to economic opportunity (Kamii, 1990; Moses & Cobb, 2002). With this recognition, mathematics departments must acknowledge that GTA instruction is critically important at not just the departmental or university level, but also the national level. In light of this responsibility, one of the primary goals of mathematics departments should be to develop graduate students to provide high quality instruction. To meet this goal, an increasing number of mathematics departments are providing GTAs with professional development (Border, Speer, & Murphy, 2009; Deshler, Hauk, Speer, 2015; Ellis, 2015). For this reason, it is necessary and important to study not only *how* to provide professional development to graduate students, but also the *impact* that professional development has on the development of GTAs as teachers. In this case study, the researchers examine how two GTAs leveraged their professional development experiences to use observations about undergraduate student work to inform teaching actions.

Previous Literature on Professional Development

While the researchers acknowledge that there are important differences between teaching at the K-12 and post-secondary level, there is also much that can be learned from K-12 professional development (Deshler, Hauk, & Speer, 2015). Following this suggestion, this work draws on studies of effective characteristics of professional development for post-secondary and K-12 teaching.

Opportunities to Learn From Reflection on Student Thinking and Teaching

In 2009, Blank and de las Alas conducted an extensive meta-analysis of research reports between 1986 and 2007 to determine the key characteristics of effective K-12 professional development. They found that the greatest improvements in teaching could be attributed to the teacher experiencing intensive initial professional development in combination with multiple opportunities for sustained engagement, such as plan-teach-reflect cycles and reviewing student work. At the post-secondary level, similar results have been found to hold, especially when professional development opportunities allow GTAs to attend to student thinking (e.g., Kung & Speer, 2009).

It is widely accepted that teachers can and should improve their teaching by reflecting on instruction and student thinking. In addition, reflection should occur within communities of teaching. Multiple national policy documents for K-12 teacher education cite such reflection as a critical component for improvement (e.g., InTASC, 2011; NSDC, 2015). Also, reflection certainly can be a key contributor to teachers' ability to learn from their teaching experiences. However, simply providing time and a mandate for teachers to reflect on their instruction is no guarantee of improved instruction. For instance, teachers who catalogue good and bad moments without hypothesizing about factors that contribute to the quality of these moments are unlikely to increase the quality of their teaching. Also, teachers who characterize their students' conceptions without attending to how instruction shapes students' conceptions are unlikely to leverage their knowledge of student thinking. As Horn and colleagues have argued, it is not merely the presence of reflection in communities that is important, but rather the opportunities to learn that teachers create from these reflections (Hall & Horn, 2012; Horn, 2005; Horn & Kane, 2015; Horn, Kane, & Wilson, 2015).

The critical insight that the researchers gleaned from Horn and colleagues' work is the following theory: *in teachers' reflections, the more tightly linked the observations of instruction and students are to future teaching actions, the greater the opportunity to learn from reflection*. In other words, it is not sufficient to just make observations, however astute, about previously experienced instruction and student thinking. It is also not sufficient to just make claims about what one might do in future teaching actions. Rather, the greatest opportunities to learn from reflection occur when observations about previously experienced instruction and student thinking inform future teaching actions. If the model from K-12 holds, then one would expect that GTAs' opportunities to learn will also be more meaningful when their reflections link observations about instruction and student thinking to future teaching actions.

Characterizing Opportunities to Learn From Reflection

Several studies have examined variation in teachers' opportunities to learn from reflection on teaching. Using an analysis of 17 hours of secondary teachers' workgroup conversations across an entire year, Horn and Kane (2015) found that not only were opportunities to learn not equally distributed, they also represented a developmental story of "accumulated advantage" (p. 8). Where there were more opportunities to learn in the beginning, there were even more opportunities to learn later. In a comparison of two middle school teachers' workgroups, Horn, Kane, and Wilson (2015) found that how teachers interpret data about students impacts their opportunities to learn from reflection on teaching and student thinking. One group focused on increasing proficiency rates by determining how to allocate resources to particular groups of students, and thus did not focus on students' understandings. The other group attended to students' understandings but was limited by pressure to go over as many of the instances where their students might improve, rather than to discuss any instructional implication deeply.

Horn and colleagues' work on opportunities to learn contributes a frame for characterizing variation in opportunities to learn from reflection on teaching and student thinking. Namely, their work suggests that it may be beneficial to examine how well teachers are able to interpret data about student thinking in order to inform their future teaching.

Lai, Smith, Wakefield, Miller, St. Goar, Groothius, & Wells (2016) used this frame to examine GTAs' opportunities to learn from reflection on teaching and student thinking. To compare clarity of reflection, the authors modeled GTAs' reflections as arguments about future teaching actions based on data about student thinking. The clarity was conceptualized as how specific and connected the logical argument was when connecting data to future teaching action. These authors used a modified version of Toulmin's (1958) model to analyze the connections GTAs made between what they observed their students doing and their future plans for teaching. Lai et al. performed a qualitative analysis of 16 final papers written by mathematics GTAs and developed a coding scheme that categorized papers as low connectivity, medium connectivity, high connectivity with low coherence, and high connectivity. The authors concluded that even when GTAs are teaching the same course, participating in the same professional development, and completing the same task, the clarity of their reflections on the nature of student thinking varies widely.

However, no attempt was made to look at the growth that the GTAs experienced. For example, while the authors found examples of GTAs with high connectivity in their final papers, there was no indication of what growth may have occurred over the course of the professional development program. An important question that resulted from this is whether these cases of high connectivity are representative cases of individuals who entered the professional development program with these skills.

Study Description

The purpose of this intrinsic case study (Stake, 1995) was to better understand the growth experienced by two mathematics GTAs over the course of their involvement in a professional development seminar. During the seminar, GTAs collectively reflected on their teaching each week, sometimes in the context of informal discussions on readings about learning and teaching and other times in more formal writing assignments. These two GTAs selected for this case study were identified because their mathematics department had recognized them as strong teachers and pedagogical leaders. In this paper, GTA growth is conceptualized as enhanced opportunities to learn from teaching through reflection on instruction and student thinking, over time, as described in Lai et al. (2016). The central question that is guiding our inquiry is: *How did GTAs grow as learners of teaching over the course of involvement in a professional development seminar?* The central question is decomposed as follows:

1. How did the GTAs' capacity to connect student thinking to future teaching actions in their formal reflections change over time?
2. How did GTAs' capacity to use resources from the professional development seminar in their formal reflections change over time?

Using similar analytic methods as what Lai et al. (2016) used to analyze a set of papers collected from GTAs at the end of a professional development seminar, the researchers conducted this longitudinal case study to examine the growth of the GTAs over the course of the seminar. Although the context of this case study makes it hard to generalize, this analysis does help identify what GTA growth looks like and provide one possible frame from which providers of professional development can evaluate their programs.

Theoretical Frameworks

In this paper, GTA growth (as learners of teaching) is viewed as the enhanced opportunity to learn from reflection about instruction and student thinking, where the strength of an opportunity to learn is conceptualized as the connectedness from observations of student thinking and prior instruction to proposals for future teaching actions. The researchers model teachers' reflections as an argument about how observations of student thinking and instruction inform future teaching actions. They also examine the connections between student data, student thinking, hypothesis, and future teaching actions. These four components and the logical connections between them constitute our model, which is depicted in Figure 1. Our model is an adaptation of Toulmin's (1958) argumentation model, which he developed for analyzing the grounds, claims, and warrants used in legal arguments. In Toulmin's model, grounds are the evidence underlying a claim and a warrant justifies the relationship between the grounds and the claim. Recently, Toulmin's argumentation model has been applied in other fields, such as mathematics education (Inglis et al., 2007).

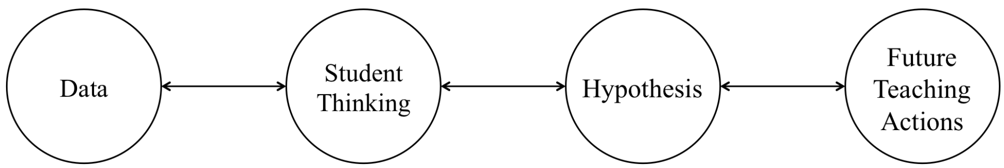

Figure 1. Framework for GTA arguments.

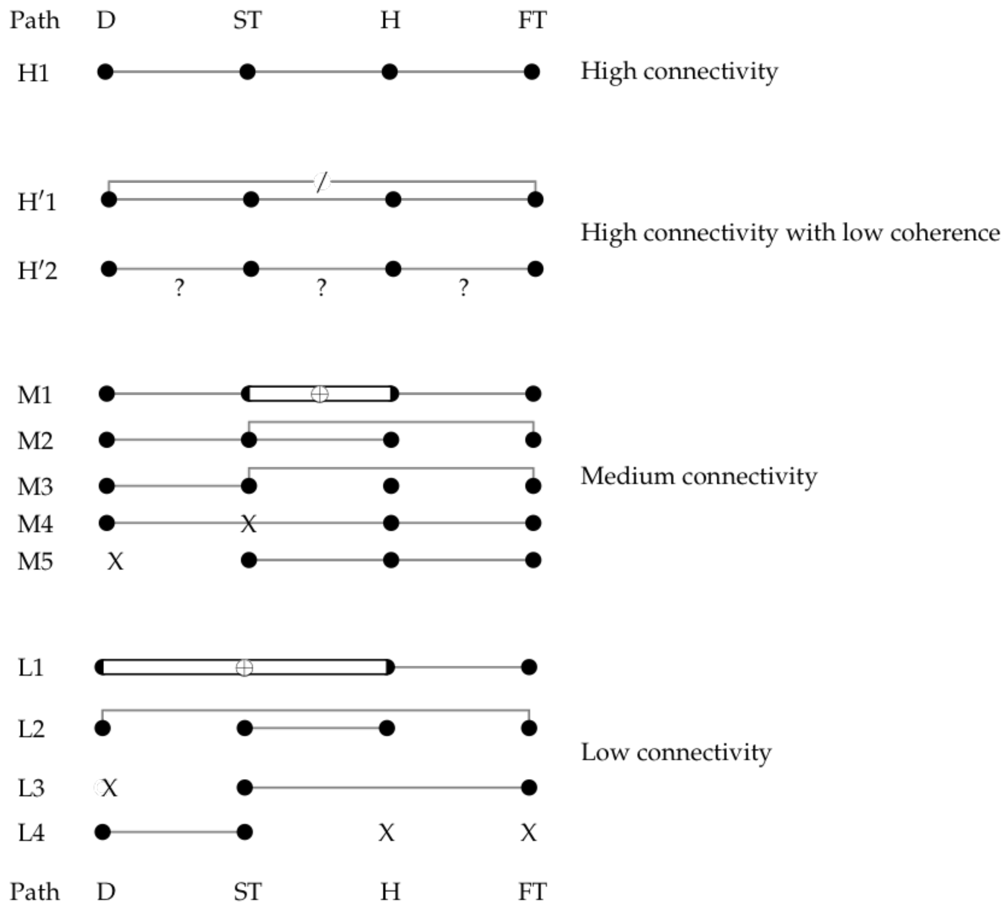
Following Lai et al. (2016), *data* is defined to be the written student work collected by the instructor and any memory-recalled communication observed by the instructor and recorded in their writing. In their argument, the instructor may interpret this data in the form of *student thinking.* That is, student thinking is the instructor's expression of how he or she believes the data should be interpreted in order to reflect the student's work. Also, instructors may make a *hypothesis* about the likely reasons for a student to think in the way in which the instructor has interpreted. This hypothesis depends upon the underlying origin of student thinking. Finally, an instructor may plan a *future teaching action* based upon any or all of the previous elements. These four elements, and the connections between them, form the framework the researchers used to analyze GTA work.

Using this framework, a GTA's work can be characterized by the presence or absence of any of the four elements and the connections between them. When looking at connections, coding captures not just the presence or absence of a connection but also the plausibility of a connection. Plausibility refers to the strength of a connection. For instance, if the instructor interprets the student thinking in a way that is not supported by the data, this would be coded as an implausible or weak connection. Using this coding scheme, a GTA's work is characterized as having *low connectivity* if explicit references to two or more of the four elements were missing, or the connections between these elements are not present or plausible. On the other hand, a GTA's work is characterized as having *high connectivity* if the GTA clearly articulates all four elements and makes explicit and plausible links between these elements. The tag *low coherence* is added when the four elements are articulated, but weak, implausible, or implicit links are present. A final category of *medium connectivity* is used when at least three of the four elements are present and most, but not all, of the links are explicit and plausible. A visual representation as well as an explanatory key of these various types of connectivity can be found in Figure 2.



Key: D = data, ST = student thinking, H = hypothesis, FT = future teaching actions, X = component absent, ⊕ = conflated components, •—•= link was attempted and satisfied criteria, $\bullet\overset{?}{—}\bullet$= no consensus from research team on whether link is plausible, •-/-•= future teaching actions do not plausibly address student thinking identified in data.

Figure 2. Categories of connectivity of GTA arguments.

Data and Methods

Using the framework described, the researchers examined the growth of two particularly strong GTAs by studying the written work they submitted while enrolled in a pedagogy professional development seminar course taught in a mathematics department during the fall 2015 semester.

Data Collection

Context. At the university in the study, every graduate student who is assigned to be the primary instructor of a course for their first time is required to enroll in a seminar on teaching and learning mathematics at the post-secondary level. A graduate student is a primary instructor if they have independent authority to make classroom decisions and assign grades.

In the past few years, approximately 15 students have enrolled in this class each year. This seminar meets for two hours a week in the fall semester and one hour a week in the spring semester. The graduate students in this course read educational literature, including articles ranging from foundational pieces, such as Erlwanger's (1973) discussion of Benny, to expository articles, such as Tsay and Hauk's (2013) explanation of constructivism.

While enrolled in the seminar, the graduate students are assigned to teach either intermediate algebra or college algebra, which have a typical enrollment of 34 and 40 students respectively. Small group discussions are a focus of these courses and the GTAs involved in the seminar make up the majority of the instructional team for these courses. While there are a few adjunct instructors who occasionally teach the courses, they do not participate in the seminar. The faculty member who leads the seminar may also teach one of these courses, including the term in which the data were collected for this report.

Since the graduate students enrolled in the seminar are all teaching one of two courses, the seminar provides an opportunity to discuss shared challenges and experiences. The shared experience of teaching common courses and reading common articles provides the backbone of weekly discussions for the seminar. In these discussions, the graduate students are encouraged to reflect on their own teaching utilizing the vocabulary of mathematics education.

Data. The data for this study were collected in the fall of 2015 and includes three assignments completed by the GTAs throughout the fall semester. The first assignment asked GTAs to work in teams of three and analyze student work on a quiz in order to identify an area of unproductive student thinking. In the group paper, the GTAs described the unproductive student thinking they had identified and planned an intervention for use in office hours or class to help students. Finally, the assignment called for a one-page summary explaining why the team believed the intervention would be successful. The second assignment had the same requirements, but this time the GTAs had to complete the assignment individually and analyze a different set of student work. The third assignment, which functioned as the final project for the course, followed a similar format. However, in this final assignment, the GTAs were explicitly asked, as opposed to implicitly asked, to theorize about the roots of the unproductive student thinking.

Paper Summaries

Susan. In the first group assignment, Susan analyzed a quiz question that asked students to explain how they know that a given table of data is exponential. Of the six samples of student work Susan included, three samples claimed that the data was exponential because the rate of change was not constant. Susan used the data to argue that students were thinking unproductively about exponential functions as nonlinear. As Susan reflected on possible roots of this unproductive student thinking, she referenced two hypotheses: (1) "in the semester we had spent most of our time on linear and exponential functions so they were fresh in our students' mind" and (2) "in teaching exponential functions, we emphasized the fact that they are not linear and often compared them to linear models" (Page 2). Finally, the intervention that Susan's group planned involved asking students to analyze four different functions in an attempt to demonstrate the plurality of families of functions.

In her second paper, Susan analyzed a quiz problem where students were given the graph of a piecewise-linear function and asked to graph the function $-1/2g(x)+2$. Susan analyzed two samples of student work that had identical incorrect graphs, but different steps written down to describe how they got their graphs. One student listed steps that were not only incorrect (given the formula), but also did not match the graph they drew. The other student listed steps that were correct (given the formula), but also did not match the graph they drew. The unproductive student thinking that Susan identified was that the students did not recognize the connection between the graphical and analytical representations of transformations. She then hypothesized that the root of this unproductive thinking was that the students had survived on merely a mechanical understanding of the analytical steps to transform a function. Susan intervention was designed to help students discover a step-by-step process for transforming graphs in order to tie their analytical understanding to the graphical representation. The intervention directed students to identify "important" points on a piecewise-linear graph (i.e., corners and endpoints of the piecewise function), list the analytical steps involved in the transformation, transform the "important" points at each intermediate analytical step, and then use the transformed points to sketch the transformed graph.

For the final assignment, Susan analyzed another transformation problem, but this time it came from an exam. In the problem, students were given the domain and range of $f(x)$ and asked to find the domain and range of three different transformations of $f(x)$. In analyzing the student work, Susan found that 53% of her students "used the wrong operation, the wrong order of operations, or some combination of the two" with the third transformation, which was $f(2(x+3))$. Drawing upon this data, Susan identified that students had unproductive thinking when trying to determine what order to apply the multiple horizontal transformations. Her hypothesis about the roots of this unproductive thinking was that students had attempted to memorize the order of horizontal transformations as a rule and did not understand why it worked. This caused problems when they attempted to apply the rule, because it contradicts their intuitive desire to follow the order of operations. To help students move towards a more productive way of thinking about the order of horizontal transformations, Susan developed a worksheet. The worksheet started by connecting transformations to function compositions, considered the transformation of a single point, asked the students to hypothesize about the order, and ended with a graphical application of transformations.

Karen. For the first group assignment, Karen analyzed a team quiz problem that asked students to explain how many answers there were to a system of two linear equations. Karen analyzed two sets of student work. One had the correct answer (no solutions), but an incorrect explanation, while the other one provided an incorrect answer (exactly one) and an incorrect explanation. Karen identified that both students had unproductive thinking in the explanations they gave to support their answers. In particular, the first one claimed that if all of the variables cancel, then there are no solutions. On the other hand, the other one claimed that if the lines are not the same, then they must have exactly one solution. Karen hypothesized that "if either of these groups had a better understanding of the geometric interpretation of a linear system, then they would have been able to provide better explanations as well as come to the right conclusion" (p. 21). In order to address the underlying root of the unproductive thinking, Karen designed an intervention that starts with a linear system that has infinitely many solutions. She would let the students solve it their own way, with the hope that they would come to the erroneous conclusion that there are no solutions. To show them their error, they would graph the two equations. Finally, they would consider a system of equations that has no solutions and consider its graphical representation.

For the second assignment, Karen analyzed a quiz problem on function notation. Overall, students did well on this problem, but there was one common mistake that was made. Given the function $f(x)=x^2+1$, several students were able to correctly find $f(2)$ and $2f(x)$, but incorrectly claimed that $f(2x)=2x^2+1$. Karen identified that the students had unproductive thinking when working with function compositions. Karen hypothesized that due to the fact that function compositions had previously only been done with linear equations, students had erroneously generalized properties that are only true for linear function compositions. In order to address the root of the unproductive student thinking, Karen's intervention focused on building connections between concrete and abstract algebraic operations. The intervention starts with some simple computations of $f(2)$ and $f(4)$. Then, students used their own method to find an equation for $f(2x)$. To test whether or not they got the right equation, the intervention directed them to substitute $x=1$ and $x=2$ into their new equation and see if that matches what they got for $f(2)$ and $f(4)$. Finally, the intervention ended with a discussion of how to find the correct formula for $f(2x)$.

In Karen's final paper she analyzed a problem from a quiz on algebraic fractions. Karen focused on one type of cancellation mistake that was commonly made by her students. When attempting to simplify a rational expression, Karen found that many students followed the unproductive thinking that you can cancel out factors that are common to only the denominator and one of the addends in the numerator. At the root of this unproductive thinking, Karen hypothesized that students think in terms of rules instead of concepts. In particular, they are not thinking about the mathematical idea of fraction, multiplication, and division when simplifying rational expressions. In order to help students form a more productive way of thinking, Karen developed an intervention that began by exploring the arithmetic involved in simplifying fractions. They begin by exploring two fractions, one where the denominator shares a common factor with only one of the addends in the numerator, and the other where there is a common factor in the denominator and entire numerator. Then, Karen used this familiar context to explain why cancellation doesn't work in the original rational expression.

Analysis

For each of the two GTAs in this study all three papers were collected and coded following the coding scheme developed by Lai et al. (2016). GTA names were redacted to protect the privacy of individual GTAs. Coding was completed independently by two of the researchers who then met to reconcile codes. Upon analyzing the team project submitted by one of the students, one of the researchers became aware that she had been a member of the team who had submitted that paper. To overcome any potential bias caused by having been part of the group project, another researcher assisted with triangulation for this assignment. The researchers then compared notes and reconciled differences. It is worth nothing that this particular group paper provided the research team a unique opportunity to compare codes with what the writers had intended to communicate. Differences between the intention of the paper and the coder's interpretation of the paper were taken into consideration and having a researcher reflect on her own work help strengthen triangulation.

After initially coding using Lai et al. (2016) coding scheme, the researchers noticed that there seemed to be important details that the coding scheme failed to capture. In particular, the research team all agreed that Susan had grown in ways that were not captured by the initial coding. In order to address this unexpected finding, the research team decided that a second phase of analysis was needed. To accomplish this, the research team reread all the assignments and focus on how claims were made and supported. To do this, the research team identified which articles from the seminar the GTA had used to support their arguments and how these articles were used. The reason why the researchers chose to look at the references used was driven by the research questions. While our initial analysis addressed the first research question, the researchers realized that the second analysis was needed to address the second research question.

Findings

Over the course of the professional development seminar, Karen's arguments changed from being characterized as having medium connectivity to high connectivity. Susan's arguments, however, were consistently characterized as having medium connectivity (Figure 3).

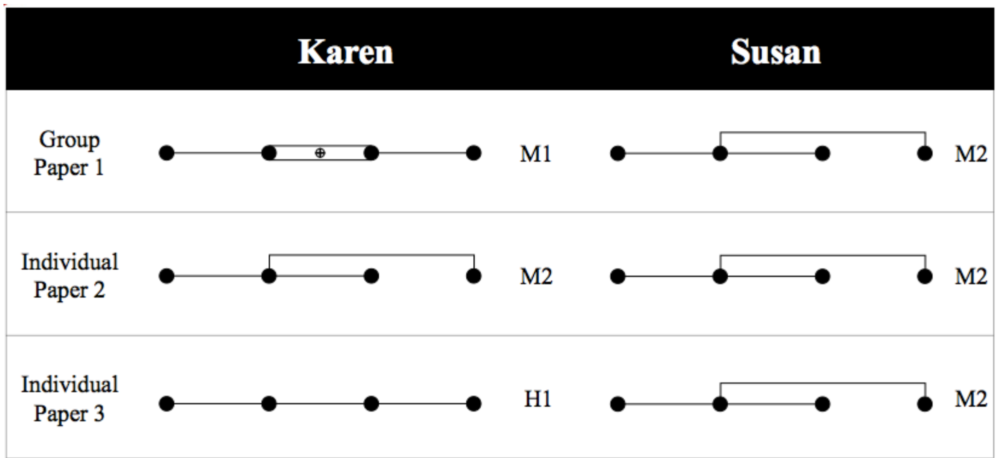


Figure 3. Classification of connectivity of Karen & Susan's arguments.

In Karen's first paper, there were strong links between the data, problem, hypothesis, and intervention. However, it was somewhat difficult to tease the problem and hypothesis apart. At first, the researchers thought that the hypothesis was missing. However, after further examination, they were able to redefine the problem in a way that disentangled it from the hypothesis. However, since it was difficult to separate the two, they felt that Karen did not make a strong case for each one individually, and therefore unintentionally conflated them together. In the second paper, Karen made strong links between the data, problem, and hypothesis. However, the link between the hypothesis and the intervention was weakly supported. Finally, Karen was able to make strong links between all four components in her final paper. In each of Susan's papers, there were strong links between the data, problem, and hypothesis, but the intervention seemed linked more to the problem than to the hypothesis.

When considering the ways claims were made and supported, a different picture is formed. In her first group paper, Susan's group did not use literature to support her claims, but instead referred to things like "well-known-facts" without supporting evidence. However, over the course of the term, Susan began to incorporate existing research into her discussions of students (Figure 4). Karen, on the other hand, did not begin directly citing existing research until the third paper. However, in her final paper, Karen synthesized multiple points of literature to support her arguments (Figure 5). It is important to note that on the rubric for the third paper, there is an item that does not appear on the previous rubrics: "Paper theorizes about the roots of the misconception drawing on literature to support the claim." The previous assignments, on the other hand, stated no requirements for citing literature. This could explain Karen's choice to use begin citing literature in her final paper. However, Karen chose to use existing literature not just for the hypothesis but also for the intervention. Furthermore, Karen did try to anchor her previous interventions in the language of constructivism. The exact effect that the change in the rubric had is unknown.

Nothing of Interest	"As Lage and Gaisman observe in `An Analysis of Students' Ideas about Transformations of Functions,' looking at students' understanding of function transformations provides an opportunity to analyze students' ideas on functions and variables."	• "That is, in the language of constructivism, this topic will introduce a disequilibrium for the student that is not easily assimilated or accommodated." • "Not only is this a generally destructive attitude to have toward math, but the reinforcement of an external locus of control may cause the student to slip into a `Benny'-like reaction: believing that mathematics is simply a set of arbitrary rules, some of which might contradict each other." • "As one mathematically competent student in Hauk's `Mathematical Autobiography Among College Learners in the United States,' reflects, `I always try to find the answer right away and if I can't find it, I say those three words, `I hate Math.''"

Figure 4. Susan's use of literature in her arguments.

Another factor that may have contributed to the increased use of literature by both Susan and Karen is the increase in the literature available to both GTAs. The professional development seminar can be roughly broken into four themes throughout the semester: setting the stage, discussing classroom dynamics, discussing assessment, and looking at who our students are. Within each section a series of articles are used to motivate discussion. As seen in Tables 1 and 2, Susan and Karen both incorporated literature from the professional development seminar into their arguments. Moreover, Susan and Karen referenced literature that spanned multiple themes, synthesizing ideas from the literature. Figure 6 provides a temporal bipartite graph showing how literature appeared in Susan and Karen's writing.

Discussion

By taking a longitudinal approach, the researchers were able to examine how GTAs grow over the course of the professional development seminar. Using our original coding scheme, changes in the GTAs' ability to clearly reflect on the nature of student thinking were characterized. However, the researchers found that this analysis did not capture the ways in which Susan had experienced growth or provide us with a clear answer to our second research question. To address that issue, the researchers conducted a second analysis that focused on GTAs' capacity to use resources from the professional development seminar in their formal reflections by looking at how the GTAs' claims were made and supported. Based upon the analysis done in the previous study that looked at all of the final papers (Lai et al., 2016), the need for a second type of analysis was not anticipated. However, using our coding scheme as a way to analyze longitudinal data brought some of its weaknesses to the forefront.

Group Paper 1	Individual Paper 2	Individual Paper 3
"Learning, in the constructivist scheme, occurs when a student is put in a state of disequilibrium and must assimilate new information, reject it, or accommodate their mental constructions to the new data. Our intervention aims to spark disequilibrium in our students so that they must reevaluate and reform their conception of solutions to systems of linear equations."	"This understanding is built by provoking disequilibrium, in the constructivist terminology.... This is the moment of disequilibrium that forces them to construct a new understanding of the relevant concepts"	• "In this way, they are similar to "Benny" in Erlwanger's study, since they think in terms of rules divorced from concepts. We shall see more commonalities with Benny shortly" • "Erlwanger identified a "behaviorist" approach to mathematics instruction as one of the root causes of Benny's misconceptions, and I believe that a similar issue can be seen here…. While the average high school math class may not be as explicitly behaviorist as Benny's "IPI," teachers nonetheless focus (unwittingly, perhaps) on obtaining answers, at the expense of developing understanding." • "I'm reminded of another article we read, about Brazilian schoolchildren who easily solved math problems when selling produce on the streets, but were unable to solve the exact same problems when presented with them in a classroom setting. Using students' existing knowledge an[d] mathematical intuition as a base off of which to build the theory would promote deeper understanding, I think."

Figure 5. Karen's use of literature in her arguments.

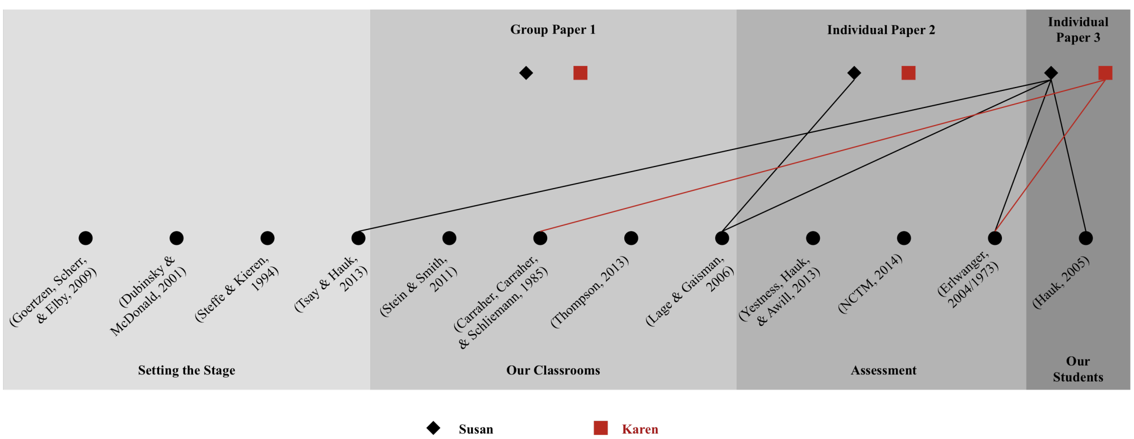

Figure 6. Temporal bipartite graph of Susan and Karen's use of literature.

While the original framework developed may not be able to capture every aspect of GTA growth, one strength that it does have is its adaptability. In particular, the researchers believe that our framework could be used as a way to analyze GTA growth in a variety of contexts. For example, there are several departments who integrate video case studies into their professional development seminars as a way to provide GTAs with the opportunity to reflect on and respond to classroom situations. Our framework would fit nicely with this type of activity, where the data is the video case study, the student thinking and hypothesis are the GTAs reflection on the video, and the future teaching actions are the GTAs plan for what they would do next. Another adaptation the researchers have considered is using this framework to analyze GTAs ability to reflect and plan future teaching actions when looking at student thinking in a way that does not focus on a deficit model. For example, GTAs could analyze student data in an attempt to identify what the students do understand, hypothesize what contributed to the development of that understanding or how they could build upon that understanding, and plan future teaching actions. In this case, the researchers believe that the hypotheses would be intrinsically connected to the future teaching actions, which would strengthen the connectedness of the GTAs arguments.

In this paper, the researchers have attempted to better understand the effects that this particular professional development program has on GTAs. Analyzing the two particular GTAs chosen has provided some insight into how GTAs might grow over the course of their involvement in a pedagogy professional development seminar course. Both GTAs did exhibit growth, but in different ways. Karen's arguments evolved to show more connectivity between data, student thinking, hypothesis, and future teaching action. On the other hand, Susan began to utilize literature from the seminar in her reflections on student thinking. However, both GTAs adopted a more constructivist approach to teaching as evidenced through their arguments. A stated goal of this particular professional development program is to support GTAs as they become evidenced-based practitioners of mathematics education. For these two GTAs, this goal appears to have been met.

Implications and Directions for Future Research

This intrinsic case study provides evidence that the professional development program discussed may have some effect on the growth experienced by two mathematics GTAs over the course of their involvement in a professional development seminar. This suggests that mathematics Ph.D. students can benefit from reading mathematics education literature, analyzing student work, and planning future teaching actions. Future research might look at similar activities across a larger sample and, in particular, analyze how GTAs who might not be identified as strong teachers grow. Secondly, it would be interesting to rework the three papers assigned in the professional development seminar to remove the apparent deficit view of student thinking and then conduct similar research from a strength-based perspective. The growth of graduate student professional development in the mathematics community is exciting and should provide a rich ground for mathematics education researchers.

Learning to Notice and Use Student Thinking in Undergraduate Mathematics Courses

Anna E. Pascoe
Michigan Technological University

Shari L. Stockero
Michigan Technological University

This study evaluated the outcomes of an intervention focused on developing mathematics graduate teaching assistants' (GTAs') skills of noticing and effectively responding to instances of student mathematical thinking that have significant potential to further students' learning. Four GTAs participated in a semester-long intervention that included individual analysis and group discussion of video of undergraduate mathematics lessons. The MOST Analytic Framework (Stockero, Peterson, Leatham, & Van Zoest, 2014) was introduced to aid in these activities. The GTAs also completed a pre- and post-interview to document their real time noticing and an assessment of common content knowledge. Results indicate that the intervention was successful in improving the GTAs' noticing skills in a variety of ways and in their ability to propose student-centered responses.

Key words: Graduate Teaching Assistant Training, Teacher Noticing

Research has shown that student-centered instruction leads to more effective learning for people of all ages (National Research Council [NRC], 2005). Higher education has been slow or unsuccessful in implementing student-centered instruction (Barr & Tagg, 1995; Felder & Brent, 1996), however, with transmissive instruction (i.e., lecturing) still prominent (Ramsden, 2003; Svinicki & McKeachie, 2014). Challenges for adopting student-centered instruction include student resistance, instructor comfort level, and the time needed to see results (Felder & Brent, 1996; Seymour, 2002). Some researchers suggest promoting changes in higher education teaching methods through GTA training (e.g., Cano, Jones & Chism, 1991). Since effectiveness of GTAs typically affects undergraduate students in their early years of study, GTA training is also important in student retention (Cano et al., 1991; Speer, Gutmann, & Murphy, 2005). With a workforce shortage in science, technology, engineering, and mathematics (STEM) fields (President's Council of Advisors on Science and Technology, 2012), student retention is crucial in university STEM departments (Seymour & Hewitt, 1997; Suchman, 2014).

At the K-12 level, a teacher's ability to notice aspects of instruction as it unfolds has been recognized as important in the implementation of student-centered instruction. Many studies have found that *professional noticing of [students'] mathematical thinking*—defined to include attending to, interpreting, and deciding how to respond to students' strategies and understanding (Jacobs, Lamb, & Philipp, 2010)—can be learned and improved through teacher education (e.g., Jacobs et al., 2010; McDuffie et al., 2014; Sherin & van Es, 2009; Stockero, Rupnow, & Pascoe, 2015, 2017). Although teacher noticing interventions are not widely practiced in higher education, the gains made with K-12 mathematics teachers suggest that similar results may be possible.

Also foundational to effective mathematics teaching are the six domains of mathematical knowledge for teaching proposed by Ball, Thames, and Phelps (2008). Critical to this study is common content knowledge (CCK), the mathematical understanding and proficiency used in diverse contexts not exclusive to teaching. Without CCK, a teacher could not adequately guide students in building such knowledge. In addition, mathematics teachers would not likely be able to determine which instances of students' mathematical thinking are important to notice without a strong command of CCK. Because both noticing skills and CCK are important for effective mathematics teaching, it would be of interest to investigate if and how these factors are related.

This work examines the outcomes of a GTA training intervention focused on analyzing undergraduate mathematics lesson videos with a teacher noticing framework as a means to support GTAs' more effective noticing and use of student thinking, which has the potential to support their enactment of student-centered instruction in their classrooms. Of particular interest is measuring the effectiveness of the intervention in improving GTAs' noticing of high-potential opportunities to build on student thinking (Leatham, Peterson, Stockero, & Van Zoest, 2015) and in supporting their ability to propose student-centered responses to such instances. This work seeks to answer the following research questions: (a) How effective is the intervention in improving GTAs' noticing of MOSTs?; (b) How effective is the intervention in supporting the GTAs' ability to propose in-the-moment student-centered responses to instances they identified in video?; and (c) What is the relationship between the GTAs' CCK and their noticing skills?

Theoretical Framework

With the goal of improving GTAs' use of student mathematical thinking in undergraduate mathematics classrooms, this study used the MOST Analytic Framework (Leatham et al., 2015) to characterize instances of student mathematical thinking that are not only important to notice, but also the most fruitful to discuss in a lesson because of their potential to support students' mathematical learning. MOSTs—**M**athematically Significant Pedagogical **O**pportunities to Build on **S**tudent **T**hinking—are defined as "instances of student thinking that have considerable potential at a given moment to become the object of rich discussion about important mathematical ideas" (p. 90). To be a MOST, a moment must satisfy three characteristics: student mathematical thinking, mathematically significant, and pedagogical opportunity. To satisfy these characteristics, the student mathematics must be inferable and related to a mathematical point, the mathematical point must be appropriate to the learning level of the students and a central goal for student learning, the student mathematics must create an intellectual need for students to understand the mathematical point, and it must be the right time to address the intellectual need at that moment.

Methodology

Participants and Intervention

The participants were four mathematics GTAs from a Midwestern U.S. university. Three had completed their first year of graduate study and had one to two semesters of teaching experience, and one had completed two years of graduate study with six semesters of teaching experience. All four participants had previously completed training required by the mathematical sciences department: a one-week GTA orientation prior to their first semester of study, a course entitled Teaching College Mathematics in which the GTAs prepared and delivered lessons three times throughout a semester with feedback and support from peers and their instructor, and a six-week seminar during their first semester of teaching in which the GTAs read and met weekly with an instructor to discuss select chapters of *Teaching Tips* by Svinicki and McKeachie (2014). Their participation in the current study was voluntary.

The GTAs engaged in a ten-week professional development intervention facilitated by the first author in the fall 2015 semester. The goal of the intervention was to improve the GTAs' skills in attending to, interpreting, and responding to MOSTs in a student-centered manner. The design of this study was adapted from Stockero and colleagues' work with prospective secondary school mathematics teachers (Stockero, 2014; Stockero et al., 2015, 2017) focused on helping them learn to notice and respond to MOSTs that surface during a mathematics lesson. Both before and after the completion of the intervention, each GTA completed a one-on-one, video-recorded interview with the researcher/facilitator; the purpose of this interview was to capture their in-the-moment noticing. During the two interviews, the GTA watched the same short video clip from an undergraduate mathematics lesson that was recorded at the same university in which the GTAs were enrolled. The GTA was prompted by the researcher to stop the video if they thought a *mathematically important moment that the instructor should notice (MIM)* occurred. A definition of these moments was not given to the GTA to establish baseline data. When a GTA stopped the video, the researcher asked them to describe the moment they noticed, why they chose it, and what they might do if such a moment happened in their own classroom. Using Studiocode video analysis software (SportsTec, 1997-2016), the instances chosen by the GTAs were marked on a video timeline for later analysis.

In each week of the intervention, the GTAs and the researcher/facilitator individually analyzed a minimally edited video of a lesson from an undergraduate mathematics classroom that was recorded by the researcher at the university. This individual analysis was in preparation for a weekly group meeting held among the four GTAs and the facilitator to discuss the video collectively. One of the classroom videos was recorded in one of the GTAs' classrooms during a previous semester, but otherwise the videos were not of the GTAs' own classrooms.

In the first three weeks of the intervention, the GTAs used the Studiocode video analysis software to tag *MIMs* and add text to describe what they noticed and why they chose each instance (i.e., why it was important to notice). Again, the definition of such moments was left open-ended to establish baseline data. The researcher, as an experienced user of the MOST Analytic Framework, used the Studiocode software to tag and document MOSTs—the types of instances that were the goal for GTA noticing—in the same videos. The researcher reconciled any instances of uncertainty with one of two other researchers experienced in the use of the MOST framework. Before the group meeting with the GTAs, the researcher examined the participants' tagged video timelines and associated text and compared the instances chosen by the GTAs and the MOSTs identified by the researcher. Instances discussed at the group meeting were chosen with care by the researcher/facilitator, limiting the number of instances so that the meeting did not, on average, last more than one hour. Instances were selected for discussion for a variety of reasons. These included instances that one or more GTAs marked—both those that the researcher identified as MOSTs and that the researcher did not identify as MOSTs—as well as instances identified by the researcher as MOSTs that were not noticed by the GTAs.

In the group meetings, the facilitator pushed the GTAs to articulate how each moment fit the early prompt of *MIMs*; that is, what the instructor had to notice in each moment and why it was mathematically important. Through discussion with peers and guidance from the facilitator, the GTAs worked toward building a definition of *MIMs*. This early phase of the intervention was intended as an introduction to the teacher noticing construct. That is, it got the GTAs to start thinking about what might be important for an instructor to notice during a lesson and to create a need for a more formal language and criteria with which to describe such important instances (i.e., the need for a framework).

After three weeks of analyzing video and constructing a meaning for the early *MIM* prompt, the GTAs were introduced to the MOST Analytic Framework by being given a paper to read that defined MOSTs (Stockero et al., 2014). In the week that they read the paper, the GTAs reexamined two of the videos they had already analyzed and picked out instances that they believed met the characteristics of a MOST. The group meeting discussion of the reexamined videos then revolved around whether instances fit all six criteria of a MOST.

In the remaining six weeks of the intervention, the GTAs were prompted to tag MOSTs in the new classroom videos that they analyzed and to describe in text how each instance satisfied all six MOST criteria. The GTAs were provided a text template to prompt them to specifically address each MOST criterion in their written responses in the last five weeks of the intervention. In these weeks, the facilitator similarly chose with care which instances to discuss at the weekly group meetings, with the important moments now having a clear definition. The group meetings revolved around how each instance that was discussed fit or did not fit the definition of a MOST.

During the group meeting discussion of the eighth of a total of nine videos, the facilitator prompted the GTAs to propose *building* moves in response to the MOSTs that were discussed—a teacher move that engages students in collaboratively discussing the significant student mathematical thinking that is present in the classroom (Stockero et al., 2014). These building moves, if proposed and practiced effectively, would use student mathematical thinking to further the learning of all students, which aligns with effective student-centered mathematics instruction (National Council of Teachers of Mathematics [NCTM], 2014). The GTAs were then prompted to include proposed building moves as part of the text template in subsequent video analyses.

Additionally, at the conclusion of the intervention the GTAs completed the Calculus Concept Inventory [CCI] (Epstein, 2013) to measure their knowledge of calculus content. The researcher also completed the CCI and reconciled the answers with a mathematics faculty member to create an answer key. The purpose of taking the CCI was to see whether there was a relation between GTA performance on the CCI (a measure of their CCK) and noticing of MOSTs.

Data Collection and Analysis

The data for this study included the CCI results and the video timelines that indicated the instances marked and described by the GTAs in the classroom videos during the interviews and the intervention. The CCI results were scored according to the answer key. The score of each GTA was compared to the rest of the group to see whether there were any obvious differences in scores that could potentially account for differences in noticing skills.

Categorizing Instances. Each instance marked and described by the GTAs in both the interview data and in the weekly timelines was coded and analyzed by the researcher in several different ways in order to examine changes in the GTAs' noticing. First, like in the work of Stockero et al. (2015, 2017), each instance was coded according to *agent* (who or what was noticed) and *mathematical specificity* (the way in which the mathematics was discussed). Instances that had any type of student agent were also coded for *focus* (what about the student(s) was noticed). See Figure 3 for coding categories and code descriptions.

Second, like the work done by Stockero and colleagues (2017), each instance was coded according to whether it was a MOST and whether the reasoning provided by the GTA was consistent with the MOST criteria. The MOSTs for each timeline were determined by the researcher's coding since she was an experienced user of the MOST Analytic Framework. A GTA instance was coded as a MOST if it occurred at around the same time in a video as a MOST. In an instance coded as a consistent MOST, the GTA identified the characteristics of the instance that qualified the instance as a MOST according to the framework (student mathematical thinking, mathematical significance, and pedagogical opportunity). In an inconsistent MOST, the GTA captured an instance related to a MOST, but was not focused on the student mathematical thinking or was focused on non-mathematical aspects of the instance, such as student participation or motivation. A GTA instance was coded as a non-MOST if it did not correspond time-wise with a MOST in the video.

Coding Categories	Category Description	Codes	Code Description
Agent	Who or what was noticed	Teacher	The teacher is the sole object of noticing
		Teacher/ Student	Both the teacher and student(s) are noticed, with the teacher receiving more emphasis
		Student/ Teacher	Both the teacher and student(s) are noticed, with the student receiving more emphasis
		Student Group	A collection of students is the object of noticing
		Student Individual	An individual student's contribution is the object of noticing
		Math	The mathematics itself, not a person or persons, is the object of noticing
Mathematical Specificity	Whether and how the mathematics was discussed	Non-Math	The mathematics is not discussed, usually because a non-mathematical aspect of the classroom is discussed instead, like classroom management or student engagement
		General Math	The mathematics is referenced with little to no detail
		Specific Math	The mathematics is clearly stated with enough detail to recognize the mathematical topic without having to watch the video
Focus	For instances with a student agent, what about the student(s) was attended to	Affective Interaction	A non-mathematical interaction between student(s) and teacher, usually focused on something like classroom management or student engagement
		General Understanding	The nature of a student's or students' comprehension of a concept, problem, or answer
		Mathematical Interaction	An interaction between students or between students and teacher that is mathematical in nature, usually focused on the process of working together for the purpose of learning mathematics
		Noting Student Mathematics	A specific instance of student mathematical thinking is described, like a student statement or question
		Analyzing Student Mathematics	Not only is a specific instance of student mathematical thinking referenced, but an attempt to interpret is made, like reasoning why a question was asked or a solution method was proposed

Figure 3. Components of noticing coding scheme (adapted from Stockero et al., 2015, 2017).

Response Coding. Because one of the goals of the intervention was for GTAs to propose student-centered responses, the pre- and post-interview instances were additionally coded according to whether the response to each instance proposed by the GTAs was student-centered or teacher-centered. A student-centered response was one in which the teacher would involve one or more students in responding to the instances, whereas a teacher-centered response would only involve the teacher. For example, in an instance where a student shared a solution step, a GTA proposed, “Maybe ask them, 'Why would you do that? What is the purpose of that? How does that help us going forward?'” This response was coded as student-centered since the student or students in the class would be the ones thinking about and addressing the mathematics of the instance rather than the teacher explaining the significance of what the student said. In another example, a student asked a question, and the GTA proposed, “I would quickly explain.” This response was coded as teacher-centered since the teacher would be the only one involved in reacting to the student question, rather than perhaps posing the question to the class.

Coding Analysis. After the coding was complete, the data were summarized to look for changes in the GTAs’ noticing week to week throughout the intervention. The analyses focused on the components of noticing (agent, mathematical specificity, and focus) and MOSTs. Comparisons of student-centered responses from pre- and post-interviews were also made to look for changes in how the GTAs might respond to the moments they selected.

To provide a common unit of measure among all GTA coding, percentages were calculated for each code out of each GTA’s total number of marked instances in each video. These percentages were used to track changes in the GTAs’ noticing on an individual basis. Averages for all the GTAs’ coding per video were also calculated to reflect changes of the group as a whole. The intervention data was then split into three stages—early, middle and late in the intervention—and the data were summarized and average percentages were calculated for each stage of the intervention. In this analysis, *baseline* refers to Videos 1, 2, and 3, the first three videos of the intervention and before the introduction of the MOST framework. *Middle* refers to Videos 4, 5, and 6, the three videos immediately following the introduction of the MOST framework, and *final* refers to Videos 7, 8, and 9, the last three videos of the intervention when the GTAs should have had the best understanding of the framework. Data from the pre- and post-interviews, including the response coding, were analyzed separately due to the difference in the nature of the interviews. Recall that in the interviews, the GTAs engaged in in-the-moment video analysis, whereas in the individual video analysis, repeated viewings and lengthy deliberation about instances were possible.

Results

Components of Noticing

Agent. Because the goals of the intervention placed an emphasis on noticing students and their mathematical thinking, changes were examined in the GTAs’ noticing of instances in which students were the primary agent (i.e., Student/Teacher, Student Individual, and Student Group agents). Table 1 provides the percentages of such instances in each stage of the intervention and the pre- and post-interviews. In the table it can be seen that both individually and as a group the general trend was an increase in the GTAs’ noticing that had a primary student agent from baseline to middle to final. Impressively, the majority of GTAs averaged 100% and the group averaged 94% of primary student noticing in the final data.

Table 1
Noticing of Primary Student Agent by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	41%	100%	100%	29%	100%
GTA 2	50%	89%	100%	41%	100%
GTA 3	63%	100%	100%	75%	100%
GTA 4	28%	67%	75%	80%	100%
Group	46%	89%	94%	56%	100%

Table 1 also shows improvement in the GTAs' noticing of instances with a primary student agent from pre- to post-interview. While GTAs 3 and 4 displayed a high level of noticing of students in the pre-interview (75% and 80%, respectively), GTAs 1 and 2 showed the most growth in this type of noticing. Most notably, 100% of the GTAs' noticing in the post data was primarily on students. This indicates that the GTAs developed the ability to focus their noticing on students, rather than on the teacher or the mathematics itself, in their in-the-moment analysis of video.

Mathematical Specificity. With student mathematical thinking and mathematical significance being two of the three characteristics of a MOST, a possible indicator of improvement in noticing of MOSTs is the ability to speak about the mathematics of an instance in a detailed manner. Thus, changes were examined in the GTAs' percentages of instances that were coded for mathematical specificity at the most detailed level, Specific Math.

Table 2 shows that the baseline percentages for Specific Math were rather high for all GTAs with the exception of GTA 4, who only had 6% of their instances coded as such. The middle data showed an increase in mathematical specificity for all GTAs, with the most considerable increase being that of GTA 4, who had a 77% increase in instances coded as Specific Math. Perhaps most important is that all of the GTAs exhibited 100% Specific Math noticing in the final data.

Table 2
Specific Math Noticing by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	97%	100%	100%	100%	100%
GTA 2	85%	100%	100%	59%	100%
GTA 3	81%	100%	100%	75%	100%
GTA 4	6%	83%	100%	40%	100%
Group	67%	96%	100%	69%	100%

Table 2 also indicates improvement for all of the GTAs in instances coded as Specific Math from pre- to post-interview. While GTA 1 already discussed the mathematics in a high level of detail in the pre-interview, it is worth noting that this level of mathematical specificity was maintained in the post-interview. GTA 4 showed the most improvement from 40% in the pre-interview to 100% in the post-interview data. Like the final data, the post-interview data indicated 100% Specific Math coding for all participants, implying that the GTAs reached 100% Specific Math noticing not only when completing individual data analysis with time to reflect and write about each instance, but also when put on-the-spot in an interview setting for their video analysis.

Focus. Recall that the focus codes were only assigned to instances with a student agent and describe what about the student(s) was attended to. The two focus codes that most aligned with the goals of the intervention, due to their focus on student mathematics, are Noting Student Mathematics and Analyzing Student Mathematics. Because of their relationship to the goals, changes were explored in the GTAs' noticing with both of these focus codes. While the focus codes only apply to those instances with a student agent, the percentages calculated in the following results are out of the total instances identified by the GTAs to reflect an overall, and not a narrow, sense of their noticing.

The first focus analysis examined both Noting and Analyzing Student Mathematics in sum to capture changes in the total percentage of instances in which the GTAs were focused on student mathematics. Table 3 shows widespread improvement for all GTAs in describing and/or interpreting the student mathematical thinking in an instance. Of particular importance is that, with the exception of GTA 4, the GTAs were Noting and/or Analyzing Student Mathematics 100% of the time as soon as the middle data, immediately following the introduction of the MOST framework. While GTA 4 did not reach 100% for these noticing foci, substantial increases were still made throughout the intervention.

Table 3
Noting and/or Analyzing Student Mathematics by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	32%	100%	100%	29%	100%
GTA 2	48%	100%	100%	19%	100%
GTA 3	52%	100%	100%	13%	100%
GTA 4	9%	50%	83%	20%	100%
Group	35%	88%	96%	20%	100%

The pre- and post-interview data also exhibit increases in Noting and/or Analyzing Student Mathematics for all GTAs, with all of the GTAs reaching 100% of instances with these focus codes. Thus, even for in-the-moment video analysis in an interview setting, all of the GTAs developed the ability to describe and/or interpret the student mathematical thinking in their noticing of classroom instances as a result of the intervention.

The second focus code analysis investigated changes in just the Analyzing Student Mathematics code, where the GTAs made an attempt to interpret a specific instance of student mathematical thinking. This focus code was honed in on specifically since the MOST Analytic Framework requires not only a focus on student mathematical thinking, but also that an inference be made about the student mathematics. Therefore, changes in Analyzing Student Mathematics could be an indicator of growth in Jacobs and colleagues' (2010) second noticing skill of *interpreting [students'] understandings* and in the analysis of MOSTs.

The data in Table 4 indicates that Analyzing Student Mathematics was absent or low in the baseline videos, both individually and as a group. By the middle videos, substantial increases were made by all GTAs, with GTAs 1, 2, and 3 improving in this aspect of noticing from the baseline to middle data by a range of 72% to 84%; only GTA 3 reached 100% in the final data. While improvements were made overall throughout the intervention, there were small decreases observed for GTA 1 and GTA 2 from the middle to the final data.

Table 4
Analyzing Student Mathematics by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	16%	100%	94%	14%	100%
GTA 2	0%	72%	67%	0%	75%
GTA 3	24%	96%	100%	13%	100%
GTA 4	0%	33%	47%	0%	100%
Group	10%	75%	77%	7%	94%

The pre-interview and post-interview data exhibit remarkable growth for in-the-moment noticing that included Analyzing Student Mathematics. GTA 4 demonstrated the largest growth at 100% from pre- to post-interview, while increases for the other GTAs were also large, ranging between 75% to 87%. Interestingly, GTA 4's final percentage for instances coded as Analyzing Student Mathematics in the individual analysis was still quite low at 47%, but reached 100% for this focus code in the post-interview video that was analyzed in-the-moment. A possible reason for this could be that GTA 4 more completely communicated what they noticed with spoken word in the interview as compared to written word in their text that accompanied the individually-analyzed video timelines. Another possible reason is that the shorter video used for the interview was more manageable to make sense of for GTA 4. In general, these results suggest that the intervention was successful in developing the GTAs' abilities to focus on and interpret student mathematical thinking in an in-the-moment context.

MOST Analysis

While the data related to the noticing components of primary Student agent, Specific Math, and Noting and/or Analyzing Student Mathematics point to improvements in noticing aligned with the goals of the intervention, the main goal was to improve the GTAs' noticing of MOSTs. Naturally, changes were examined in the GTAs' noticing of these instances. Like the other analyses, the percentages reported are out of the total set of instances marked by the GTAs.

Inconsistent and Consistent MOSTs. The GTAs' noticing of MOSTs, both inconsistent and consistent, was first investigated. Table 5 shows that all of the GTAs improved in their noticing of MOSTs during the three stages of the intervention. That is, the percentage of the instances marked by the GTAs that aligned with MOSTs increased from stage to stage, with the group's average percentages increasing from a baseline of 19%, to 33% in the middle data, and finally to 73% in the final data. This result indicates that the intervention improved the GTAs' noticing of moments with significant potential to improve student mathematical learning, even if perhaps the GTAs were not focused on the student mathematics in those instances (making them inconsistent MOSTs).

The pre- and post-interview data showed that all of the GTAs improved in their in-the-moment noticing of MOSTs, with increases ranging from 29% to 60%. It is worth recalling that the prompt for both the pre- and post-interview was to identify *MIMs*, which may explain why there was not a higher percentage of instances that were MOSTs among those identified in the post-interview. An idea underlying the intervention was that the MOST Analytic Framework would provide a way to characterize mathematically important moments that the instructor should notice, but perhaps the connection between *MIMs* and MOSTs was not made by the GTAs, or was not internalized for in-the-moment analysis. Still, it is encouraging that improvements were made in the noticing of important student thinking as a result of the intervention.

Table 5
Noticing of Inconsistent and Consistent MOSTs by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	32%	61%	87%	29%	60%
GTA 2	19%	36%	76%	19%	50%
GTA 3	25%	57%	78%	38%	67%
GTA 4	19%	33%	53%	40%	100%
Group	24%	47%	73%	31%	69%

Consistent MOSTs. The subset of MOSTs that were consistent MOSTs was then further examined; that is, those instances that both aligned with MOSTs time-wise in the video and were correctly characterized according to the MOST Analytic Framework. Table 6 shows improvement in the noticing of consistent MOSTs from stage to stage of the intervention. Of particular interest is that in comparison to the inconsistent and consistent MOST data in Table 5, the consistent MOST data have lower baseline percentages, but the middle and final data percentages match exactly in these two analyses. This signifies that all of the GTA-identified instances that aligned with MOSTs in the middle and final data were also instances that were correctly characterized according to the MOST Analytic Framework, which alludes to the framework being an important tool in not only recognizing the right moments (align with MOSTs) but also for the right reasons (consistent MOSTs).

Table 6
Noticing of Consistent MOSTs by Stage and Interview

Participant	Baseline	Middle	Final	Pre	Post
GTA 1	24%	61%	87%	14%	40%
GTA 2	19%	36%	76%	11%	50%
GTA 3	25%	57%	78%	13%	67%
GTA 4	8%	33%	53%	20%	100%
Group	19%	47%	73%	14%	64%

The pre-interview and post-interview data shows considerable increases in the GTAs' in-the-moment noticing of consistent MOSTs. As with the trends in the intervention data, the interview percentages for consistent MOSTs were lower in comparison to the combined inconsistent and consistent MOST percentages for the pre-interview, but were very similar in the post-interview (see Table 5 and Table 6). In fact, with the exception of GTA 1, the post-interview percentages for consistent MOSTs matched those of the combined inconsistent and consistent MOSTs. Like the intervention data, the interview data suggests that the intervention was successful in improving the GTAs' ability to notice MOSTs and reason about them in accordance with the MOST Analytic Framework, even in an in-the-moment noticing context.

Responses

The other main goal of the intervention was to increase the number of student-centered responses that were proposed by the GTAs to instances that they identified in the video. Table 7 displays the percentage of instances in the interview data for which the GTAs provided a student-centered response to explain what they would do if the identified instance occurred in their classroom. It can be seen that substantial increases in the percentage of such responses were made from pre- to post-intervention. In fact, with the exception of GTA 4, 100% of the responses provided by the GTAs were student-centered in the post data. While GTA 4 did not reach 100%, the percentage of student-centered responses that they proposed still increased from pre- to post-interview. These results suggest that the intervention was successful in improving the GTAs' skills in proposing student-centered responses in an in-the-moment context.

Table 7
Student-centered Responses by Interview

Participant	Pre	Post
GTA 1	0%	100%
GTA 2	57%	100%
GTA 3	83%	100%
GTA 4	33%	50%
Group	43%	88%

CCI Scores

After the intervention, the GTAs took the CCI assessment to determine whether their CCK may have had an effect on their noticing. Table 8 shows the GTAs' performances, both as a raw score and as a percentage. Overall, the GTAs' performances on the CCI were quite similar, suggesting that all of the GTAs in the study had roughly the same aptitude for calculus concepts; therefore, there was no evidence to suggest that differences in CCK accounted for differences observed in their noticing.

Table 8
CCI Scores

Participant	Score out of 22	Percentage
GTA 1	17	77%
GTA 2	17	77%
GTA 3	19	86%
GTA 4	19	86%
Group	18	82%

Discussion

This study sought to answer research questions related to the effectiveness of an intervention in improving GTAs' noticing of mathematically significant pedagogical opportunities to build on student thinking (MOSTs), the effectiveness of the intervention in supporting the GTAs' ability to propose in-the-moment student-centered responses, and the relationship between the GTAs' common mathematical content knowledge and the development of their noticing skills during the intervention. Results showed that the intervention was successful in improving the GTAs' noticing in a number of ways and in two different video analysis contexts. When analyzing video both individually and in an in-the-moment interview context, the GTAs greatly increased in their noticing of instances primarily focused on students, the percentage of instances in which they discussed the mathematics of an instance in a specific manner, their focus on describing (Noting) and/or interpreting (Analyzing) the student mathematics of an instance, and their noticing of consistent MOSTs. These results add support to the successes already seen at the K-12 level of interventions that use video and a defined framework to improve the noticing skills of preservice and inservice mathematics teachers (Santagata, 2011; Schack et al., 2013; McDuffie et al., 2014; Stockero et al., 2015, 2017) and suggest that such interventions can be successful at the undergraduate level as well.

The intervention was also successful in improving the GTAs' skills in proposing student-centered responses to instances they identified in video, the *deciding how to respond* skill of noticing (Jacobs et al., 2010). Specifically, these gains were documented from pre- to post-interview in an in-the-moment context. This finding builds upon those of existing studies (Jacobs, Lamb, Philipp, & Schappelle, 2011; Jacobs et al., 2010; Schack et al., 2013) that suggest that professional development structured around noticing students' mathematical thinking in video and/or classroom artifacts can develop teachers' abilities in not only the noticing skills of *attending to and interpreting [students'] strategies and understandings*, but also the skill of *deciding how to respond* (Jacobs et al., 2010).

While most of the GTAs showed similar improvements in their noticing skills and in the proposal of student-centered responses to instances in video, GTA 4's improvements were not as consistent. This raises questions as to why. One explanation would be a difference in CCK, as measured in this study by the CCI. The CCI scores were very similar among the GTAs, however, providing no evidence to support the idea that differences in mathematical knowledge were related to differences in noticing skills. Recall also that GTA 4's stronger post-interview results for Analyzing Student Mathematics suggested that perhaps they were better able to communicate in spoken word than in written text, another potential explanation for the lower percentages in the individual analysis data. While this participant had received the same previous departmental training as the other GTAs after admission to the university's graduate program, GTA 4 was the only international student in the study, and thus had a different cultural and educational background from the other domestic GTAs. Perhaps, then, not having a similar educational background provided a challenge to GTA 4's development in their noticing skills. This suggests that international GTAs may need additional support when engaging in a noticing intervention such as the one in this study. However, the data available from this study is limited to one international GTA, and thus further study is required.

While the results of this study suggest that similar interventions could be successful in supporting GTAs in learning to notice student mathematical thinking, there are limitations to this study and further questions to investigate. This was one, isolated study with a small number of participants. The significance of the results, therefore, must not be overgeneralized. Future work could involve replicating this study with more GTAs, with GTAs of varying cultural backgrounds, at other universities, with another set of videos, and in other subject areas to see whether there are similar results. To expand on this study further, the following questions could also be investigated: How does such an intervention affect the GTAs' classroom teaching? What role does the facilitator play in building the GTAs' noticing skills during meetings? How does the set of videos used in the intervention affect the improvement of the GTAs' noticing skills?

Limitations aside, the intervention in this study was successful in improving the noticing skills of mathematics GTAs and in the proposal of student-centered responses, both steps in the right direction for advancing student-centered instruction in undergraduate mathematics courses. The development and improvement of these skills, while achieved in this study in the structure of a professional development intervention, have the potential to improve the GTAs' classroom instruction. Thus, an intervention such as this that targets mathematics GTAs could possibly influence the instructional methods used in higher education and improve the retention of first- and second-year undergraduate students (Cano et al., 1991; Speer et al., 2005). Completing professional development focused on noticing important student ideas could not only improve mathematics pedagogy in general, but provide opportunities to practice student-centered instructional methods, which are essential for effective teaching (NRC, 2005; NCTM, 2014).

Student Conceptions of Three-Dimensional Solids

Stepan Paul
UC Santa Barbara

Monica Mendoza
UC Santa Barbara

In the exploratory study presented in this paper, the authors aim to construct a model for the processes by which students in a multivariable calculus class conceptualize solid regions in three dimensions. We designed and recorded student work from two tasks in which students must decode a description of a solid figure and answer questions assessing the strength of their conception of the figure. Presented here are findings and common themes that emerged from the analysis of interviews and group work on two of these tasks, including five generalizable observations about how students process three-dimensional information.

Key words: multivariable calculus, spatial reasoning, three-dimensional solid

Introduction

As motivation for our study, we consider the following problem, variations of which appear in many multivariable calculus textbooks.

> **Task 0:** Let P be the solid region in $\mathbb{R}^3$ defined by the following set of inequalities.
>
> $$\begin{array}{ccccc} 0 & \leq & x & \leq & 1-z \\ z^2 & \leq & y & \leq & 1 \\ 0 & \leq & z & & \end{array}$$
>
> Find the volume of P.

In anecdotal observations of student work, the authors found that students would attempt to solve this problem, apparently without attempting to conceptualize the solid figure *E* as a subset of $\mathbb{R}^3$. In particular, students would set up the triple integral using the given bounds without attempting to form a visuospatial conception of the solid. While this observation calls into question the validity of such problems in building and assessing students' understanding of volume, it also raised the question, through what process would students decode sets of inequalities such as those presented in Task 0 as a solid figure? More generally, when working with three-dimensional spatial information, on what strategies do students rely, and what obstacles do they encounter?

In the present study, we use data from 76 undergraduate multivariable calculus students collected in individual interviews and recorded group work, to identify common strategies and obstacles in decoding, processing, and communicating representations of solid figures.

Theoretical Background

There is a rich history of studying student conceptions of three-dimensional solids in the context of spatial reasoning. Much of the work in this area relies on methodology in which subjects must interpret a two-dimensional drawing of a solid figure and then perform some spatial task such as rotation (Bodner, Guay, 1997) or identification of cross-sections (Cohen, Hagerty, 2007). However in studies where a two-dimensional drawing is used, Gorgorió (1998) warns, “Individuals’ demonstration of their spatial orientation ability depends also on their abilities for interpreting and communicating spatial information.” Indeed it has been shown that misconceptions can lead to errors both during interpretation (Parzysz, 1988; Hallowell, et al, 2015), and communication (Ben-Chaim, Lappan, & Houang, 1989; Hershkowitz, 1990). Thus, building on the paradigm set forth by Parzysz (1991), we model student responses to the tasks as information that has passed through three phases: decoding, processing, and communication.

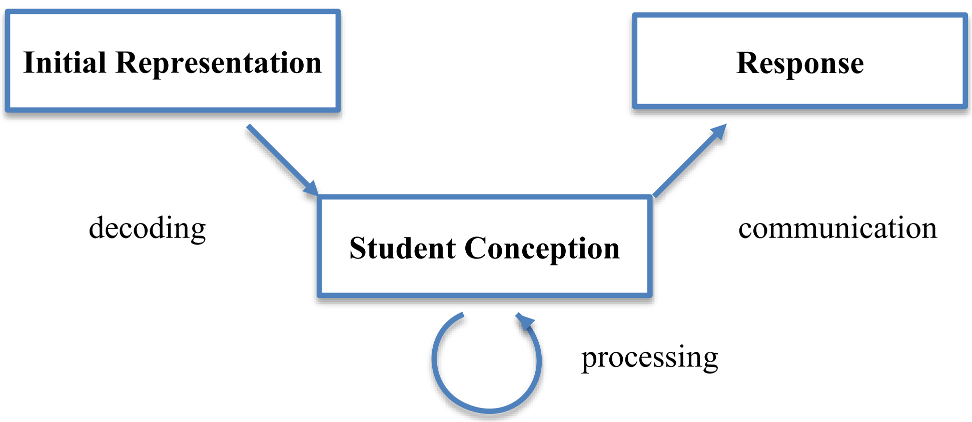

Figure 1. Model for student responses. This figure illustrates the flow of information resulting from students’ response to a task. Errors or loss of information may occur in each phase.

The *decoding* phase encompasses interpretation of the given representation. The *processing* phase includes any mathematical or visuospatial treatments the subject performs, as well as conversions between registers. Finally, in the *communication* phase, subjects encode their responses to the task. Included in the communication phases are written work, drawings, conversation with other students, and building physical models.

In a multivariable calculus class, students are asked to become fluent in interpreting descriptions of figures in $\mathbb{R}^3$ which come in a variety of forms: written descriptions, equations or inequalities in three variables, two-dimensional drawings, and combinations of these. Viewed from the theoretical framework of semiotic representation theory, this requires students to coordinate representations in several registers (Duval, 1993), and perform conversions from one register to another (Duval, 2006). Trigueros and Martínez-Planell (2010) investigate how students use this coordination of registers to perform tasks related to surfaces and equations in multivariable calculus. Our study builds on this work by applying the same theoretical framework to solid figures in three dimensions.

In particular, our study focuses on three-dimensional solid figures that are likely unfamiliar to students. Our rationale for working with such figures is threefold. First, by focusing on *unfamiliar* solids, we aimed to remove the possibility that students would use prior knowledge about the figures to answer questions. Responses to questions about the volume of a familiar solid, like a cone or sphere, we reasoned, would likely better reflect students’ knowledge of memorized formulae rather than their reasoning about the solid figure itself.

Secondly, dealing with unfamiliar solids of the type described in Task 0 requires students to comprehend the combination and interaction of primitives like planes, lines, and parabolas, with which we assume that students are familiar. Here we borrow the term *primitive* from the field of computer graphics to mean a simple geometric figure out of which more complicated structures can be built. We aimed to create tasks for which the challenge would be to conceptualize the interaction of simple parts rather than the conceptualization of the parts themselves.

Finally, we hypothesized that the lack of close representations of solid figures in traditional instruction and assessment might mean that students' framework for thinking about such figures may be entirely divorced from the three-dimensional nature of the figures themselves. Here we use the term *close* representation in the sense of Parzysz (1988) to mean that the abstract figure and its representation are in the same dimension. For three-dimensional solid figures, two-dimensional drawings (like those in Figure 3) would be *distant* representations, and three-dimensional models would be close representation. We use tasks involving close representations to force students to reckon with three-dimensional information directly.

Methodology

The present exposition is part of a larger study in which we seek to understand how students process three-dimensional information in the context of multivariable calculus. In this exploratory phase, we designed several tasks meant to elicit responses that would give insight into the strategies students use and the obstacles they face in conceptualizing solid figures. We will discuss results from Tasks 1 and 2 below.

Task 1: Let G be the solid region described by the inequalities

$$\begin{array}{ccccc} 0 & \leq & x & \leq & 1 \\ 0 & \leq & y & \leq & 1 \\ 0 & \leq & z & \leq & x+y \end{array}$$

(a) Build the region G out of clay.

(b) Write 2–3 sentences explaining how you determined the shape of the solid region from the inequalities

Task 2: Your group will be given two models, labelled Model E and Model F.

(a) Below are two sets of inequalities. Which one describes E and which one describes F? Give reasons for your answer.

$$\begin{array}{ccccc} 0 & \leq & x & \leq & 1-z \\ z^2 & \leq & y & \leq & 1 \\ 0 & \leq & z & & \end{array} \qquad\qquad \begin{array}{ccccc} 0 & \leq & x & \leq & z+1 \\ 0 & \leq & y & \leq & (z-1)^2 \\ 0 & \leq & z & \leq & 1 \end{array}$$

(b) Which region has a larger volume, E or F? Explain your answer in a few sentences.

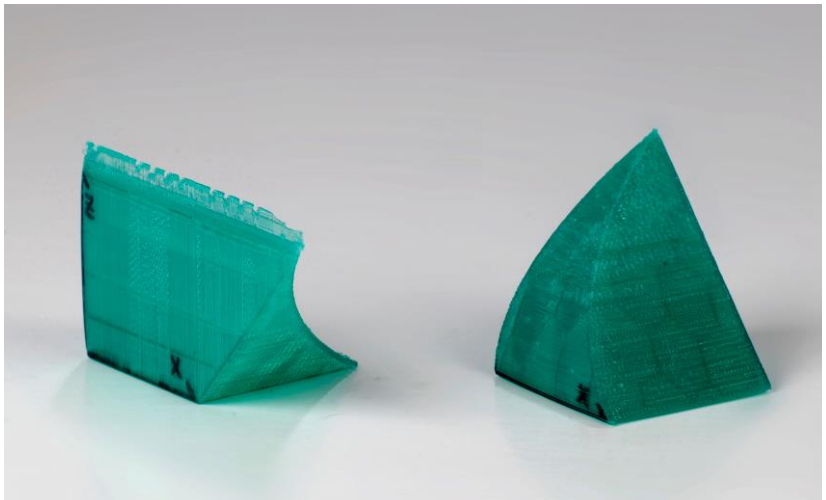

Figure 2. Photograph of the 3D printed models E and F provided to students in Task 2. The coordinate axes were drawn onto the models.

Rationale for Tasks

Our design of these tasks was motivated by the model illustrated in Figure 1. Each of these tasks pairs a close representation of a solid figure with an algebraic one. Underlying the rationale behind this pairing is the assumption that students will face little difficulty in decoding the close representation, nor in communicating a robust enough conception of the figure into the medium of a clay model. Under this assumption, errors in student work on Task 1 could be attributed to misunderstandings or miscalculations related to the decoding and processing of the sets of inequalities[1]. Likewise, in Task 2, we assume that the spatial information represented by the 3D printed models is easily decoded, and difficulties for part (a) will only arise in decoding the sets of inequalities, and the processing required for the matching task.

The figures chosen for these tasks were carefully selected so that they would likely be unfamiliar to students, so that their defining inequalities were either linear or parabolic, and so that they would be sufficiently complex. The figure for Task 1, which is described by linear inequalities only, has six planar faces corresponding to the six inequalities, of which only $z \leq x + y$ involves more than one variable. The two figures in Task 2 were chosen so as not to be easily distinguished by superficial characteristics of the figures and inequalities: each has five faces, four of which are planar, and one of which is a parabolic cylinder, and x, y, and z are all non-negative at every point in the figure. The two figures from Task 2 also satisfy Cavalieri's Principle, in that the cross-sections of the two solids by planes of the form $z = z_0$ have the same area for every constant z_0 and therefore the figures have the same volume. See Figure 2 for a photograph of the 3D models used in Task 2, and Figure 3 for drawings of the abstract figures in the tasks.

[1] This assumption was not entirely accurate since some students who demonstrated a robust conception of the solid made errors in the model the produced related to the relative scaling in the x, y, and z variables.

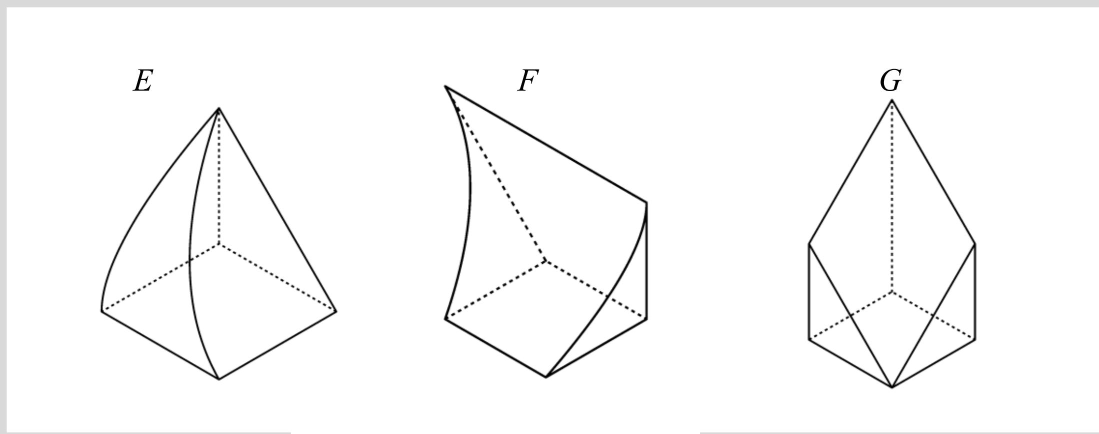

Figure 3. Isometric projections of the solid figures *E*, *F*, and *G* from Tasks 1 and 2.

Participants and Data Collection

Data collection involved videotaping students working in groups on the tasks during nine class sections from two different instructors in the spring and summer of 2016. One of these sections was a designated honors class, specifically intended to emphasize conceptual understanding, and in which students had previously interacted with 3D printed models. The rest were graduate student led discussion sections for lecture-based classes. Additionally, we conducted individual interviews with four students. In total, 76 students participated, and we grouped students into 29 response groups. We also collected students' written work and photographed the clay models produced by the students in Task 1. Because our study was exploratory and not comparative in nature, we favored variety and breadth in our data collection over rigorous control for confounding variables.

Data Analysis

We used a grounded theory approach (Glaser & Strauss, 1967) to learn what processes students used to go from a subset of inequalities in $\mathbb{R}^3$ to a robust mental image. In our early passes through the data, we transcribed the video and focused on using coding to categorize response types for each task, and to identify and classify students' task-specific strategies and difficulties. From this preliminary analysis emerged several "generalizable observations"—observations of student work that were common to both tasks, and which may be more generally applicable and observable in student work involving three-dimensional information.

Results

We organize the results of our analysis by first describing observations from each task individually, and then explaining the generalizable observations that emerged from this preliminary analysis.

Observations From Task 1

We grouped students' responses to Task 1—in the form of the clay models they built—into four categories of clay models emerged from the coding of student responses: rectangular prism

(P), tetrahedron/pyramid (T), conflicted (C), and accurate (A); examples of each are shown in Figure 4 below.

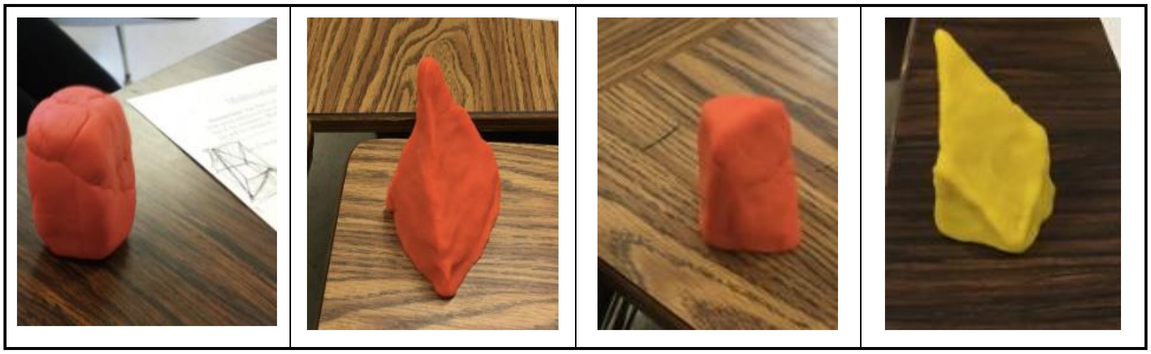

Figure 4. Examples of the four categories of responses. From left to right: rectangular prism (P), tetrahedron/pyramid (T), conflicted (C), and accurate (A).

The categories of (P) and (T) are self-explanatory. A clay model was classified as accurate (A) if it reflected all the correct faces and edges of figure described by the given inequalities; models in which the x, y, and z variables were scaled differently could still be considered accurate. Models that fell into none of the other three categories were classified as conflicted (C); in all cases, these models were some hybrid between a tetrahedron/pyramid and an accurate model.

From analysis of video and written work, we identified several distinct strategies that were used by students while completing the tasks. These are described below, along with examples of each.

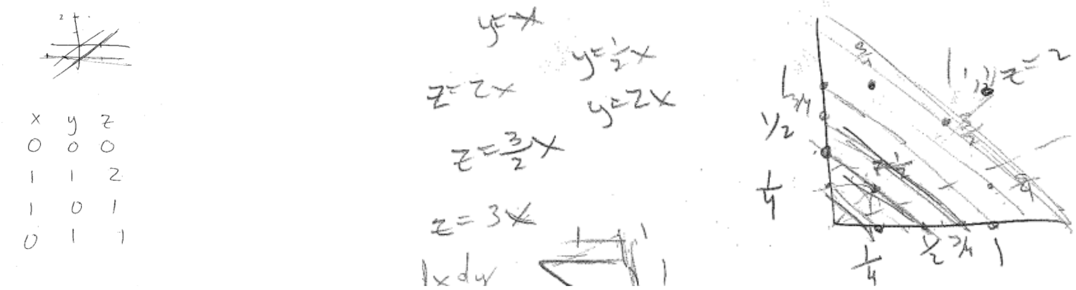
Maximum/Minimum. This strategy involved identifying the absolute maximum and minimum values for each variable; in Task 1, the only nontrivial identification is that $z \leq 2$. One student wrote, "The first two inequalities are the same, so we concluded that the base of the region is a square. The third inequality is dependent on x and y, and the largest value is 2, so the region can range from a rectangular prism to a 2d square."

Covariation. Many students invoked the observation of covariational dependence of two or more variables to explain features of the figure. In the videos, we observed students verbalizing the idea of covariation with accompanying gestures. For example, one student explained, "The z starts at zero and the origin corner at the square then goes to 2 at the (1,1) corner," indicating that the change in z is linked to the change in x and y.

Finding Vertices. Many students found it helpful to identify the extremal points of the figure, and then decide how these points would be connected. An example of a student's work can been seen in Figure 5.

Level Curves. Several students sketched level curves of the surface defined by $z = x + y$ in order to understand the top face of the figure. See Figure 5 for an example written work using this strategy.

We organized strategies by response category, as shown in Table 1. The most notable trend is that response groups that produced an accurate model seemed to use a wider range of strategies than those that produced other models.



Finding Vertices Level Curves

Figure 5. Examples of Finding Vertices and Level Curves.

Applying our model for interpreting student responses from Figure 1, we can attempt to infer in which phase information was lost or mishandled from both the response type and the strategies used. For example, we hypothesize that for students who responded model type (P), most of the information never made it past the decoding phase—that students did not correctly interpret the meaning of the inequalities taken as a set. For students who responded with model type (T), it seemed that some information was lost in the decoding phase, and that only minimal processing had taken place. For model type (C), a hybrid between (T) and (A), the mishandling of information seemed to occur in the processing phase; these students had a conception of the figure in one representation register, but failed to accurately convert it to another.

Table 1. Strategies used, organized by response category. Responses submitted by a group of students were treated as a single response. In many cases, groups reported using more than one strategy, which is reflected in the table.

Student's Strategies	**Rectangular Prism (P)**	**Tetrahe-dron/Pyramid (T)**	**Conflicted (C)**	**Accurate (A)**
Responses in this category	5	2	7	15
Maximum/Minimum	5 (100%)	2 (100%)	4 (57%)	7 (47%)
Covariation/Path			1 (14%)	3 (20%)
Finding Vertices	1 (20%)	1 (50%)		7 (47%)
Level Curves			4 (57%)	5 (33%)

Another observation from the videos that we do not include in the table above is what we will call the *knife strategy*[2]. The knife strategy refers to a specific gesture we saw repeatedly on Task 1 in which students build a model of type (R) then gesture in a slicing motion, indicating a

[2] The name derives from a video clip in which a student used a pocketknife to slice away part of his group's model.

part of the figure that is to be removed. We did not include this as a strategy because it is unclear whether this gesture indicates a particular thought process, or if it serves primarily as a means of communication.

Observations From Task 2

In this task, all of the response groups eventually arrived at the correct conclusion that the left set of inequalities corresponds to Model E and that the right set of inequalities corresponds to Model F although many groups' initial guesses were reversed. Below we list some of the common strategies we observed from video of student work.

Association of primitives across registers. We observed students seeking to find a correspondence between features of the inequalities to aspects of the models. For example, one student, pointing to the face of Model E in the xz-plane, said, "So if you just look at it from this plane [positions Model E to demonstrate], you could kinda of see this triangle shape. And this line created is the line $1 - z$ because it's in the xz-plane," referring to the inequality $x \leq 1 - z$. Another student explained, "You see this is the z [points to the point (1,0,1) on Model F], and so this is the $z + 1$ [moving over 1-unit along the edge of Model F to the point (2,0,1)]."

Covariation. Students identified covariations among variables in both the inequalities and along edges and faces of the models. In particular, they distinguished between quadratic and linear relationships in the inequalities, and associated these with parabolic and linear edges of the models. For example, the student in Figure 7 explained, "There is a quadratic relationship between the y-axis and z-axis, and we found that relationship is $y = z^2$ [positions Model E to show the face in the yz-plane] which fits with this first condition z^2 to y to 1. And along the xz-plane… [positions Model E to face the xz-plane] If you look at it at the right angle, you get a line, which is the line $z = 1 - x$ so then you get $x = 1 - z$ as a boundary."

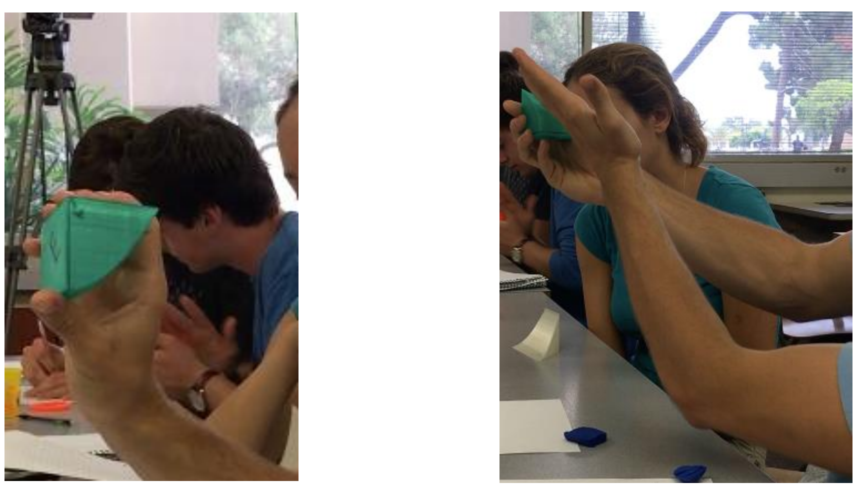


Figure 7. A student uses covariation between pairs of variables to associate features of the model to features of the inequalities.

Projecting onto a plane. We observed students frequently orienting the models so that their view of the model would be an orthogonal projection onto a coordinate plane, as in Figure 8. Each of the inequalities in the descriptions of Models E and F involves at most two of the three coordinate variables, and so seemed to allow students to temporarily disregard one variable in their analysis. Similarly, one group of students attempted to sketch orthogonal projections starting from the inequalities for comparison against the two models. This sort of thinking is also evident in the quotation above in the description of the covariation strategy.

Figure 8. A student positions Model F to give himself a view of the figure orthogonally projected onto the *yz*-plane.

Generalizable Observations

Here we make five generalizations of the observations witnessed in the two tasks, especially those that were common between the two tasks, and which may be observable more generally in students' approach to solving problems involving three-dimensional solid regions.

Use knowledge from two dimensions. In both tasks, we observed students using knowledge about two-dimensional geometry to aid in their decoding and processing of the three-dimensional figures. Students identified covariational relationships between pairs of variables in the algebraic descriptions and in the three-dimensional models. A particularly common observation in Task 2 was students' identification of the parabolic curves on the models, and the quadratic covariations described by the inequalities. Students' use of the projection strategy on Task 2 and the level curves strategy on Task 1 also fall into this category, as would the analysis of cross-sections more generally.

Absolute bounds. The maximum/minimum strategy appears in both tasks. Establishing a bounding box for a three-dimensional figure was observed as the first step for many of the response groups. In Task 1, for example, many of the groups that started by concluding that $z \leq 2$ went on to employ other strategies as well (see Table 1). In Task 2, Figure 9 shows that used similar reasoning to conclude that the set of inequalities describing Model E implies an absolute bound of $z \leq 1$, and another group of students similarly concluded that $x \leq 1$, distinguishing the inequalities from Model F.

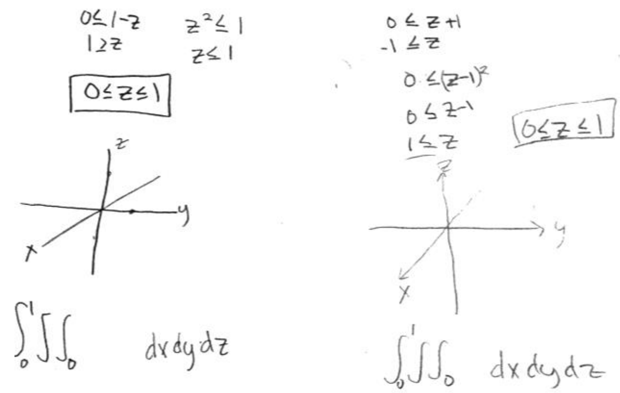

Figure 8. A student positions Model *F* to give himself a view of the figure orthogonally projected onto the *yz*-plane.

Multimodal communication. Students frequently struggled to clearly and unambiguously verbally communicate features of the figure. However, we observed extensive use of gesture and interaction with models, drawings, and algebraic statements. This mixed use of gestures and words creates what is referred to as a *multimodal* representation of mathematical objects (MacNeill, 1998), and its use by high school geometry students was studied by Chen and Herbst (2013). We hypothesize that multimodal communication is especially important for students describing three-dimensional figures because they lack an established common language for describing objects in $\mathbb{R}^3$. The knife strategy from Task 1 is a particularly salient example of this kind of communication.

Rigidity and reliance on norms. In several cases, we found that students struggled to adapt their thinking to figures and presentations that differed from examples seen in class. One student explained his difficulty with the inequalities in Task 2, "I'm just not used to seeing it in this format," referring to the fact relationships between variables did not have the familiar $z = f(x, y)$ form. Another group of students struggled to communicate with drawings while working on Task 1 because one student insisted upon orienting his axes differently than his peers.

Conversion of part-whole relationships across registers. In both tasks, we observed students seeking to associate particular inequalities with faces or other aspects of the models. This was communicated with multimodal phrases like, "This [points to parabolic cylinder face of *E*] comes from here [points to inequality $z^2 \leq y$]." Another student explained during Task 1, "Since x and y are both between 0 and 1, the base is obviously a square." In each of these statements, students identify a familiar geometric primitive with some subset of the algebraic description. However, we observed several students who seemed to suffer from a cognitive overload from the three-dimensional spatial information being presented to them (Huk, 2006), with one student initially claiming, "I don't know where to start." Considering one primitive at a time may serve as a means of coping with the complexity of the entire figure. However, the frequency of the "conflicted" response type for Task 1, which is comprised of parts that are mostly correct, shows that converting one part of the figure at a time does not necessarily lead to a correct conversion of the whole.

Implications

For instructors of multivariable calculus, awareness of the types of strategies students employ to consider three-dimensional solids may be helpful in lesson design and in identifying and addressing student difficulties. Our use of three-dimensional models in this study was, in part, meant to uncover a possible disconnect between multivariable calculus students' procedural knowledge about things like volume, and their visuospatial conception of the underlying figures. There is evidence that multivariable calculus student perceive a benefit from the use of instruction that incorporates manipulation of three-dimensional models (McGee, Moore-Russo, Ebersole, Lomen, & Quintero, 2012; Wangberg & Johnson, 2013), perhaps because the models bridge this disconnect. In addition to providing context for instructional design, we hope that cognizance of our observations will aid in the design of appropriate assessment.

While the scope of our study is limited to multivariable students' conceptions of three-dimensional solids, we have framed our generalizable observations from the previous section so that one could test our hypothesis that these strategies and difficulties will show up in student work with other objects in $\mathbb{R}^3$ from multivariable calculus, such as surfaces and space curves. While the particular solid regions chosen for analysis in this study are not especially interesting or useful, we believe that their complexity led to a wider variety of observations than a simpler or more symmetric figure would have. Also of interest would be the study of how students conceptualize functions and vector fields defined on such objects.

Finally, since the present study was largely exploratory—in the sense that we mostly wanted to see what kinds of observations we could make from administering these particular tasks—we believe there would be benefit to conducting controlled interviews with students to better understand the process students go through in working through these sorts of tasks.

Student Mathematical Connections in an Introductory Linear Algebra Course

Spencer Payton
Washington State University

In an introductory linear algebra course, students are expected to learn a plethora of new concepts as well as how these concepts are connected to one another. Learning these connections can be quite challenging for students due to the vast number of connections and student inexperience with mathematical logic. The study reported here consisted of an investigation into how inquiry-oriented teaching methods could be employed in an attempt to create opportunities for students to develop mathematical connections in an introductory linear algebra course.

Key words: linear algebra, mathematical connections, inquiry-oriented teaching

Introductory linear algebra courses have traditionally been quite challenging for students. There are several reasons for this, including the fact that students are introduced to a plethora of brand new concepts and terminology. Further, many of these concepts are connected to one another in various ways, and students are expected to learn these connections as well. While many researchers and teachers would agree that students should be able to make mathematical connections, the phrase "mathematical connection" is often loosely defined. This study considers two particular types of mathematical connection in an introductory linear algebra course: *connections between symbolic representations of a linear system* and *logical implication connections*. The symbolic representations of a linear system consist of the augmented matrix, the matrix equation, the vector equation, and the linear system itself; these representations are presented in Figure 1.

Linear System	**Augmented Matrix**	**Matrix Equation**	**Vector Equation**
$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m \end{aligned}$	$\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} & b_1 \\ a_{21} & a_{22} & \cdots & a_{2n} & b_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} & b_m \end{bmatrix}$	$\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{n2} & \cdots & a_{mn} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{bmatrix}$	$x_1 \begin{bmatrix} a_{11} \\ a_{21} \\ \vdots \\ a_{m1} \end{bmatrix} + x_2 \begin{bmatrix} a_{12} \\ a_{22} \\ \vdots \\ a_{m2} \end{bmatrix} + \cdots + x_n \begin{bmatrix} a_{1n} \\ a_{2n} \\ \vdots \\ a_{mn} \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{bmatrix}$

Figure **1**: A linear system can be represented as an augmented matrix, a vector equation, and a matrix equation.

Each of these mathematical objects is connected to the other three due to the fact that they are all representations of each other; as the augmented matrix is the tool through which many linear algebraic problems are solved, particularly at the introductory level, connections between symbolic representations of a linear system are some of the first connections many linear algebra students encounter.

Relationships between various linear algebraic concepts are often summarized in theorems of logical equivalence such as the Invertible Matrix Theorem (IMT) (Lay, 2011). The statements in this theorem are all logically equivalent, meaning any statement in the theorem logically implies another (and vice versa). Thus, the logical implications present in the IMT could be described as logical implication connections. While the IMT provides a convenient presentation of logical implications in introductory linear algebra, it is somewhat restrictive due to the fact that it only applies to square coefficient matrices (as only square matrices can be invertible). However, subsets of the logical implications inherent in the IMT could be applied to non-square matrices. The IMT could actually be divided into two “sub-theorems,” which will hereby be known as the First and Second Theorems of Logical Equivalence; these theorems are presented in Figure 2.

Theorem 1: Let A be an $m \times n$ matrix. Then the following statements are logically equivalent. a) The equation $A\mathbf{x} = \mathbf{b}$ has at least one solution for each $\mathbf{b}$ in $\mathbb{R}^m$. b) A has m pivot positions; that is, A has a pivot position in every row. c) Every vector $\mathbf{b}$ in $\mathbb{R}^m$ is a linear combination of the columns of A. d) The columns of A span $\mathbb{R}^m$. e) The linear transformation $T: \mathbb{R}^n \rightarrow \mathbb{R}^m$ defined by $T(\mathbf{x}) = A\mathbf{x}$ maps $\mathbb{R}^n$ onto $\mathbb{R}^m$.	**Theorem 2:** Let A be an $m \times n$ matrix. Then the following statements are logically equivalent. a) The equation $A\mathbf{x} = \mathbf{b}$ has at most one solution for each $\mathbf{b}$ in $\mathbb{R}^m$. b) For each $\mathbf{b}$ in $\mathbb{R}^m$, the linear system corresponding to $A\mathbf{x} = \mathbf{b}$ does not have a free variable; that is, the linear system only has basic variables. c) A has n pivot positions; that is, A has a pivot position in every column. d) The equation $A\mathbf{x} = \mathbf{0}$ has only the trivial solution. e) The columns of A form a linearly independent set. f) No column of A is a linear combination of the other columns. g) The linear transformation $T: \mathbb{R}^n \rightarrow \mathbb{R}^m$ defined by $T(\mathbf{x}) = A\mathbf{x}$ is one-to-one.

Figure **2**: Unlike the Invertible Matrix Theorem, these theorems of logical equivalence are not restricted only to the case of square matrices.

As learning all of these mathematical connections can be challenging for students, it would be beneficial to improve the teaching of these connections. The study described in this report was part of a larger study that attempted to determine how inquiry-oriented teaching methods could be implemented in an introductory linear algebra course that, due to considerations such as large class size, limited amount of class time, and wide range of required material, would not lend itself to the traditional demands of inquiry-oriented teaching. In particular, the study explored how inquiry-oriented teaching could specifically be used toward the teaching of mathematical connections in a constrained environment. To that end, the goal of this study was to answer the following research questions:

- *What does it look like when a teacher attempts to incorporate inquiry-oriented teaching in an undergraduate introductory linear algebra class?*
- *What mathematical connections do students appear to evoke within the context of an introductory linear algebra course that employs inquiry-oriented teaching?*

This report will primarily discuss the second research question; however, the classroom context and overall goals of the study had implications for the research methodology and results that were found. Thus, it is necessary to discuss the second research question within the context of the greater study to some extent.

Literature Review

There has been research into logical implication connections in linear algebra (Selinski, N. E., Rasmussen, C., Wawro, M., & Zandieh, M., 2014; Wawro, 2014); these studies primarily considered logical implication connections within the context of the IMT. In contrast, the study reported here focuses on logical implication connections within the broader context of the three theorems of logical equivalence previously described. That said, results of IMT-focused studies are applicable to this study. In particular, Selinski et al. (2014) describe a *hub concept*, which is a concept that a student frequently uses as an intermediary concept through which other logical implication connections are evoked and justified. In adapting this construct for this study, I will refer to a *hub statement* as a statement from one of the three theorems of logical equivalence that a student frequently uses as an intermediary in evoking and justifying logical implication connections.

It is not uncommon for students to know that two linear algebraic concepts are connected but not understand *why* they are connected. This issue was well described by Harel:

> So if a student thinks of 'linear independence' to mean 'the echelon matrix which results from elimination has no rows of zeros,' without being able to mathematically justify this connection, then he or she does not understand the concept of linear independence. (Harel, 1997, p. 111)

This issue of the quality of student understanding has been previously discussed by Skemp (1987) in his description of instrumental and relational understanding. The understanding presented in Harel's example is *instrumental understanding*; that is, knowing what to do but not why. According to Skemp, true understanding of a concept involves *relational understanding*, which is "knowing both what to do and why" (Skemp, 1987, p. 153). This characterization of the quality of understanding could be applied to mathematical connections. Thus, a student has made an *instrumental connection* if the student has formed a connection but does not understand why that connection exists; similarly, a student has made a *relational connection* if the student has formed a connection and understands why that connection exists. For example, a student could present relational understanding of a logical implication connection if he or she can form a chain of logical implications beginning with one statement in a theorem of logical equivalence and ending with another. Unfortunately, students at this level often struggle with mathematical logic, and in particular, many students struggle to form these chains of reasoning (Dorier & Sierpinska, 2001).

Regarding inquiry-oriented teaching, there is a wealth of literature on inquiry-oriented teaching of linear algebra, notably through the IOLA project (Larson, C., Wawro, M., Zandieh, M., Rasmussen, C., Plaxco, D., & Czeranko, K., 2014; Wawro, M., Rasmussen, C., Zandieh, M., Sweeney, G. F., & Larson, C., 2012; Wawro, M., Zandieh, M., Rasmussen, C., Larson, C., Plaxco, D., & Czeranko, K., 2014). However, as previously described, one goal of this study was to determine to what extent inquiry-oriented teaching could be developed and implemented within an introductory linear algebra course that faced constraints such as a large class size, limited class time, wide range of required material, and coordinated common sections. In light of this goal, I opted to start with a general definition of inquiry-oriented teaching and explore how that definition could be implemented in the aforementioned constrained class. There are several ways to define inquiry depending on the context or academic subject. Rasmussen and Kwon (2007) characterize student inquiry in a mathematics class through Richards' (1991) definition of mathematical inquiry, which is the mathematics of mathematically literate adults. Thus, mathematical inquiry involves participating in mathematical discussion, solving new problems, listening to mathematical arguments, and proposing conjectures. Rasmussen and Kwon (2007) also highlight the role of teacher inquiry in their definition of inquiry-oriented teaching, which refers to a teacher inquiring into student thinking. In determining how I would specifically define inquiry-oriented teaching for the purpose of this study, I decided that the teaching constraints previously described were immediate obstacles to fostering student inquiry. As my ultimate goal was discovering how opportunities for student inquiry could be provided in a constrained teaching environment, I opted to define inquiry-oriented teaching as "a practice of creating opportunities for students to engage in mathematical inquiry." While teacher inquiry is not explicitly referenced in this definition, this is not to say that teacher inquiry did not occur throughout the course of this study. Researching teacher inquiry was simply not a specific goal of this research study, while researching attempts to foster student inquiry was.

Setting and Methods of Analysis

The research question focusing on the implementation of inquiry-oriented teaching in a constrained teaching environment was born out my own desire as a teacher to explore how I could implement inquiry-oriented teaching in a specific introductory linear algebra course. Thus, this research goal is a reflection of my goal to improve my own practice. Consequently, I opted to conduct this study through an action research methodology (Mertler, 2006). This action research study began with a pilot study in the summer semester of 2015 and continued into the fall semester of 2015 and spring semester of 2016. Each of these action research cycles consisted of research in an introductory linear algebra course that I had taught. While the results of the pilot study and fall 2015 research cycle informed the spring 2016 research cycle, this report will primarily focus on the spring 2016 cycle.

In the spring of 2016, I taught an introductory linear algebra course at a large state university in the Pacific Northwest. The class consisted of sixty students; the majority of these students were engineering majors, while others were mainly math and computer science majors. The course was a two credit course, which placed considerable time constraints on the instructor. As a result of these constraints, inquiry-oriented teaching activities were largely reserved for concepts closely related to logical implication connections and connections between symbolic representations of a linear system. For example, several activities were provided as opportunities for students to have an active role in construction of the aforementioned theorems of logical equivalence; the activity presented in Figure 3 was the activity through which students developed the second theorem of logical equivalence.

Let A be an $m \times n$ matrix such that, for every vector $\mathbf{b}$ in $\mathbb{R}^m$, $A\mathbf{x} = \mathbf{b}$ has at most one solution; that is, for any particular $\mathbf{b}$ in $\mathbb{R}^m$, $A\mathbf{x} = \mathbf{b}$ will have either no solution or exactly one solution. With this information, what else can you say about the matrix A? To aid in your discussion, provided below are some of the various concepts and terms we have seen in the course so far.

• System of linear equations	• Consistent system	• Augmented matrix
• Coefficient matrix	• Basic and free variables	• Pivot position
• Vector equation	• Linear combination	• Span
• Matrix equation	• Homogeneous equation	• Trivial solution
	• Linearly independent	

Figure **3**: This activity was designed as an opportunity for students to have an active role in the construction of the second theorem of logical equivalence.

In this activity, students worked in small groups as they discussed the various relationships between linear algebraic concepts. I would then lead a whole class discussion in which I connected student suggestions to the formal mathematics by translating those student suggestions into statements in the theorem of logical equivalence. Students also worked on several activities that focused on concepts that play prominent roles in the theorems of logical equivalence. For example, students were offered opportunities to explore span and linear independence, as these concepts play parallel roles in the first two theorems of logical equivalence; two of these activities are presented in Figure 4.

Without solving a linear system or using any elementary row operations, determine whether the following sets of vectors span the given space. For each set of vectors, formulate a conjecture about span based on that set.	Without solving a linear system or using any elementary row operations, determine whether the following sets of vectors are linearly independent or dependent. For each set of vectors, formulate a conjecture about linear independence or dependence based on that set.
• Do the vectors $\begin{bmatrix}1\\-2\end{bmatrix}, \begin{bmatrix}-2\\4\end{bmatrix}$ span all of $\mathbb{R}^2$?	• $\left\{\begin{bmatrix}1\\-2\end{bmatrix}, \begin{bmatrix}-2\\4\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\2\end{bmatrix}, \begin{bmatrix}3\\4\end{bmatrix}, \begin{bmatrix}5\\6\end{bmatrix}$ span all of $\mathbb{R}^3$?	• $\left\{\begin{bmatrix}1\\3\\-5\end{bmatrix}, \begin{bmatrix}3\\9\\-10\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\2\\3\end{bmatrix}, \begin{bmatrix}4\\5\\6\end{bmatrix}$ span all of $\mathbb{R}^3$?	• $\left\{\begin{bmatrix}1\\2\end{bmatrix}, \begin{bmatrix}-3\\-4\end{bmatrix}, \begin{bmatrix}-2\\4\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\7\\0\end{bmatrix}, \begin{bmatrix}3\\8\\0\end{bmatrix}, \begin{bmatrix}-2\\9\\0\end{bmatrix}$ span all of $\mathbb{R}^3$?	• $\left\{\begin{bmatrix}2\\3\\4\end{bmatrix}, \begin{bmatrix}0\\0\\0\end{bmatrix}, \begin{bmatrix}1\\1\\8\end{bmatrix}\right\}$
• Do the vectors $\begin{bmatrix}1\\0\end{bmatrix}, \begin{bmatrix}0\\1\end{bmatrix}, \begin{bmatrix}2\\3\end{bmatrix}$ span all of $\mathbb{R}^2$?	

Figure **4**: Each of these activities were designed as opportunities for students for explore span and linear independence in ways that would allow them to develop logical implication connections involving span and linear independence.

There were several goals inherent in the design of the span and linear independence activities. These activities were each implemented after span and linear independence had been formally defined in class. Thus, the task presented in each activity involves a question familiar to students: is the set of vectors a spanning set (or is the set linearly independent). However, each activity is presented with a specific instruction which asks the students to complete the activity without solving a linear system or using any elementary row operations. This instruction was included so that students would have to answer each question without the use of a familiar algorithm. Thus, this instruction is an attempt to take a task that would normally consist of a set of exercises and elevate that task to a set of small problems. Further, it was a goal of this activity that by forcing students to answer these questions through some alternative path, students would form and evoke logical implication connections involving span and linear independence that would assist them in their problem solving.

Data on student mathematical connections was largely collected from interviews that I conducted with nine of my students from the aforementioned class. These interviews were conducted shortly after the Invertible Matrix Theorem had been covered in class. Each interview was approximately one hour in length and consisted of students finding the solution set of a linear system, a vector equation, and a matrix equation, which are presented in Figure 5. Each task lent itself to a different theorem of logical equivalence. For example, the coefficient matrix corresponding to the linear system had a pivot position in every row, thus making every statement from Theorem 1 true for that coefficient matrix. Similarly, the vector equation lent itself to Theorem 2, and the matrix equation lent itself to the IMT. After an interviewee completed one of the problems, the interviewee was asked to describe his or her work. I would then present the interviewee with a list of vocabulary terms that had been discussed in class. The interviewees were asked to discuss as many of the vocabulary terms as they could and how they relate to each problem. I would often ask for justification of particular claims that the interviewee had made and would sometimes directly ask the interviewee whether he or she could discuss a particular vocabulary term. This was all done in an attempt to determine what logical implication connections the interviewees could evoke that incorporated some of the familiar terms and concepts involved in the theorems of logical equivalence.

$$\begin{array}{rcrcrcr} x_1 & - & 2x_2 & - & x_3 & = & 3 \\ 3x_1 & - & 6x_2 & - & 2x_3 & = & 2 \end{array} \qquad \begin{bmatrix} 1 \\ -2 \\ 1 \end{bmatrix} x_1 + \begin{bmatrix} -3 \\ 1 \\ 2 \end{bmatrix} x_2 = \begin{bmatrix} 7 \\ -4 \\ 9 \end{bmatrix} \qquad \begin{bmatrix} 1 & -2 & 1 \\ 0 & 2 & -8 \\ -4 & 5 & 9 \end{bmatrix} x = \begin{bmatrix} 0 \\ 8 \\ -9 \end{bmatrix}$$

Figure **5**: Interviewees were asked to find the solution set of a linear system, a vector equation, and a matrix equation.

In analyzing the interviews, I attempted to determine what mathematically correct logical implication connections corresponding to the three theorems of logical equivalence each interviewee evoked. Evidence of logical implication connections took several forms. Many logical implications involved words such as if, then, means, because, and so. For example, “The vectors, if a linear combination of those produce every single vector in that space, then they span that space” would be considered a logical implication connection. While many logical implications were evoked entirely by the interviewees, some logical implications were evoked as a result of an interviewee responding to a question that I had asked. After determining what logical implications the interviewees evoked, I then attempted to determine which of these connections were relational connections; this was largely accomplished by determining which logical implication connections a student was able to justify.

To account for the logical implication connections that interviewees evoked, I utilized adjacency matrices, as described by Selinski et al. (2014). For each interviewee, I would construct six adjacency matrices: two for each theorem of logical equivalence. For a particular theorem, an interviewee would have one matrix consisting of evoked logical implication connections involving statements from that theorem; a second matrix would contain evoked logical implication connections involving negations of statements from that theorem. For example, consider one interviewee’s adjacency matrices for the IMT, presented in Figure 6.

Figure **6**: These adjacency matrices represent the logical implication connections corresponding to the IMT evoked by one interviewee.

Each of these adjacency matrices is a representation of a digraph; the digraph corresponding to the first adjacency matrix is presented in Figure 7:

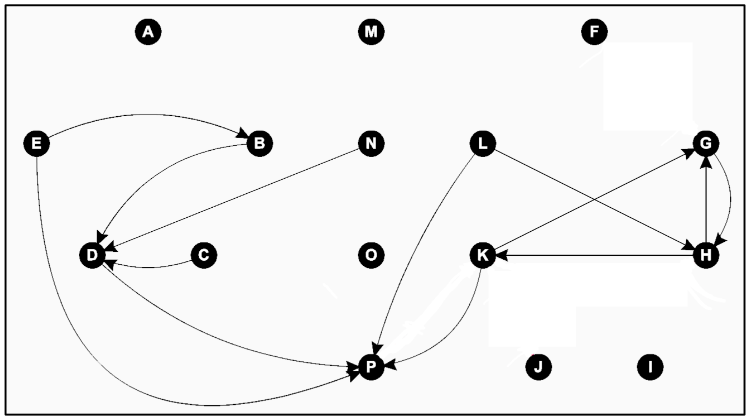

Figure **7**: This digraph represents logical implication connections that a student evoked throughout the course of an interview. Vertices A through D refer to statements from the first theorem of logical equivalence, while vertices F through L refer to statements from the second theorem. Vertices M through P refer to statements exclusive to the IMT.

Note that the digraph does not capture (and would not do so easily) the frequency of evoked logical implication connections, whereas the adjacency matrices easily do. Thus, the adjacency matrices have organizational advantages over their corresponding digraphs, and consequently, the matrices provided an effective means of analyzing the many logical implication connections evoked throughout the study.

Results

In general, the interviewees tended to evoke more connections relevant to the second theorem of logical equivalence than they did the first. This is in itself not entirely surprising; the theorems presented in Figure 2 were the versions of the theorem discussed in class, and the second theorem contains more statements than the first. As the concept of invertibility and the IMT were still new to the interviewees, they tended to evoke relatively few connections exclusive to the IMT. Due to this, the results reported here will primarily focus on connections that are not exclusive to the IMT.

Logical Implication Connections Relevant to the First Theorem of Logical Equivalence

In evoking connections relevant to the first theorem of logical equivalence, the interviewees tended to reference span, pivot positions, and linear combinations. Interestingly, several interviewees presented interpretations of span that were likely consistent with the formal definition of span, but interviewees rarely explicitly referenced the formal definition. That is, several interviewees were able to provide geometric interpretations of span or were able to describe span via linear combinations without explicitly saying the phrase “linear combinations.” For example, consider Will’s explanation of why two particular vectors span $\mathbb{R}^2$:

Will: Because these two aren't scalars of each other, they're going in different directions. They each have their own x_1 and x_2 components. If they were the same, they'd just end up looking like that.

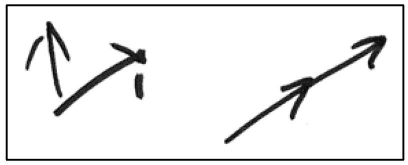

Figure **8**: Will provided a geometric description of what it means for two vectors to span $\mathbb{R}^2$. The illustration on the left represents an example Will provided of two vectors that span $\mathbb{R}^2$, while the illustration on the right represents an example Will provided of two vectors that do not span $\mathbb{R}^2$.

Seth provided an explanation that incorporated both matrix and geometric interpretations of span:

Seth: If you had a matrix, let's take this one [Seth draws the 2×2 identity matrix], then this one would span all of $\mathbb{R}^2$ because no matter how you rearrange this, you can create – uh, I'll expand it [Seth then changes his matrix to the 3×3 identity]. So uh, this one can create, because you can multiply this by infinitely many scalars outside for each row, you can create infinitely many planes, like, if you think about this geometrically, planes in any coordinate system.

Jimmy appeared to allude to linear combinations, but also referenced a geometric interpretation of span:

Jimmy: Well, for spanning, you want, uh. Every direction to be covered, every direction on the plane to be covered by some scale, er, some combination of those vectors, I think.

Jason explained that three particular vectors span $\mathbb{R}^3$ because "they go in different directions. They're not, uh, linear combinations of each other." While Jason referenced linear combinations, it was not in reference to the formal definition of span, but rather, as a description of what must be true of a set of vectors in order to span an entire space. Bill heavily alluded to linear combinations but did not explicitly reference linear combinations:

Bill: Span is having the ability to make any vector within a space. You can, like I said, manipulate any piece of the outcoming vector. You can change it by changing one of the more, one of the scalar multiples along there, not scalar multiple, scalar weights along the way you go. In this case we did at x_1, x_2, x_3. If you could change each of those to then manipulate one of the vectors in the overall value within the system, you could then change the outcome. That goes into the span. If you can do that then it does span $\mathbb{R}^3$, it does span $\mathbb{R}$ whatever. It has the ability to reach any vector, any point within that space.

Bill's description of scalar weights and manipulating vector may provide evidence that he is describing linear combinations, although he does not explicitly reference linear combinations. Thus, Bill's interpretation of span is likely consistent with the formal definition of span, even if he cannot provide the formal definition.

It should be noted that while several students provided geometric descriptions of span, geometric interpretations were not heavily emphasized in class. They were briefly referenced from time to time, but concepts were never defined from a geometric perspective. Further, prior to span being defined, the class had discussed the problem of determining whether any vector in an $\mathbb{R}^n$ space can be expressed as a linear combination of a particular set of vectors. However, when span was formally defined, it was defined more generally as the set of all linear combinations of a set of vectors. Despite this, several interviewees appeared capable of determining whether a particular set of vectors spans an $\mathbb{R}^n$ space by determining whether the vectors were linearly independent, linear combinations of each other, or go in different directions. Thus, it is likely that students developed these alternative, yet mathematically correct, interpretations of span as a result of the inquiry-oriented activity previously described.

Logical Implication Connections Relevant to the Second Theorem of Logical Equivalence

Many of the connections the interviewees evoked relevant to the second theorem of logical equivalence involved pivot positions, linear independence, and basic and free variables. The interviewees tended to refer to basic and free variables in their logical implications more than any other concept; this was particularly interesting, as the interviewees from the previous semester tended to refer to pivot positions more than any other concept. The interviewees also appeared to have understandings of the homogeneous equation inconsistent with the formal definition. For example, Fred seemed to believe that *any* homogeneous equation can only have the trivial solution:

Interviewer: If I had given you zeroes here instead of 3 and 2, would that still have a solution? That homogeneous linear system?

Fred: Yes, because homogeneous equation always have at least one solution, which is the trivial solution.

Interviewer: And what was the trivial solution again? Can you remind me one more time, what was that?

Fred: Trivial solution is $A\mathbf{x} = \mathbf{0}$, so zero is always the solution, for example $\begin{bmatrix}0\\0\end{bmatrix}$.

Jason appeared to hold a similar view:

Interviewer: Can you define homogeneous equation for me? What does that mean?

Jason: It means there's only one solution. I can't remember what it was.

Seth appeared to confound the trivial solution with the homogeneous equation:

Interviewer: Do you remember what the trivial solution is?

Seth: Uh, it's when $A\mathbf{x} = \mathbf{0}$.

Cecily, who was incredibly close to relational understanding of the connection between pivot positions and linear independence, made a similar mistake:

Interviewer: Why is it that not having a pivot position in every column tells you that these columns cannot be linearly independent?

Cecily: Because if there's not a pivot position in every column, then it can have infinitely many solutions. And for it to be linearly independent, it can only have the trivial solution.

Interviewer: Okay. So what can only have the trivial solution?

Cecily: The matrix, the linear system.

Interviewer: Okay. So what is the trivial solution?

Cecily: That's $A\mathbf{x} = \mathbf{0}$, right?

I reminded Cecily that she was describing the homogeneous equation before asking her what the trivial solution is; she claimed she did not know. As these interviewees had understandings inconsistent with the formal definition of the homogeneous equation, it is likely that any connections evoked that involved the homogeneous equation could only be instrumental; further, it suggests that these several interviewees have misunderstandings of the formal vector algebraic definition of linear independence. Some interviewees adjusted for this by providing geometric descriptions of linear independence; Bill, for example, claimed that a particular set of vectors was linearly independent "because they can all point in different directions." Others essentially appeared to instead interpret linear independence through basic and free variables instead of the homogeneous equation. For example, consider Seth's explanation of linear independence:

> **Interviewer:** How come if it has no free variables, that means it's linearly independent?
> **Seth:** Well if it has no free variable, that means that there was a pivot in every column, which would mean that it would have no free variables, because there wouldn't be, like, say a 2 out here. And, uh. This vector would always have a solution.

Seth's response was not unique. Several other interviewees tended to refer to basic and free variables often in their descriptions of linear independence, as did many students on one of the class exams.

It should be noted that when we discussed the homogeneous equation in class, we did not do this through an inquiry-oriented activity; I believed that the concept did not warrant such an activity, as students in the pilot study and fall semester appeared to understand the homogeneous equation fairly well through a mixture of lecture and whole class discussion. Looking back at the day that we discussed the homogeneous equation in the spring semester, I noticed that we concluded our initial coverage of the homogeneous equation with the following discussion of a homogeneous matrix equation that only had the trivial solution:

> **Instructor:** So, could I have free variables?
> **Student:** No.
> **Instructor:** Kay. I can't have any free variables. Why not? Why can't I have free variables?
> **Student:** You'd have infinitely many solutions.

As this was how we concluded our initial coverage of the homogeneous equation, it is possible that some students essentially replaced the concepts of trivial and nontrivial solutions with basic and free variables. That is, students made an instrumental connection between the homogeneous equation and basic and free variables, and as they did not quite understand what the homogeneous equation is and when it has nontrivial solutions, they instead considered when the homogeneous equation would have free variables. Then, when the formal definition of linear independence was provided in terms of the homogeneous equation, they tended to view linear independence in terms of basic and free variables instead of the homogeneous equation. Thus, many students in this semester relied on their instrumental connection between the homogeneous equation and free variables in order to compensate for their lack of understanding of the connection between the homogeneous equation and linear independence, thus interpreting linear independence largely through basic and free variables. This was likely exacerbated by the aforementioned linear independence activity, in which students could refer to the familiar concept of basic and free variables to determine whether the sets were linearly independent or not. Students who had not come to rely as heavily on free variables likely developed more geometric interpretations of linear independence as a result of the linear independence activity, as the sets in the activity were in $\mathbb{R}^2$ and $\mathbb{R}^3$, which can be easily visualized. Once these students had developed a more geometric interpretation of linear independence, they may have felt that the formal definition was no longer necessary for an understanding of linear independence.

Chains of Logical Implication Connections

While the unforeseen student difficulties with homogeneous equations and linear independence were disappointing, other trends appeared that suggested that students may have developed an ability to use, not just evoke, mathematical connections for the purpose of problem solving. For example, on one exam question (offered after students had learned about the IMT and subspaces), students were asked to determine, if given an invertible matrix A, what $\dim \mathrm{Nul} A$ must equal. Jimmy's response to this question is provided in Figure 9.

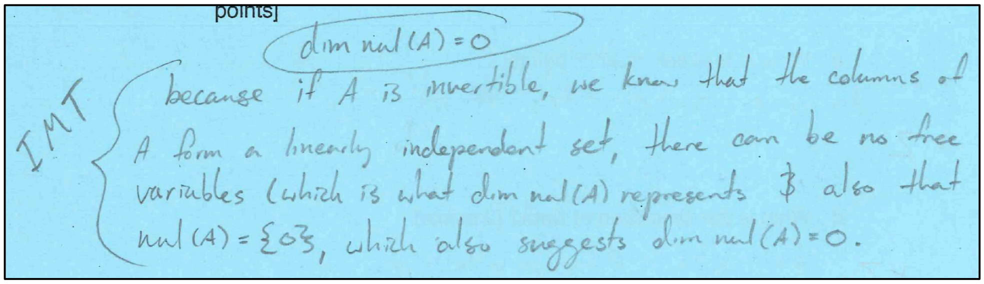

Figure **9**: Jimmy provided a chain of logical implication connections to explain why, if a square matrix A is invertible, then $\dim \mathrm{Nul} A = 0$.

Many students provided responses similar to Jimmy's in that they consisted of mathematically correct chains of logical implication connections. Students who provided such responses demonstrated not only knowledge of a number of logical implication connections, but also an understanding of how these logical implication connections could be used and chained together in order to justify another logical implication.

Connections Between Symbolic Representations of a Linear System

Several interviewees appeared to have, at the very least, instrumental understanding of several connections between symbolic representations of a linear system. Interviewees often evoked relational understanding of connections by taking a specific representation and algebraically translating it into a different representation. For example, in explaining the connection between a matrix equation and a linear system, several students used the definition of the product of a matrix and a vector to rewrite a matrix equation as a linear system.

Student understanding of the symbolic representations of a linear system appear to be influenced by their understanding of some concepts not exclusive to linear algebra. In particular, students' understanding of the term "equation" may have played a role in how they thought about vector and matrix equations. For example, when asked to describe a vector equation, several interviewees attempted to describe parametric vector form, as seen in Figure 10.

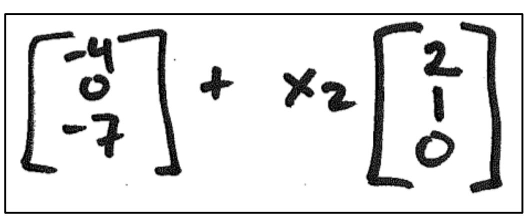

Figure **10**: Several interviewees initially referred to parametric vector form in their descriptions of vector equations. Presented here is Cecily's initial example-based description of vector equations.

Interestingly, Cecily's initial attempt to describe a vector equation did not contain an equality symbol, a necessary component of an equation. In a similar vein, several interviewees described a vector equation by providing a set of vectors corresponding to a particular coefficient matrix;

these descriptions also lacked an equality symbol despite the fact that these interviewees claimed that they were describing a vector equation. A similar trend was found in student understanding of the matrix equation. Cecily and Bobby both initially identified an augmented matrix as a matrix equation, despite the lack of any equality symbol. This was a surprisingly frequent trend outside of the interviews as well. Cecily and Bobby, in addition to several other students, identified an augmented matrix as a matrix equation on an exam problem in which they were asked to write a linear system as a vector equation and a matrix equation; Bobby's work on this problem is presented in Figure 6.

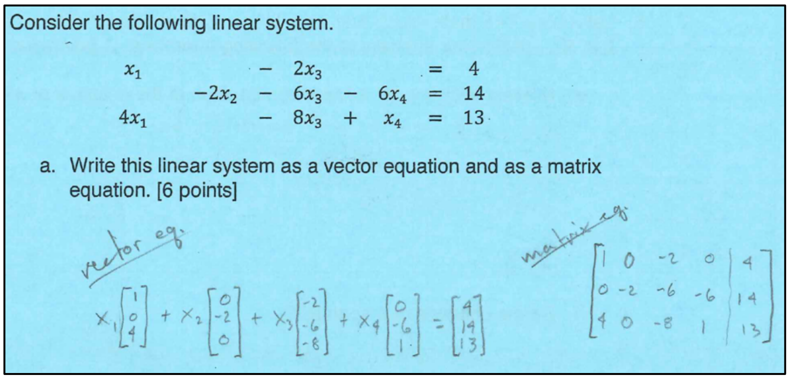

Figure **11**: Several students referred to an augmented matrix in their description of a matrix equation on this exam problem.

It should be noted that Bobby's augmented matrix does contain a bar that demarcates the coefficient matrix from the augment column, and this bar corresponds to the equality symbols in the linear system. However, several students provided augmented matrices without the bar as examples of a matrix equation. In light of this trend, it appears that student conceptions of what exactly comprises an equation may have influenced their understanding of matrix and vector equations. Had they understood an equation to contain an equality symbol, they may have been less inclined to refer to mathematical entities that do not contain an equality symbol as equations.

The Case of Will

One interviewee, Will, evoked a plethora of connections that appeared to be of a relational level of understanding. It should be noted that Will's apparent understanding was by no means representative of the rest of my students or even the rest of the interviewees. However, the connections he evoked and how he appeared to evoke those connections was particularly interesting and may shed light on how successful students understand the various connections in an introductory linear algebra course. Will evoked relational understanding of several connections between symbolic representations of a linear system, and he clearly understood that the representations of a linear system were indeed representations of each other:

Interviewer: Okay. And then what about, so you already told me how you can write [the matrix equation] as a linear system. Can you explain why you can write this matrix equation as a vector equation?

Will: Well I mean, if [the matrix equation] equals [the linear system] and this [the vector equation] equals [the linear system], then [the vector equation] would be the same as [the matrix equation].

Interviewer: Okay, okay, fair enough. Yeah. So you're saying that these are just all the same thing essentially?

Will: Yeah.

Essentially, Will appears to have formed an equivalence relation that could be described as *is a representation of*. Under this equivalence relation, Will has grouped the four representations of a linear system into an equivalence class. For example, Will appears to believe that the linear system and the matrix equation are equivalent because a matrix equation *is a representation of* a linear system. This of course is not to say that Will is consciously viewing this relationship as an equivalence relation; rather, this terminology simply provides a means to capture how Will may have organized his relational connections between symbolic representations of a linear system.

In addition to Will's representation connections, Will evoked many relational logical implication connections. Further, Will evoked connections containing versions of the statement "$A\mathbf{x} = \mathbf{b}$ has at least one solution for every $\mathbf{b}$ in $\mathbb{R}^m$" more than any other interviewee. For example, consider the following exchange with Will, which occurred after Will had found the solution set of a particular vector equation:

Interviewer: If I had given you a different vector besides 3 and 2, if I had given you any other vector, how would you know that that vector equation has a solution, no matter what vector I gave you?

Will: Because it spans all of $\mathbb{R}^2$. So any vector in $\mathbb{R}^2$ is gonna be a linear combination of these three vectors.

Essentially, I provided Will with a version of the statement "$A\mathbf{x} = \mathbf{b}$ has at least one solution for every $\mathbf{b}$ in $\mathbb{R}^m$" and asked what statements Will could connect to it. Will easily provided two such statements involving span and linear combinations. This is by no means trivial. Notice that the theorem statement, which is the version formally presented in class, contains a matrix equation. However, the version I presented to Will contained a vector equation. It is possible that Will's equivalence relation, "is a representation of," allowed him to connect to this statement so easily. Will recognizes that the matrix equation and the vector equation are equivalent. Thus, when presented with information about a vector equation, Will was able to easily replace that vector equation with the corresponding matrix equation. From there, he is able to evoke logical implication connections consistent with those presented in the theorems of logical equivalence. This suggests that there may be an important relationship between a student's understanding of the symbolic representations of a linear system and the logical implication connections that that student is capable of evoking.

Conclusions and Discussion

In light of the results from the interviews, it appears as though the inquiry-oriented activities that focused on span and linear independence were successful in creating opportunities for students to develop their own interpretations of span and linear independence. The role of geometric descriptions in the class was limited, yet several students developed interpretations of span that appeared to be more geometric in nature; further, these interpretations often heavily alluded to linear combinations while not explicitly referencing linear combinations in an algebraic sense. As many students struggled with the definition of the homogeneous equation, these students appeared to have essentially used the theorem statement "The corresponding linear system has only basic variables (has no free variables)" as a hub statement, as the concept of basic and free variables was far more accessible and easy to use. The linear independence activity allowed students to reinforce the role of basic and free variables as a hub concept, particularly as the concept pertains to linear independence and dependence. Additionally, the linear independence activity also allowed students to develop geometric interpretations of linear independence that relied on the notion that linearly independent vectors are not linear combinations of each other.

While the inquiry-oriented activities were successful in creating opportunities for students to form their own interpretations of span and linear independence and how they relate to other concepts, the implementation of these activities could be improved. Students appeared to replace their understanding of the formal definitions of span and linear independence with the understanding they developed as a result of the activities. This may have limited the students' ability to evoke logical implication connections involving these concepts and their formal definition; that is, students may be more capable of clearly evoking logical implication connections if they can connect their understandings of these concepts to the formal definitions. As an instructor, I should have devoted time to exploring how these student developments relate to the formal definitions of span and liner independence. Investigating how the inquiry-oriented activities could be improved in this regard remains an avenue for future research.

Throughout the semester, students appeared not only to form and evoke logical implication connections, but also to use these connections to evoke and justify other logical implications; this was evident in the many responses to an exam question that asked students to explain how invertible matrices and the dimension of the null space are connected. This is by no means trivial, as students often struggle to form chains of reasoning (Dorier & Sierpinska, 2001). It should be noted that, as an instructor, I would often emphasize to my class the importance of justification, particularly when providing responses to an exam question. This likely partially accounts for the numerous responses that contained a great amount of detail; however, this cannot fully account for the fact that most of these responses consisted of *mathematically correct* chains of logical implication connections. Thus, it is quite possible that the frequent opportunities to form, evoke, and justify logical implication connections through inquiry-oriented activities allowed students to develop an ability to use connections as tools in justifying other logical implication connections.

The results concerning student connections between symbolic representations of a linear system suggest that many linear algebra students may have conceptions of equations that do not contain the necessity of an equality symbol. This finding may help explain some sources of difficulty that many linear algebra students face. For example, Zandieh and Andrews-Larson (2015) describe how many linear algebra students find it easier to translate a linear system to an augmented matrix than they do an augmented matrix to a linear system. One reason for this difficulty is the reconstruction of $\mathbf{x}$, which refers to reintroducing the variables when translating from an augmented matrix to a linear system. The augmented matrix is the only representation of a linear system that does not explicitly contain reference to the variables of a linear system; it is also the only representation that does not explicitly contain an equality symbol. In light of the results of the study reported here, it is possible that students may struggle not only with the reconstruction of $\mathbf{x}$, but also with the reintroduction of the equality symbol.

Finally, while Will is by no means representative of a typical linear algebra student, his apparent understanding of various mathematical connections suggests that there may be an important relationship between student understanding of symbolic representation connections and logical implication connections. There has been previous research into symbolic representation connections (Larson & Zandieh, 2013; Zandieh & Andrews-Larson, 2015) and logical implication connections (Selinski et al., 2014; Wawro et al., 2012; Wawro et al., 2014); however, these two types of connection have been discussed largely independently of one another both within the literature and within the study reported here. Thus, a future research project emanating from this study will involve an exploration into how students use their understanding of symbolic representation connections to form and evoke logical implication connections.

The Effects of the *Epsilon-N* Relationship on Convergence of Functions

Zackery Reed
Oregon State University

Much work has been done in recent years to study students' formulations of formal limiting processes. One of the most common goals is to foster a productive understanding of the relationship between the error bound epsilon and the domain of the convergence; what is called a range-first perspective. My study examines an advanced calculus student's understanding of the relationships involved in convergence of functions, and how his prior experience with limits influenced his understanding. I unpack his cognitive organization of the dependence relationships between ϵ, N, and x in functional convergence. This case study demonstrates the effects of a persistent understanding that ϵ depend on N in the convergence of sequences.

Key words: Sequences of Functions, Formal Definition of Convergent Sequences, Advanced Calculus

Introduction

Mathematics students study convergent sequences throughout their college career. Formalizing sequential convergence provides an important yet difficult stage in the development of students' reasoning about advanced mathematical processes. A vital component of formal sequential convergence is the relationship between ϵ (*epsilon*) and the critical index N. I call this the *epsilon-N* dependence relationship, which mirrors the *epsilon-delta* dependence relationship within formal limits of functions.

In advanced analysis courses, sequences take on forms beyond just real numbers. In particular, advanced calculus students encounter sequences of continuous functions towards the end of their instruction. The convergence of such functions is defined in a manner that is structurally similar to the familiar convergence of real numbers, but it has the added complexity of also accounting for variation within the domain of the functions in the sequence. Thus, the relationships between ϵ, N, and x become vitally important to understanding the different types of convergence.

While conducting a larger study involving student understanding of metric spaces, I interviewed two students to examine their concept images and definitions (Tall & Vinner, 1981) pertaining to convergence of function sequences. A case study of one student's interview demonstrates how reversal of the ϵ-N relationship may persist beyond convergence of real numbers to affect the convergence of functions. In this preliminary report, I discuss this case to demonstrate the effect of this reversal on convergence of functions. I then go into detail about some cognitive conflicts that seemed to arise within the student's concept image. I seek to answer the following research questions: 1) How does the addition of the domain value x into the definition for functional convergence affect student understanding of convergence?, and 2) How does a student's understanding of real-number convergence affect their understanding of functional convergence?

Literature Review

There is an abundance of research on student initial understanding of limits, the potential difficulties that arise and initial interpretations of limit definitions (Bezuidenhout, 2001; Cornu, 1991; Cottrill et al., 1996, Davis & Vinner, 1986; Roh, 2008; Roh, 2009; Tall, 1992; Tall & Vinner, 1981; Williams, 1991). There have also been investigations into students' intuitions about the nature of limits (Oehrtman 2003; Oehrtman 2009). Many of these studies, however, pertain to students' intuition and reasoning with informal limits rather than formal understanding.

Targeted glimpses of student understanding of formal limit definitions began with Swinyard (2011). In his teaching experiment, two students successfully reinvented the formal definition of the limit of a function. This marked the first study in which students learned (reinvented) the formal definition of a limit as opposed to studies examining student post-instructional understanding. Swinyard's reinvention study resulted multiple useful constructs for characterizing students' perspectives of the formal limit structure. Swinyard and Larsen (2012) followed up by suggesting some strategies for fostering productive generation of formal limit definitions such as a focus on the error bounds. This particular strategy is termed a range-first perspective and contrasts an unproductive domain-first perspective. These perspectives will later be explored via theoretical framing. Formal limit reinvention was later adapted to sequences by Oehrtman, Swinyard and Martin (2014). Oehrtman et. al. also guided a pair of students through the reinvention of formal sequential convergence. Their findings refined Swinyard and Larsen's (2012) domain/range-first perspectives further, and also examined the students' progression of approximation-based reasoning in the limit reinvention. These studies utilized reinvention methodology to gain detailed glimpses into the understanding of formal limit definitions.

Other efforts have also been made to investigate student understanding of the formal definition of limits with special attention paid to the relationships between the variables controlling the limiting process (Adiredja, 2015; Adiredja, 2013; Adiredja & James 2013; Adiredja & James 2014; Roh, 2009; Roh & Lee 2016; Roh & Lee, 2011; Dawkins & Roh 2016). Specifically, Adiredja (2015) utilizes the Knowledge in Pieces (diSessa, 1993) framework to make a case for equitable cognitive research in the context of formal limit quantification. Adiredja offers a case study of a single female student (Amy) and outlines useful knowledge resources she leveraged to develop a productive understanding of the temporal $\epsilon - \delta$ order. One useful distinction that came out of this is attention to statements of the "error" between functions versus utilizing an "error bound".

Roh (2011; 2016) along with Lee and Dawkins have utilized multiple interventions to foster useful intuitions in analyzing the quantification of the limit definition. The "Mayan Activity" (2011) offers a narrative of continually refining approximations that fosters useful intuitions of the limiting process. Similarly, the "$\epsilon-$strip activity" utilizes geometric visualizations of the ϵ error bound in sequential convergence. Both interventions target quantification in the formal limit definitions, and highlight attention to the logical orderings of limits along the real line.

This study builds on the existing literature by venturing into student understanding of functional convergence. Specifically, point-wise convergent sequences of functions follow a structure identical to real number sequences, with the added complexity of accounting for variation in the domain of the functions in the sequence. In this report I model a single student's understanding of functional convergence, and demonstrate how constructs mentioned above, such as domain-first perspectives and the relationship between quantifiers, offer meaningful insights into his understanding. This study also offers an initial glimpse at a student's understanding of an advanced mathematical concept that builds on previously studied concepts.

Theoretical Perspectives

Concept Image and Concept Definition

As mathematicians, we classify mathematical objects and phenomena via formal definition according to specific identified properties. Understanding such ideas, however, entails more complicated cognitive structures built through various encounters with the mathematics. This calls for a distinction to be made between the collection of cognitive objects that are brought to bear upon recollection of a particular mathematical concept, and the words that compose the definition of the concept. This is the distinction between a thinker's concept image and concept definition (Tall & Vinner, 1981).

Tall and Vinner define the concept image as the "total cognitive structure that is associated with the concept". This includes examples, graphs, images, relationships, as well as the definition of the concept. The formal language that the student uses to identify the concept is termed the concept definition (p.2). The definitions students call upon may or may not agree with a definition proposed by the mathematical community, calling for further distinction. A student's concept definition is personal when it is the "form of words that the student uses for his own explanation of his concept image" (p.2). This might contrast the definition proposed by the mathematical community, which we call the formal concept definition (p. 2). It can be useful to note when a student's personal and formal concept definitions do not agree. In particular, differences between the two statements can highlight informal understandings that might dominate a student's understanding of a concept.

Different activities may require a student to access different parts of her concept image. Which parts are activated given certain promptings may highlight important features of the student's understanding. We therefore call the "portion of the concept image which is activated at a particular time" the evoked concept image (p. 2).

Given the complexity of students' cognitive organizations, it is clearly feasible for a student's concept image to contain elements that might be at odds with each other. It is reasonable to assume that such conflicting understandings can be held concurrently unless specifically highlighted. In particular, unless simultaneously evoked, there is potentially no reason for the student to see such an issue with holding both parts of her concept image. Such contradictory parts of a student's concept image are called "conflict factors" (p. 3). A conflict factor is "potential" if it is a part of the concept image at odds with another part, and is called "cognitive" if evoked to cause actual cognitive conflict (p. 3). Such a scenario may occur if both potential factors are prompted to be simultaneously evoked. Tall and Vinner caution that potential conflict factors "can seriously impede the learning of a formal theory, for they cannot become actual cognitive conflict factors unless the formal concept definition develops a concept image which can then yield a cognitive conflict" (p.4).

Domain-First and Range First Perspectives

Previous limit studies have revealed the particularly useful constructs of domain/range-first perspectives. These perspectives identify to where students assign control of the limiting process. Standard limit notation typically manifests $\lim_{n\to\infty} a_n$ or $a_n \to a$ to denote that a sequence a_n converges to a. This is often informally stated to include a clause describing the behavior of the index increasing to infinity. In accordance with this, there is potential for students transitioning from informal to formal limit studies to assign control of the convergence to the index behavior.

This is called a domain-first perspective. Swinyard and Larsen (2012) first defined this construct as an x-first perspective to describe student understanding of limits in calculus contexts.

In an x-first perspective, the variation in the domain values x controlled the behavior of the limit. This contrasts a range-first (y-first) perspective, where deviation from a limit candidate is measured and controlled on specific domain regions. Swinyard and Oehrtman (2014) suggest that focusing first on the behavior of the range values in limiting processes will foster useful interpretations of the formal definition. The next section describes in detail the relationship between the logical formulation of the formal definition and the underlying properties of the limiting processes.

Mathematical Discussion

Mathematical insights are useful theoretical considerations. By exploring formal constructions of the explored mathematics, we as mathematicians gain valuable perspectives on the overall structure of the mathematical activity with which the students engage.

The convergence of function sequences is an advanced concept that students examine towards the end of advanced calculus instruction. There are two such types of convergence, point-wise and uniform. We will primarily engage with a student's understanding of point-wise convergence.

Sequential convergence in real analysis contexts follows a standard approximation scheme. Such a scheme is typically first introduced through convergence of real numbers. We will thus begin this discussion by examining real number convergence; a familiar context within the literature on limits. A sequence of real numbers (a_n) converges to a real number a if $\forall\epsilon>0$, $\exists N \in \mathbb{N}$ such that $\forall n \geq N$ we have $|a_n - a| < \epsilon$. Attention to the logical structure of this definition reveals the progression of activity used to verify convergence of such sequences. An important consideration to make when reading these logical definitions is understanding what is involved in verifying that a sequence meets its requirements. To do this, note that the "for all" symbol $\forall$ at the onset of the definitions implies that verification begins by picking a specific element from whatever set follows $\forall$. In this case, a positive real number ϵ. Similarly, the "there exists" symbol $\exists$ signifies that some element of the set in question must be found that satisfies whatever conditions the definition sets. In this case, a natural number N that acts as a particular index value for the sequence.

Thus, we begin with a positive real number ϵ. ϵ acts as a bound on the error between the sequence entries a_n and the real number a to which the sequence converges. Thus, if for every possible positive error bound ϵ, we find some index N such that past N all sequence values differ from a by less than ϵ, then we say the sequence converges to a. This highlights that the critical index N, necessary to bound the tail of the sequence, depends on the particular error bound ϵ chosen. This is succinctly explained by saying the critical index N depends on the error bound ϵ.

Convergence of functions builds on this approximation scheme while accounting for variation of the functions across their domain. This adds to the complexity of the convergence structure, and also provides the primary difference between point-wise and uniform convergence. A sequence of functions(f_n) converges point-wise to a function f on a domain D if $\forall\epsilon>0$ and $\forall x \in D$ $\exists N \in \mathbb{N}$ such that $|f_n(x) - f(x)| < \epsilon$. Once again, attention to the logical structure gives insight into the behavior of such sequences. In particular, we reduce the convergence to that of real numbers by letting the domain values vary before verifying the accuracy of the sequence entries. Notice that once a domain value x is specified, $f_n(x)$ and $f(x)$ are real numbers. Thus, this sequence of functions converges if given a specific pair of values (ϵ, x), representing a fixed

Figure 1: Visualization of the sequence x^n

error-bound and domain value respectively, a critical index N may be found so that past N the difference between the real numbers $f_n(x)$ and $f(x)$ is smaller than the error. This implies that the sequence of functions converge on a domain D if evaluation across the domain creates convergent sequences of real numbers.

Consider the prototypical example of a point-wise convergent sequence of functions defined on the domain $[0, 1]$, $f_n(x) = x^n$. A visualization of sequence values is given in Figure 1.

Notice that by selecting $x = .4$ results a decreasing sequence of real numbers $.4^n \to 0$. This is similarly true for any value $x = 0 \leq \alpha < 1$. For $x = 1$, note that $1^n = 1$ and so we have a constant sequence converging to 1. Thus, if we define f to be the piece-wise function $f(x) = 0$ for $x \in [0, 1)$ and $f(x) = 1$ for $x = 1$, we have that $f_n(x) = x^n$ converges to $f(x)$ point-wise. A rigorous proof of this verifies that for each $\epsilon > 0$, $\exists N \in \mathbb{N}$ such that for $n \geq N$, $\alpha^n \leq \alpha^N < \epsilon$.

Finally, we have a sequence of functions converges uniformly if variation across the domain does not affect the approximation scheme. Formally, a sequence of functions $\{f_n\}$ converges uniformly on a domain D to a function f if $\forall \epsilon > 0$, $\exists N \in \mathbb{N}$ such that for all $n \geq N$, $|f_n(x) - f(x)| < \epsilon \; \forall x \in D$. A potential point of confusion is that both point-wise and uniform convergence of functions include the $\forall x$ statement. Attention to the logical order in the statements clarifies the distinction. In uniform convergence, the $\forall x$ occurring at the end signifies that once the error bound ϵ is chosen and the critical index N is found, the resulting bounding condition holds across all domain values. In other words, all sequences of real numbers created by evaluation across the domain satisfy the same bound by the error ϵ.

This definition is equivalent to the definition of convergence in the metric space of continuous functions when D is compact. Here, a sequence of continuous functions converges to a continuous function f if $\forall \epsilon > 0$, $\exists N \in \mathbb{N}$ such that $\forall n \geq N$, $\sup\limits_{x \in D} |f_n(x) - f(x)| < \epsilon$. The structure of this formulation is identical to convergence of real numbers, where the objects of convergence and metric function have changed. This follows because convergence in metric spaces have the same definition despite the space and metric specified.

Methods

The episode reported on was part of a larger study exploring students' reasoning about and generalization in various metric spaces. This involved conducting teaching experiments (Steffe & Thompson, 2000) with two students, each teaching experiment consisting of six hour-long sessions with a single student.

The participant reported on was a junior mathematics and engineering major named Kyle (pseudonym). Kyle had taken the introductory advanced calculus sequence at a large mid-western university and was currently taking a course on advanced calculus in vector spaces.

In accordance with teaching experiment methodologies (Steffe & Thompson, 2000), the students were prompted to engage in mathematical activity to facilitate the exploration of novel concepts in metric spaces. During the sessions, their activity was observed and there were frequent discussions between the researcher and student wherein the student described their understanding of the specific mathematics. The sessions relevant to this report examined Kyle's understanding of functional convergence. The purpose of this examination was to motivate the generation of a metric on the space of continuous functions through manipulation of the uniform convergence structure. By observing Kyle's exploration of function convergence, I built a detailed model of his concept image.

Each interview was video recorded. The retrospective analysis (Steffe & Thompson, 2000) consisted of reviewing the video records for statements of Kyle's concept definitions as well as statements and activity that suggested Kyle's evoked concept images. Special attention was paid to Kyle's activity, definitions, statements, and examples so that a model of Kyle's concept image could be inferred. Within this model, I analyzed Kyle's potential and cognitive conflict factors so that I could identify factors contributing to his eventual shift in understanding.

Results

The goal of this interview was to explore Kyle's concept images and definitions pertaining to different types of convergent function sequences. We began by establishing Kyle's concept definition for point-wise convergence of functions. This type of convergence would have been Kyle's first exposure to functional convergence of any kind in the classroom. Kyle's initial concept definition is the first of many statements he made suggesting he had adopted a domain-first perspective. Kyle wrote on the board "A sequence of functions $\{f_n\}$ converges pointwise to f if $\forall x \in D$, $\lim_{n\to\infty} f_n(x) = f(x)$". I call this Kyle's personal concept definition, as the formal concept definition involves formalization of the limit $\lim_{n\to\infty} f_n(x) = f(x)$ as demonstrated above. Note that Kyle's statement, while technically informal, is still a correct characterization of point-wise convergence. Along with the evidence given below, this statement suggests that Kyle had adopted a domain-first perspectives of real-number convergence which he now applies to point-wise convergence. In fact, Kyle unpacks this definition by saying:

Kyle: When you're talking about point-wise convergence, depending on your x your sequence of functions may converge to a different limit. So we have to say that for all x in D we have to choose our x first, because once we run through the limit, that x is going to change what our limit function is.

This is in fact a productive distinction to make with point-wise convergence. He then continues with:

Kyle: So basically ... in the ϵ definition our ϵ ends up being dependent on x for point-wise convergence.

This statement of dependence is Kyle's first evoking of a potential conflict factor, as the logical structure of the "ϵ definition" suggests an independent relationship between ϵ and x. I then prompted him to write out the ϵ definition (formal concept definition) and he produced the correct formulation given in the Mathematical Discussion.

When asked to discuss what the definition means, he said:

Kyle: When we are trying to show point-wise convergence we are trying to find some ϵ that will always be greater than the difference between our sequence and our function, however because we are selecting our ϵ and then selecting our x then this ϵ will actually be a function of x and the N from the naturals.

As he said this he wrote out $\epsilon(x, N)$. As we began to unpack the nature of the dependence of ϵ on N and x, he made the following statement:

Kyle: N will determine what your epsilon ends up being. 'Cause N plays the same role that it always plays when we're talking about convergence. It's the last index such that every index past this you're going to have this property [$|f_n(x) - f(x)|$] be true, so in so much as that ϵ is pretty much always dependent on that natural because you want to say that past this natural N, you know this ϵ is always going to be true.

The potential conflict comes from his understanding of universal quantification and basic proof structures. For instance, he understood that $\forall\epsilon$ and $\forall x$ meant to "pick an ϵ" and "pick an x". In fact, there were multiple moments in describing his proof strategies where the conflict factors were almost simultaneously evoked. I will later describe the task that prompted these potential conflict factors to become cognitive.

As we continued discussing the nature of the ϵ dependence on N and x, we discussed some typical examples of functions that converge in a point-wise manner such as x^n, x/n, and even sequences constant in x (or rather standard real-number sequences). In each of the following examples, Kyle gave evidence that he had adopted a domain-first perspective.

For example, we first examined the sequence $1 + 1/n$ which converges to 1. Kyle justified the convergence of this sequence by saying:

Kyle: As n goes to ∞ it's going to converge to 1 ... so let n increase without bound and as you look at $[1/n]$ as n gets closer and closer to ∞ and $[1/n]$ will just go to 0 and you'll be left with 1.

Further, when examining x^n, Kyle again productively assessed that evaluation of the sequence at different x values would yield a different "limit".

Kyle: Let $x = 1$ to begin with. Then as n increases without bound, your x^n is going to equal 1 ... If you look at x between 0 and 1, then your limit as n increases without bound of x^n is always 0.

Notice that throughout these examples, Kyle is justifying convergence of the limits based on the behavior of the index (domain) values n. This further suggests that Kyle had adopted a domain-first perspective. The nature of his perspective fully came to bear when cognitive conflict resulted from evaluating x^n at $x = 1/2$. After isolating this x value, I asked Kyle to prove for me why $1/2^n$ converged to 0 using ϵ. After writing the contents of Figure 2 on the board, he said the following:

Kyle: The thing I'm confused about here is we need $[.5^n]$ to be less than ϵ, ϵ is any number greater than 0, so we need $[.5^n]$ to converge towards 0, but it doesn't converge for a finite n ... we want n to increase without bound ... Without thinking of things as limiting functions I don't know what we're trying to do. I'm so used to letting n increase without bound, well clearly if n increases without bound that's gonna be less than ϵ ... because it's getting arbitrarily small.

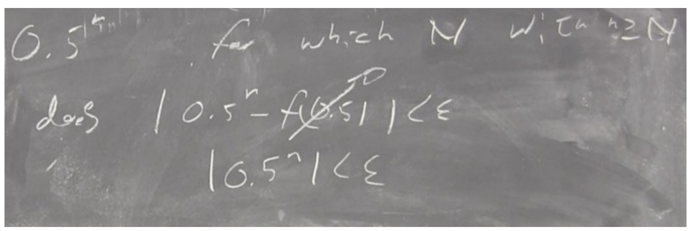

Figure 2: Kyle's initial work with x^n at $x = 1/2$

The above suggests that Kyle's evoked concept image of real number convergence involved a domain-first perspective, wherein the increasing index value controlled the behavior of the sequence. What is intriguing is how Kyle accounted for the added complexity of incorporating the domain of the function as well. As a first example of Kyle's resulting concept image, we examine Kyle's description the following *x*-*N*-ϵ relationship for the sequence of functions x/n:

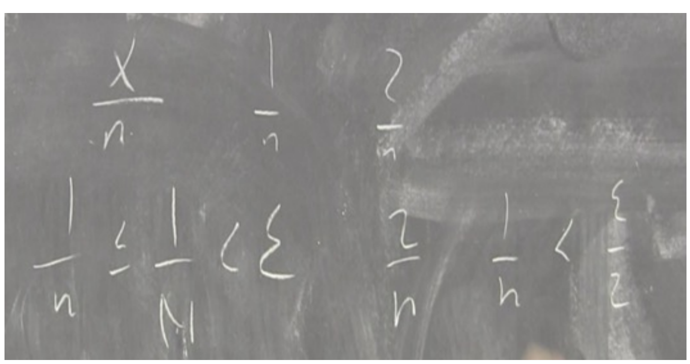

Figure 3: Kyle's work with x/n

Kyle: If you are thinking about $1/n$ as being less than ϵ, then that means $2/n$ would imply that $1/n$ is less than $\epsilon/2$. So if you're increasing the value of these $x's$, your epsilon is going to get smaller and smaller.

Consistent with his understanding that ϵ was a function of x and n, Kyle's concept image included an ϵ that was small enough to trap the arbitrarily increasing index n. Indeed, if (as above) ϵ satisfies the convergence of $1/n$, then $\epsilon/2$ would satisfy the convergence of $2/n$, and similarly $\epsilon/3$ would satisfy $3/n$ and so on. This highlights the relationship between x and ϵ, namely that variation in x results variation in the ϵ necessary to trap the sequence as n increases arbitrarily. The following demonstrates Kyle's geometric interpretation of this phenomena:

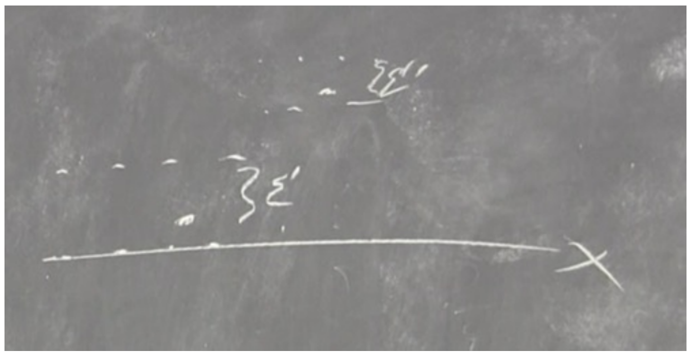

Figure 4: Changing ϵ windows

Kyle: If you have some point, and you pick some x, it might have some window that's ... we'll call it ϵ'. But if you pick another x it's possible that it has maybe a smaller window that's just like ϵ''.

Kyle's drawing of the ϵ windows demonstrates that Kyle had constructed a mathematical phenomenon that was logically consistent with his understanding of the $\epsilon - x - N$ relationship. He made use of the convention that variation in x potentially changes the limit of the resulting real-number sequence to formulate a consistent mathematical limiting process. Surely if real number convergence entails finding an ϵ window to trap a sequence of arbitrarily increasing index, then dependence of the sequence values on x implies that the ϵ window may vary. Kyle's understanding that variation in the quantifiers affects the limiting process contributed to his successful accommodation upon examining cognitive conflict factors.

Recall that evaluation of x^n at $x = 1/2$ was a cognitive conflict factor for Kyle.

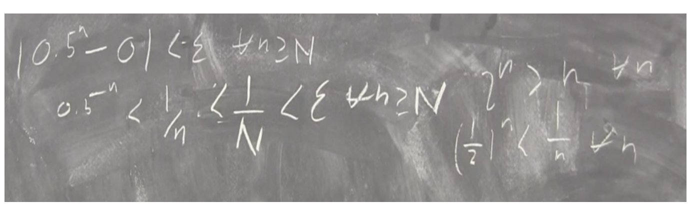

Figure 5: Kyle's work on $1/2^n$

When he could not verify the convergence in the manner he wanted, I suggested using the fact that 2^n is greater than n for all n, and so then he tried bounding $1/2^n$ by $1/n$ which could be bounded by ϵ. Thus, if $1/n$ converges to 0 then $1/2^n$ converges to 0. In showing that $1/n$ converges to 0, Kyle attempted to call upon the Archimedian property. It was through examination of the Archimedian property that Kyle resolved his cognitive conflict. I prompted Kyle to examine the structure of the Archimedian property, and he realized that for a particular number ϵ, we can find an N such that $1/N<\epsilon$. This then allowed him to complete the proof. Examination of the other examples in light of the Archimedian property revealed to Kyle the actual relationship between x, N, and ϵ. Kyle concluded by realizing that "N is doing most of the work", and re-stating the dependence to agree with the logical structure of the formal limit definition.

By resolving that the index N is found for a fixed ϵ, he immediately restructured his understanding of not only real number convergence, but also for all of his previous dependence claims. This understanding resulted in Kyle adopting a range-first perspective for real number convergence, which then transformed his understanding of point-wise convergence of functions. Kyle demonstrated a robust understanding of how variation in x affected the convergence of the function sequence. It was this understanding that was ultimately leveraged to result a fluency with the structure of point-wise convergence.

Discussion and Further Directions

This episode provides an example of the complexity that accompanies understanding advanced formal mathematical concepts. Point-wise convergence of functions utilizes the same logical structure as convergence of real numbers, with the addition of accounting for variation across the domain of the functions in the sequence. Kyle had clearly built a cognitive structure that incorporated this complexity into his existing understanding of convergence. Note that Kyle's mathematical system was logically consistent with his understanding of the fundamental structure of sequential convergence. This demonstrates Kyle's mathematical maturity, and his ability to adapt a productive understanding into his existing cognitive framework. From this case study we see that students' can develop complex and consistent mathematical systems even based on "incorrect" understandings. This conclusion is made to the credit of students' mathematical abilities, and is consistent with the idea that mathematics developed by students can be the result of productive thought despite deviation from normative understanding. At the same time, this study warrants the caution that proficiency with advanced mathematical concepts does not imply fully correct understanding of the ideas upon which they are built. This is in line with Tall and Vinner's (1981) warnings about potential cognitive factors.

Exploring the model of Kyle's concept image for functional convergence reveals a natural relationship between formal and informal knowledge when studying advanced mathematical processes. Kyle could indeed produce the formal concept definition of functional convergence, and yet his understanding of the mechanism for convergence was dominated by an informal domain-first perspective. While Kyle's concept image contained a robust understanding of how to ascertain the limit functions for point-wise convergent sequences, his understanding was primarily informal. This opens up a greater inquiry into the interplay between students' leveraging of formal and informal knowledge when exploring advanced and formal concepts. It is natural for this phenomena to occur in a real analysis setting, as students build informal understandings of the material in calculus courses. This raises an interesting question, namely when do students call upon their formal and informal knowledge when exploring advanced formal mathematics? In this particular episode, Kyle mainly attended to formality when prompted to prove claims of convergence. The logical structure of the formal definition was not as meaningful to Kyle as his informal knowledge until he was required to attend to formalism through proof. Further investigation can explore advanced mathematics students' attention to formal and informal knowledge when working in formal mathematical settings.

This episode also demonstrates the importance of logical quantification in understanding formal limit definitions, and the persistent effects of a domain-first perspective. It was evident that Kyle's domain-first perspective influenced his interpretation of the $\epsilon - N$ relationship for real number convergence. This was then compounded with the added complexity of domain variation in the functions. Thus, Kyle's interpretation of the logical structure of point-wise convergence was heavily influenced by his understanding of real number convergence. This highlights the importance of attending to logical quantification early in formal mathematics. While Kyle understood the meaning of the quantifiers and could correctly apply them in a proof scheme, the implications of such meanings came second to his informal understanding. As mathematicians, we learn to communicate greater meaning through formal symbolism and logical structure. Attending to the greater meaning of such symbolism early on may facilitate productive understanding of formal mathematics. In light of the earlier discussion of formal versus informal knowledge, further studies can investigate student's informal understandings and uses of logical quantifiers in real analytic statements.

This case study highlights the complex relationships that exist in understandings of formal and advanced mathematical concepts. By investigating point-wise convergence of functions, we were able to observe the progression of theoretical constructs developed for convergence of real numbers, and explore the nuances of a single student's understanding.

Hypophora: Why Take the Derivative? (no pause) Because it is the Rate

Kitty L. Roach
University of Northern Colorado

Abstract: *Part of a larger study of the development of teaching among novice college mathematics instructors, this report focuses on one participant, Disha, and her use of a questioning technique called hypophora. At the beginning of the observations, 25% of her questions were hypophora. After video-case based activities during weekly coordination meetings, her use of hypophora decreased to about 10% of questions. Although Disha rejected the idea that her teaching had changed in any way, she acknowledged that she began "breaking things into smaller pieces" to help students understand.*

Keywords: questions, calculus, hypophora, professional development

In college mathematics, from gateway classes for future teachers to advanced courses for future engineers, instructors learn about teaching almost entirely by trial and error (Kung & Speer, 2009). The result is reflected in pass rates below 50%, particularly in calculus and its prerequisite courses (Hastings, Gordon, Gordon, & Narayan, 2006; Herriott & Dunbar, 2009).

Bressoud, Carlson, Mesa, and Rasmussen (2013) report that among students who enroll in college calculus ready for the course (i.e., meeting pre-requisites and placement requirements), at least 28% fail it. If we consider the fail rate reported by Bressoud and colleagues, approximately 85,000 students will fail Calculus I each fall semester. In response to course surveys, students reported that the teaching of Calculus I was "ineffective and uninspiring… 'over-stuffed' with content and delivered at too fast a pace, assessments were poorly aligned with what was taught and the instructor lacked connection to students and the course" (Bressoud et al., 2013, p. 10). The national problem driving the research presented here is the ill-spent time, effort, and money resources when so many students arrive at college ready for calculus and fail the class.

Research has found that when teachers have a better understanding of student thinking, it improves teaching (Ball, 1997; Carpenter & Fennema, 1992; Fennema et al., 1996). By learning how to ask students questions, an instructor can open up a dialog with students and learn about the student thinking in the room. The collegiate mathematics education literature points to a need for insight into how graduate student Teaching Assistants (TAs) learn about student thinking (Speer & King, 2009). The research needed includes exploration of how novice instructors learn from their own practice and through professional development (Speer & Hald, 2008). Included in the field's identification of needed work is a call for research on the instructional practices that support learning to learn from the teaching process itself, such as the in-class use of questions (Deshler, Hauk, & Speer, 2015).

This qualitative and descriptive statistical study focused on one possible way to improve college mathematics instruction: support instructors to understand what their students are thinking. I investigated how course coordination that included video case based activities might facilitate reflection on and asking of questions in the classroom. The research questions were:

1. What is the nature of questions and change in question strategies within a semester during classroom discourse by the instructors?
2. How does video case based professional development shape the perceptions and intentions about the role of questions in teaching held by TAs?

Theoretical Framework and Researcher Stance

The conceptual framework for the work is built on the foundation of pedagogical content knowledge. Pedagogical content knowledge (PCK) is the collection of knowledge instructors have about the discipline-specific challenges students encounter, strategies for helping students, ways to listen to identify learners' thinking processes, and skills for regulating practice (Ball & Bass, 2000; Shulman, 1986). Novice college mathematics instructors acquire PCK in many ways, such as grading, examining their own learning, observing and interacting with students, reflecting on and discussing practice (Kung, 2010; Kung & Speer, 2009; Speer & Wagner, 2009). College mathematics PCK includes knowledge about formal and informal mathematical discourse, including teachers' anticipations regarding their adult students' thinking and how to turn teacher intentions into actions (Hauk, Toney, Jackson, Nair, & Tsay, 2013). These ideas were operationalized in this study by a focus on seeking and responding to student thinking through questions.

The emerging consensus in faculty development is that it is clinical work: instructors must evaluate, diagnose, and prescribe, while also developing their practice (Hinds, 2002; Persellin & Goodrick, 2012). Great success in preparing clinicians in medicine, psychology, law, and education has come through case- or story-based study (Boud & Feletti, 1997). Improving college mathematics teaching can productively start with ways to build instructional self-awareness through opportunities to compare and contrast to other people in a variety of contexts (Mason, 2010). This method has been making its way into college instructor preparation through case-based materials (Friedberg et al., 2001; 2011; Hauk, Speer, Kung, & Tsay, 2010; Hauk et al., 2013).

My epistemological stance was constructivist, both social and radical. I held to the belief that people construct their own knowledge and that knowledge is influenced by their environment. This knowledge can be a shared knowledge within a group, as in social constructivism, or the knowledge can be individually constructed, as in radical constructivism (Schunk, 2004).

Methods

Participants taught Calculus for Biological Scientists at a doctoral granting public university, referred to here as BRU. There were five participants in the larger study. All five were novice instructors. Four were graduate TAs and one was a recently graduated PhD student. I refer to those who are instructor-of-record (both TAs and other non-graduate student instructors) as "instructors." Only one of the instructors, Disha, will be reported on in this paper.

Each instructor was observed and video recorded six times during the semester. Observations focused on the type of question asked, the depth of the question, and the discourse surrounding those questions. Instructors were interviewed prior to any observations, again after two observations, and had a final interview after final exams. Instructors participated in weekly video case based course coordination meetings which focused on student thinking about mathematics. Each video case based session included activities and prompts for discussion among the instructors.

Starting with a framework I developed with colleagues (Roach, et al., 2010), four of the six original observations were coded in depth. These classes were viewed and partially transcribed as needed to provide thick, rich, descriptive detail (Merriam, 1998). After two rounds of observation I determined that an additional question category, hypophora, was needed to address a technique used by the instructors in the study. A hypophora is a question that speakers pose and then immediately answers themselves. Table 1 defines the question categories of Roach et al. (2010) and includes the additional category, hypophora, used in the coding of the observations. Table 2 illustrates the depth of the questions as defined by Roach et al. (2010).

Table 1: Question Categories

Category	Definition
Comprehension Check	To assess one or more students' declarative understanding of a topic, procedure or task (e.g., What should we do next?, Does that make sense?)
Content Check	Used to push the mathematical focus or direction of the students' attention (e.g., Should we try the chain rule?)
Elicit Student Thinking	To draw out what the students were thinking, including prompts for students to communicate their *what* they thought to other students or teacher (e.g., What do you first notice about this graph?)
Probe Student Thinking	Investigate reasoning behind or explanation for a given response or procedural work, including prompts to communicate *why* a person or group thought what they did (e.g., That's correct, but why?)
Hypophora	**A question that speakers pose and then immediately answer themselves (e.g., Why do we want to take the derivative? Because it is the rate.)**

Table 2: Relationships Among Categories and Depth of Questions

	Comprehension Check	Content Check	Elicit Thinking	Probe Thinking
Depth 0	Calls for memorization or recall			
Depth 1	Goal is procedural, without connection to concepts			
Depth 2	Purpose is connection between solution and reason/sense-making			
Depth 3	Target is "doing math": create, synthesize, make and justify conjectures			

Disha

At the time of the study, Disha was in her fifth semester of teaching (one class per semester). Disha was a doctoral student in mathematics. She grew up and went to school in India. She completed her undergraduate degree in mathematics from a major university in India. Disha saw the instructor's responsibility as presenting knowledge to students and the students' responsibility was taking that knowledge and making sense of it on their own.

In the semester of the study, Disha taught one section of Calculus for Biological Scientists with 30 students enrolled. Of these, 20 students (67%) regularly attended class meetings. Disha relied on lecture throughout the observed lessons. She indicated that she did not like group work because it seemed to her that inevitably "one person will end up doing all the work." She believed that students learn mathematics best by working individually.

Disha regularly spoke up in coordination meetings and stated in informal conversation with me, that she enjoyed coordination meetings. Her weekly logs indicated that she often used ideas from coordination with individual students, small groups of students, or in the classroom. Working with individual students, or small groups of students occurred during her office hours. She also indicated she felt that the ideas presented in coordination *sometimes* increased student confidence in mathematics, led to a deeper understanding of the mathematics, and helped increase student interest in mathematics.

Results

Disha's most common question was a "do you understand" type of question. Her next most common question type was hypophora. Across the four focus classes, Disha posed an average of 128 questions per 50-minute class period. Most of these (74%) were Comprehension Checks, the most common two questions being "Is that ok?" and "Do you understand what I am saying?"

Table 3 shows Disha relied primarily on Comprehension Check questions during the observed lessons. Disha asked few Content Check and Elicit Thinking questions and rarely asked Probe Thinking questions.

Table 3*: Disha's Question Category Percentage Per Class*

	Comprehension Check	Content Check	Elicit Thinking	Probe Thinking	Hypophora	Classroom Management
Obs A	67%	3%	5%	0%	25%	0%
Obs B	75%	0%	1%	0%	11%	12%
Obs C	76%	3%	7%	1%	12%	1%
Obs D	77%	6%	0%	0%	10%	5%
%Total[a]	74%	3%	4%	0%	14%	5%

[a] Due to rounding, rows may not add to exactly 100%.

However, the per-class distributions of these and other types of questions varied over time (see Figure1).

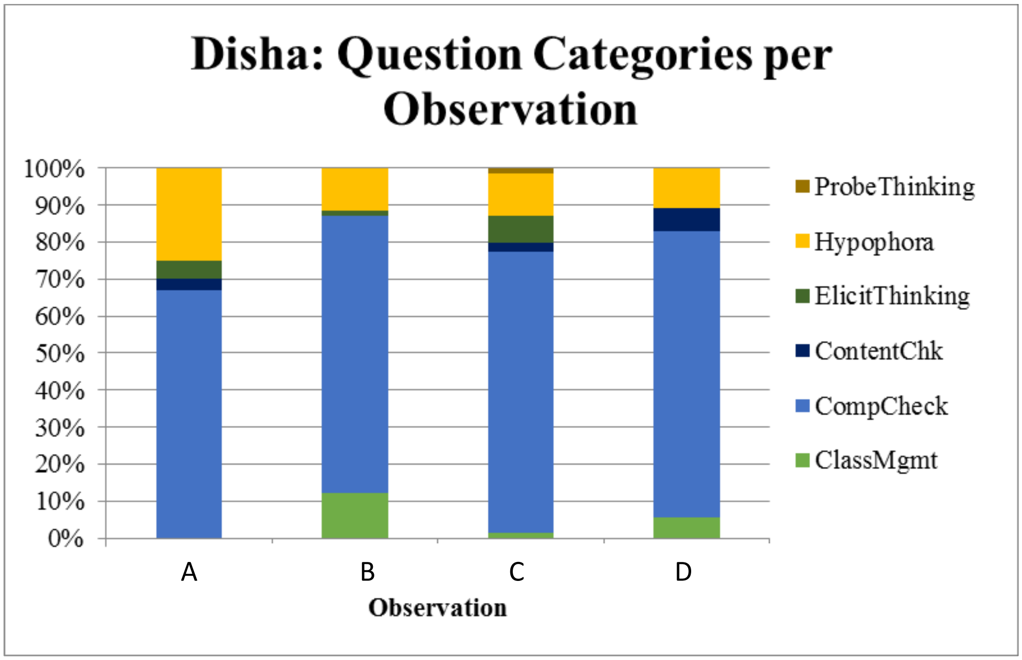

Figure 1. Relative frequencies of question codes in observations, for Disha.

During Observation C, Disha had the greatest number of Elicit Thinking questions such as, "What would you think differential equations are?" and she asked Probe Thinking questions such as "Why not?" after students responded "No" to "Will this represent the given situation?" A change in hypophora was notable across the study. In the first observation, she used the greatest number of hypophora (25% of questions). During subsequent observations, it was less likely for Disha to answer the questions she posed. Instead, she waited for students to answer. In at least one situation she asked a question and stepped away from the board and waited 30 seconds for students to respond. In Interview 3, I asked about her choice of which questions to use and why wait longer for answers on some. Disha said, "those were the questions I thought of when I [as a student] learned the material and I thought the students should think about those questions as well. I thought it would help them learn the material better." I did not gather information about how each of the instructors learned specific calculus concepts themselves. In this particular case, the questions Disha used were those she had when she was a student. I return to this, below, in discussion of what Disha valued as a "good" question.

Disha most frequently asked, "Does that make sense?" "Is that ok?" or "Do you see what I am trying to say?" The next most common questions were depth 1 Comprehension Checks and hypophoras. Below is an example of her use of hypophora, with the hypophora underlined:

> *Disha*: "<u>What do we have in stability criteria</u>? [no pause] We start with *dt*/*ds* ["dee tee dee ess"], ok. We start with *dt*/*ds*, I'm not going to do a bunch of examples here, ok. Now if *m* is the measurement, then this is how the *dt*/*ds* is represented by [pointing to "*f*(*m*)" written on the board]. Right? [no pause] then we will figure out equilibrium point. <u>Why</u>? [no pause] Because we are trying to find the stability of the equilibrium points."

This kind of reflective exchange was common for Disha during her first observation. It is important to note that Disha did not pause after asking a question and immediately continued with the answer to the question she posed. It is not clear that much cognitive demand is made of students during a chunk of hypophoric lecture. It appeared to have the same effect as a statement on the students. While it was unusual for students to attempt to answer these questions, I did observe at least one instance in which a female student attempted to answer a hypophoric question posed by Disha. Disha did not acknowledge the student in any visible way and continued with her own answer to the question.

After video case based coordination Disha began to wait after asking questions. During Observation C, Disha wrote the problem $\int 2xe^{x^2}dx$ on the board. She then asked the students what rules they had learned so far that might help with this problem. The students suggested the power rule and quickly realized that would not work because it was "weird looking." Disha continued with the following.

> *Disha*: So we cannot apply the power rule when we have the weird looking function over there. So what else can we apply? What else do we know?
> *Student*: Integral of e to the x is e to the x.
> *Disha*: [nodding] Integral of e to the x or antiderivative of e to the x is e to the x. [Looks around the room (4 seconds)] Right? (no pause) Can we make use of this rule over there? [pointing to the original problem. She waits four seconds then a student responds.]
> *Student*: No.
> *Disha*: No, Why not?
> *Student*: Because that's e to the x squared.
> *Disha*: [nodding] Because this is e to the x squared. Which function when differentiated would give me e to the x squared? [10 second pause while looking around the room] We don't know that do we? We can't make a guess out of that. Can we make a guess? [Students are quiet and then start to shake their heads no.]

After this exchange, Disha smiled and continued, reviewing all the rules for antiderivatives they had learned until this point in the semester. She pointed out that none of the current rules they had would work for this problem. She then stated, "How do we solve this? We are going to solve this with a slick trick." Then smiled, and began to discuss *u*-substitution.

This interaction was a noteworthy change for Disha. In the first observation, if Disha asked a "why" question, she would answer it herself. However in later observations, after video case based coordination, Disha waited after asking questions and the students would often respond verbally.

Discussion

The most notable change in Disha's questioning techniques was a change in her use of Hypophora, 25 (25%) in her first observation (before video case activities) and 12 (11%) in her final observation (after four video cases). Disha expressed during one of her interviews that she was impressed with the "wait time" of one of the instructors in the second video case shown during coordination (*Office Hours*). She related this "wait time" to "breaking things into smaller pieces" or scaffolding the information. After this case, Disha, declared her intention to give more time for students to answer questions. I also saw Disha giving the students more time to answer questions. In Observation A, if Disha asked a question that could be considered an Elicit Thinking or Probing question, she would immediately answer, making the question a Hypophora. However, after course coordination efforts, she gave time for students to answer questions. She stated in her final interview how impressed she was with the instructor observed in the *Office Hour* video case and that she used his methods of "breaking things into smaller pieces" and waiting for an answer, while working with students during office hours. At the same time, she rejected the idea that this video case changed her classroom teaching in any way.

Kung (2010) observed that one way TAs learned about student thinking was through interacting with students watching them work problems and listening to them discuss mathematical content, as one would during office hours. It is possible that Disha gained an understanding of student thinking while in office hours that translated to her classroom instruction. The influence of the video case may have been indirect: as a moderator of her perception of her own office hour experiences, which were in turn a moderator of her classroom practice. Disha also spent more time exploring incorrect answers with students and, in observations after video case activity began, asked questions of a greater depth. By exploring incorrect answers and asking deeper questions, it is likely that Disha was gaining further insight into student thinking (Ball, 1997; Carpenter & Fennema, 1992; Fennema et al., 1996).

Disha did not appear to be aware of an increase in wait time after asking questions during classroom instruction. One possibility is that Disha was creating "think time" not "wait time." She could have been leaving time after asking questions for the students to *think* about the question and organize their thoughts, not *waiting* for them to answer. It is possible that her intent was to answer the questions herself, but the students answered them while she was allowing time for them to think about the mathematics. If Disha was simply giving the students time to think about a question and not waiting for an answer, this could explain why Disha did not believe she had changed her teaching in any way. In a review of the literature, there did not seem to be any distinction between "wait time" and "think time." Further research could address the differences of "think time" versus "wait time" and student perceptions of these constructs.

Emerging from the qualitative analysis of Disha's questions was what Disha valued as a "good" question. She related "good" questions as questions that would have occurred to her. In one observation, after a student asked about why a certain *u* was chosen for a *u*-substitution, Disha responded with "That is a good question because that is a question that I would have thought of." In my second interview with Disha she said "I chose to ask those questions because those are the questions that I thought of when I was learning the topic." This data suggests that what Disha valued when asking and answering questions, were questions that aligned with her own way of thinking. Data was not gathered on types of questions the instructor were asked when they were students learning calculus. Future studies could examine the teaching styles of mathematics professors and how closely the professors' questioning techniques align with the instructors' questioning techniques.

Student perceptions of questions were not examined in this study. Future studies could examine the relationship of the types of questions instructors ask to the types of questions students ask--from the start of a semester until the end of the semester. Interviewing both the students and instructors about the questions asked could provide valuable feedback about student thinking and instructor response to student thinking. This would further build on Speer's (2001) work by investigating not only the instructor reason for asking questions, but also the students' reasons for asking, answering, and not answering questions as well as student thoughts about questions. Such a study would possibly include video-clip based student focus group interviews--where students watch and discuss a question-driven interaction--at least twice during a semester and a comparison of the students' perception of questions to the instructor's perception of questions. Learning more about how students think about questions could aid in identifying what types of questions can contribute to student learning. This, in turn, could shape the development of new video cases that focus on questioning.

Future studies could also compare the nature of student responses on a particular task to examine the correlation between instructional style and the nature of student understanding of a particular concept. This could be done for many concepts and one could compare the nature of student understanding from concept to concept. Such a study could inform researchers about instructional styles and how they many contribute to student learning.

Conclusion

Many questions remain. Are hypophora questions? Are hypophora useful to classroom instruction? Could hypophora be an important phase in teaching development for those who for whom English is a second language?

Hypophora seem to be an illustration of an internal thought process of the instructor. During one of the weekly coordination meetings, Disha stated "those are the questions [the students] should be thinking" when discussing questions asked by the instructors in the video case. Disha seemed to be talking about an internal dialogue that "should" be happening with students. However, while hypophora might be helpful to the instructor in organizing information, I do not believe that hypophora allow the students the time needed to process and organize thoughts. By offering the students time to think and process questions, they can construct meaning of the mathematics. More research is needed to examine the effect hypophora have on students and how it may or may not be helpful to students.

Students' Conceptions of Mappings in Abstract Algebra

Rachel Rupnow
Virginia Tech

In an effort to understand ways students approach constructing homomorphisms and isomorphisms between groups, six undergraduate math and engineering students in a lecture-based introductory abstract algebra course were interviewed. These students experienced varied success in creating isomorphisms and homomorphisms, which allowed both successful techniques for map creation and stumbling blocks to map creation to emerge from the data. Additionally, a genetic decomposition for homomorphism is outlined and students' mental constructions of both homomorphism and isomorphism are discussed. Finally, students' conceptual metaphors for homomorphic and isomorphic mappings are examined. Combining these three analyses paints a picture of the interaction between students' knowledge of properties of groups and mappings and their flexibility in creating mental images while interpreting those properties.

Key words: Abstract Algebra, Homomorphism, Isomorphism, APOS, Conceptual Metaphor

Purpose and Background

Experts have identified isomorphism and homomorphism as two of the most central topics to abstract algebra (Melhuish, 2015). Although some research has been done on how students approach isomorphism, including designing an inquiry-oriented curriculum that addresses isomorphism (Larsen, Johnson, & Bartlo, 2013), research explicitly on students' understanding of homomorphism has been scarce. Thus, a purpose of this study is to examine students' approaches to finding both isomorphisms and homomorphisms and what prevents students from finding appropriate mappings between groups.

A homomorphism between groups is defined as follows: "Let $(G,\star)$ and $(H,\boxdot)$ be groups. A map $\varphi\colon G \to H$ such that $\varphi(x \star y) = \varphi(x) \boxdot \varphi(y)$ for all $x, y \in G$ is called a homomorphism" (Dummit & Foote, 2004). Thus a homomorphism is a map that preserves the structure of the original group in the domain of the second group. It does not require the groups to have the same cardinality; group G may be larger or smaller than group H. There is always at least one homomorphism between groups; namely, the trivial homomorphism, in which every element of G is mapped to the identity in H. Further, an isomorphism between groups is defined as follows: "The map $\varphi\colon G \to H$ is called an isomorphism and G and H are said to be isomorphic or of the same isomorphism type, written $G \cong H$, if φ is a homomorphism, and φ is a bijection" (Dummit & Foote, 2004). Thus isomorphisms are a specific type of homomorphism in which the cardinalities of both groups are the same and all elements of the first group are mapped to distinct elements of the second group. For example, V, the Klein four-group, is isomorphic to $\mathbb{Z}_2 \times \mathbb{Z}_2$. However, $\mathbb{Z}_2 \times \mathbb{Z}_2$ is not isomorphic to $\mathbb{Z}_4$ because the homomorphism property is not satisfied by any bijective map. While homomorphisms are mappings that preserve the structure of groups, isomorphisms are mappings that verify the two groups are essentially the same.

Previous studies have examined isomorphism in different ways. Early studies mostly provided students with two Cayley tables or stated two groups and asked if they were isomorphic or how they could tell they were isomorphic. The Dubinsky, Dautermann, Leron, and Zazkis

(1994) study indicated that when students considered isomorphisms between groups, they considered the cardinality of each group, but not whether the homomorphism property was satisfied. Leron, Hazzan, and Zazkis (1995) also noted students' tendency to check the cardinality of a group, but their students continued to test multiple other properties by finding the identity element (in Cayley tables), the orders of individual elements (the smallest positive integer m such that a^m is the identity for each element a), the number of elements of given orders in each group, whether a group is generated by a single element, and if it is commutative. Despite the many factors to check, students would still struggle if more than one way to construct an isomorphism existed, demonstrating a "craving for canonical procedures" (p. 168).

Other studies have considered isomorphism in the context of proof. In related studies, Weber and Alcock (2004) and Weber (2002) asked undergraduate and doctoral students to prove a number of theorems related to isomorphism and to prove or disprove specific groups were isomorphic. While both doctoral and undergraduate students were able to prove the initial simple propositions, the doctoral students continued to be successful in proving the remaining five propositions, while collectively only two (of twenty) proofs of the remaining propositions given by undergraduates were successful. Much like in Dubinsky et al. (1994), these difficulties largely related to undergraduates' tendency to form arbitrary mappings once they had ascertained that a bijection between groups could be formed. They would not apply other properties of the groups when trying to find or disprove the existence of an isomorphism.

Recent studies on isomorphism have shifted the focus to how to develop local instructional theories that could be transformed into an inquiry-oriented curriculum that included topics such as isomorphism. In the process of examining how students used their existing ways of reasoning to engage with mathematically rich tasks, other student views of isomorphism have come to light. In 2009, Larsen recorded a teaching experiment in which participants were expected to generate a definition of isomorphism. In that study, participant Jessica noted that the definition of isomorphism should include bijection because "…it has to go both ways" (p. 133). Her statement brought to light another approach to isomorphism: reversible mapping. Later, Larsen et al. (2013) noted that the homomorphism property was more challenging for students to unpack than the bijection property. Additionally, Larsen (2013) noted, "students' use of the homomorphism property is usually largely or completely implicit" (p. 722). Thus a number of tasks in his curriculum engage students in forming an explicit homomorphism in order to help students formulate the definition of homomorphism and, later, isomorphism. These studies highlight that students attend to the properties of the two groups, but that generating mappings between the groups was either ignored or very difficult for students.

In these isomorphism studies, some research has been conducted on homomorphism in the process of researching isomorphism. However, a few studies have examined homomorphism more closely in the context of proof. Nardi (2000) noted students' struggles in proving the First Isomorphism Theorem for Groups stemmed from three major sources: an inability to recall definitions or a lack of understanding of definitions, poor conceptions of mapping (such as thinking a homomorphism was an element of a group), and not realizing specifically what each part of the proof was proving. Weber (2001) observed that despite undergraduates' ability to recall relevant theorems, they struggled to move past syntactic, "definition unpacking" techniques when trying to prove theorems related to isomorphism and homomorphism, such as proving a group was abelian given the map was a surjective (onto) homomorphism. He also noted doctoral students had a tendency to use conceptual knowledge to formulate proofs more strategically and experienced more success in proving.

Theoretical Perspectives

APOS Theory

Two different theoretical lenses are used for this study. The first is APOS theory, which decomposes students' thinking into Action, Process, Object, and Schema level conceptions (Arnon et al., 2014). An action is an external transformation of objects; a process is an interiorized action; an object is an encapsulated process; and a schema coordinates objects and processes (Asiala, et al., 1996). For example, one genetic decomposition for function says a student with an action conception of function needs to take specific elements from a set and apply a rule to obtain an explicit output to make sense of a function. When students are able to internalize this procedure so they recognize elements of the domain are manipulated through a rule to produce outputs, and they can run through this procedure mentally, they are said to have a process conception. Eventually, a student will encapsulate this process into a static entity, allowing them to perform operations on functions; at this point a student has an object conception of function. Finally, indicators that a student has developed a schema conception of function are that the student can recognize whether a relationship represents a function and can determine the domain and range of a function (Arnon et al., 2014).

Previously, Leron et al. (1995) created a genetic decomposition of isomorphism based on understanding groups, functions, and existential quantifiers. Specifically, a student with an action level conception of isomorphism would likely check that individual elements of two potentially isomorphic groups act in the same way by checking the orders of elements and the cardinalities of the groups. At the process level, when a student was able to apply quantification more broadly, he or she would need to check that the homomorphism property held under a mapping, allowing the elements of one group to be mapped to another. Finally, a student able to recognize that more than one mapping from one group to another might be possible, but that the existence of one such isomorphic map guaranteed the groups were isomorphic could be described as having an object conception of isomorphism. Although Leron et al.'s (1995) decomposition was based on constructing isomorphism in finite groups, students could also be asked to determine if infinite groups were isomorphic. In this context, I conjecture that students would also need at least a process level construction of infinity to be able to generate a correspondence between infinite sets of the same cardinality or to recognize two infinite sets had different cardinalities.

While Leron et al. (1995) created a decomposition of isomorphism over twenty years ago, no one has offered a decomposition of homomorphism. This may stem from differing concept images (Tall & Vinner, 1981) of isomorphism and homomorphism. While it can be easy to describe isomorphism in a "naïve" way as "two groups (and their operations) [that are] the same" (Dubinsky et al., 1994, p. 280), it is difficult to find a similar naïve way to describe homomorphism. In fact, Leron et al. (1995) note that this might be due to the "directional (rather than symmetrical) nature" of homomorphisms, which are essentially functions (p. 172). However, to an extent we can think of homomorphisms in terms of collapsibility.

Suppose f is a homomorphism from G to G'. Then the kernel of this homomorphism is a normal subgroup of G. (The kernel of a homomorphism is the elements that are mapped to the identity in G'.) We can think of a homomorphism as taking as its domain the elements of G and producing an image within G', potentially all of G'. Sometimes each element of G is mapped to a distinct element of G'. In this case, no "collapsing" seems to occur because the kernel of f is the identity of G. However, at other times, multiple elements of G are mapped to some of the elements of G'. In this case, a number of elements are "collapsed" to each element of the image because they act in a similar way in the related quotient group. (Note that not all elements of G' are necessarily elements of the image of f, and that each element of G can be mapped to at most one element of G' because homomorphisms are functions.)

Viewing homomorphisms as a collapsing relationship provides insights into a way in which the topic can be decomposed. Namely, constructing homomorphism at an object level requires constructing function as an object, because a homomorphism is a type of function. As part of this, a student would need an object conception of group to be able to determine if the domain and image of a mapping were in fact groups, as needed to be a homomorphism. Furthermore, students need to develop an object conception of coset in order to be able to determine which elements of the first group should collapse to each element in the image. In equivalence relation terms, students need to be able to determine that the elements within each coset of the kernel of the homomorphism act equivalently.

Alternatively, one may conceive of a homomorphism as a special type of function. We can further delineate this decomposition according to how students would behave at different levels of homomorphism construction. When a student has an action conception of homomorphism, they could likely be characterized by only checking the orders of elements and the cardinalities of the "domain" group and of the desired codomain group. If the orders matched, they would likely create a mapping directly. Alternatively, they might conclude no homomorphism can be formed if the orders of elements in the two groups do not match. This is because such students would be focused on what each element is doing and how each element is being mapped according to the function form they were using. Like in Arnon et al.'s (2014) decomposition of function, students would focus on what specific elements are doing. Based on their isomorphism training, they would likely struggle in situations where the kernel of the homomorphism was not the identity. Like in the context of isomorphism, when addressing infinite groups, students would also struggle if they had not constructed a process conception of infinity.

At a process conception of homomorphism, students would be more careful to check that the homomorphism property holds in a proposed mapping from one group to another. Like in Arnon et al.'s (2014) decomposition, they would be less focused on mapping each element and more focused on the set of elements that the elements of the first group would be mapped to in the second group. Additionally, they would likely check that the homomorphism property held for a number of pairings, though they may be satisfied they had produced a homomorphism before checking all pairs of elements in the first group.

At an object conception of homomorphism, a student would finally grasp the "naïve" meaning of homomorphism; that is, a student could recognize a pattern exists between the number of elements of the kernel and the number of elements mapped to each image element. Like in Arnon et al.'s (2014) decomposition, students would be able to perform operations on the mapping, including being able to form different homomorphisms by manipulating which normal subgroup formed the kernel. Therefore, students would be able to construct (without prompting) homomorphic mappings with non-trivial kernels, such as the trivial homomorphism (in which all elements of the first group, G, are mapped to the identity in the second group, meaning the kernel of the homomorphism is G). Previous work on cosets, normality, and quotient groups by Asiala, Dubinsky, Mathews, Morics, & Oktac (1997) highlighted students' difficulty in proving that the kernel of a homomorphism is a normal subgroup, noting that students commonly assumed that the kernel equaled the identity. As the focus of the question in their study was to look at students' conceptions of normality, they simply noted this was "an issue that has to do with the concept of homomorphism" and moved on (p. 268).

Conceptual Metaphor

The second theoretical lens is the conceptual metaphor construct (e.g. Lakoff & Núñez, 2000). The properties and metaphorical expressions students used when describing homomorphic and isomorphic mappings were examined based on the characterization of students' concept images in Zandieh, Ellis, and Rasmussen's (2016) study on students' explanations of function and linear transformations. When possible, students' expressions were categorized within the five metaphorical clusters of Input/Output (InOut), Traveling (Tr), Morphing (Morph), Mapping (Map), and Machine (Mach) that were found in the Zandieh, et al. (2016) paper. A sixth cluster, Matching (Match), that did not appear in their paper emerged here.

Statements that referred to properties of a map, such as being one-to-one or bijective, without unpacking the meaning of the property were classified as Properties and the property being referenced was noted. Students' metaphorical expressions were classified as Input/Output if they implied a "putting in" and "taking out" relationship or a one directional relationship. The Traveling cluster is characterized by elements "moving", "going to", or "getting to" a specific place or element. The Morphing cluster involved "transforming" or "changing" an entity through a map. The Mapping cluster involved having a "correspondence" between groups. Although students used the verb "map" frequently, their utterance was only included in this category if there was not a reference to Traveling, Morphing, or Matching at the same time. The utterance also needed to go beyond the definition of a map to be categorized as a metaphorical expression and not a property. The Machine cluster included references to an entity that caused a change from the beginning to ending state, often with words like "produces". The Matching cluster was especially used when students were describing isomorphisms. In this cluster, students would refer to a mapping as "preserving structure", "behaving" the same, or "matching" elements. This cluster is distinct from the Mapping cluster because the Matching cluster emphasizes a quality of "sameness" whereas the Mapping cluster simply links beginning and ending sets of elements.

By using these two perspectives as well as examining student work by general approach, I will provide a multifaceted analysis of student thinking and address three research questions. (1) What approaches did students take when asked to form isomorphisms and homomorphisms between groups? (2) How can we understand the student work using APOS theory? (3) What metaphors did students draw on when speaking about homomorphisms and isomorphisms?

Methods

The participants for this study were six sophomore or junior university students in a lecture-based introductory abstract algebra course. Four were mathematics majors and two were engineering majors considering double majoring in math or transferring into the math program. Students' college math backgrounds other than introductory calculus and a proof course varied but included courses in combinatorics, discrete math, vector geometry, linear algebra, multivariate calculus, differential equations, operational methods, and real analysis.

Students were recruited from two instructors' courses with one student coming from Instructor A's section (denoted participant A1) and five from Instructor B's section (denoted participants B1, B2, B3, B4, and B5). Instructor A had taught both group and ring isomorphisms and homomorphisms earlier in the semester and his students, including A1, had been tested on that material. Instructor B had just begun teaching about group homomorphisms and isomorphisms when his students were interviewed. Four of his students were interviewed after learning about isomorphisms but before learning about homomorphisms in class (B1-B4), and one student was interviewed after learning about both isomorphisms and homomorphisms (B5).

Participants were recruited in two ways. The author asked for an announcement to be sent to Instructor A's students with interested students sending the author a message. In Instructor B's section, the author visited the class and asked interested students to provide their email address in order to be contacted. Students were given their preference of $10 or an hour of tutoring to try to incentivize students with a range of abilities to participate.

1. What is a homomorphism?
2. How do you determine if [a map or whatever used above] is a homomorphism?
3. What is an example of a homomorphism?
4. What is an isomorphism?
5. How do you determine if [a map or whatever used above] is an isomorphism?
6. What is an example of an isomorphism?
7. Is the homomorphism example you gave also an isomorphism?
8. Is the isomorphism example you gave also a homomorphism?
9. Interpret the following definitions of homomorphism and isomorphism.
   Definition: Let $(G,\star)$ and $(H,\boxdot)$ be groups. A map $\varphi\colon G \to H$ such that $\varphi\colon (x \star y) = \varphi(x) \boxdot \varphi(y)$ for all $x, y \in G$ is called a homomorphism.
   Definition: The map $\varphi\colon G \to H$ is called an isomorphism and G and H are said to be isomorphic or of the same isomorphism type, written $G \cong H$, if
   φ is a homomorphism, and φ is a bijection.

For each of the following pairs of groups in 10-17, is it possible to form an isomorphism between them? Why or why not? Is it possible to form a homomorphism between them? Why or why not?

Figure 1. Interview protocol for semi-structured interviews.

Each participant engaged in a semi-structured interview (Fylan, 2005) lasting approximately one hour. The interview questions were drawn from those in Figure 1, but time and students' backgrounds prevented some students from seeing certain questions. However, all students answered questions 6, 10, 11, and 13. A listing of all questions answered by each student is given in Table 1. The interviews were all audio-recorded and five of the six were video-recorded. Participants' written work was also collected. To analyze the data, the interviews were coded in multiple iterations. First, participants' interviews were transcribed and open coded for students' problem solving strategies regarding isomorphism and homomorphism. This coding generated themes, which were verified by utilizing multiple iterations of coding (Anfara, Brown, & Mangione, 2002). In this cyclic process, each task given to a student was analyzed for the problem solving strategy used. As new strategies emerged in later transcripts, early interviews were reviewed, making sure that strategies identified later in coding had not been overlooked in early interviews. After the open coding and theme generation were completed, the transcripts were reviewed again for classification according to APOS theory and for students' use of conceptual metaphors. The APOS decomposition of homomorphism was created based on previous literature and the previous analysis of problem solving strategies. The conceptual metaphor construct was used to gain insight into students' concept images of mappings.

Table 1
Questions Answered by Each Student

Student	Questions Answered
A1	1,2,3,4,5,6,7,8,10,11,12,13,14,15,16,17,18,19,20
B1	3,6,7,9,10,11,12,13,14,15,16,17,18,19,20
B2	4,5,6,9,10,11,13,14,15,16,17
B3	4,5,6,9,10,11,13
B4	4,6,9,10,11,12,13
B5	1,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18

Results

Because this study is viewed from multiple lenses, we begin with general problem solving approaches for isomorphisms and homomorphisms as well as stumbling blocks to finding maps. This is followed by students' classification using the genetic decompositions for isomorphism and homomorphism. Finally, students' use of conceptual metaphors is explored.

Problem Solving Approaches

Participants' approaches to mappings fell into three major categories: successful methods of determining that a map was an isomorphism or whether such a map could be generated between groups; successful methods of determining that a map was a homomorphism or whether such a map could be generated between groups; and stumbling blocks to success.

Isomorphisms. Students exhibited a variety of successful strategies when trying to determine whether two groups were isomorphic or whether a given map could be an isomorphism. Because a one-to-one and onto mapping must exist for a bijection to exist, groups must have the same cardinality to be isomorphic. Thus, one strategy students used was to check whether the groups were the same size. Four of the participants (A1, B2, B3, and B5) utilized this strategy at some point with three of them checking this characteristic first when faced with any of problems 11-17. For example, in response to the isomorphism part of question 11 ($\mathbb{Z}_5 \to 5\mathbb{Z}$), B2 answered, "I don't think, um, I can form isomorphism between them because, um, I don't think it is bijective, um, because I think this group [points to $5\mathbb{Z}$] is larger than this one [points to $\mathbb{Z}_5$]."

Another successful strategy was to look for a reversible map between given groups or to note that a previously stated map was reversible. A1, B1, and B2 all utilized this strategy, with B1 using this as her main approach. For example, consider this exchange when asked question 16.

B1: I believe so. Like, to get from $\mathbb{Z}$ to $2\mathbb{Z}$, you just multiply by 2. To get from $2\mathbb{Z}$ to $\mathbb{Z}$, you just divide by 2.

I: You said $\mathbb{Z}$ to $2\mathbb{Z}$, multiply by 2. Is that an isomorphism? Homomorphism?

B1: Well that in itself is, that's only a one way mapping. Its inverse also exists so paired together, isomorphism, I'd say.

When pressed on details of the "inverse" map, namely explaining why it was acceptable even though division was not the operation defined for $\mathbb{Z}$ and ½ was not an element of $\mathbb{Z}$, she said it did not matter because "1 isn't in $2\mathbb{Z}$. There is nothing that will get you to a non-integer. If it's written as 2 times something, dividing by 2 just gets rid of that." She realized that the maps she had defined would map to and from the same elements. In reference to the same problem, A1 noted $2\mathbb{Z}$ to $\mathbb{Z}$ was "the same one. Since they were isomorphic before, it works the other way." He realized that when an isomorphism exists, the mapping between the groups can be inverted so each group is the domain of an isomorphic mapping to the other.

B2 and B4 considered another potential strategy for determining whether groups were isomorphic: creating a Cayley table for each group. Additionally, B2 recognized this was only a feasible option for small groups. In question 5, when asked how to determine if a group was an isomorphism, he said he would like to make a Cayley table if possible, but if the group was too big, it would be challenging: "a Cayley table will be 16x16 and I cannot make it, but, you know, 4x4, that would be fine, so kind of [a] small example." In the reverse situation, when presented with the Cayley tables in question 10, A1 and B1 also compared the orders of elements or mapped the identities of each group to each other without being prompted to do so.

Homomorphisms. The most straightforward argument given for determining whether a mapping was a homomorphism stemmed from determining it was an isomorphism. Because all isomorphisms are homomorphisms, if a student determined an isomorphism could be formed between groups, a homomorphism could automatically be formed too. A1, B1, and B5 clearly recognized this property, making statements similar to what A1 said: "It's part of the definition to be isomorphic: you have to have homomorphism in there." The other three participants may have also recognized this concept based on their explanations of the definitions of isomorphism and homomorphism, but they never directly used this concept to answer other questions.

Closure (associated with cardinality arguments) was a property students used to check whether a map they proposed could be a homomorphism. This idea was especially used to rule out maps they had created in response to questions 11 and 13. Five of the students successfully used this strategy, with B4 making a typical response as shown in Figure 2. She used her work with Cayley tables that would not close (on the mid-right and bottom right of Figure 2) to conclude she could not map all elements in $\mathbb{Z}_5$ (pictured on the mid-left) to distinct elements in $5\mathbb{Z}$ and have a closed group result. From this, she concluded she could not create an isomorphism or homomorphism. Although her conclusion that she could not form an isomorphism was valid, her conclusion that there was no possible homomorphism was flawed because the trivial homomorphism, $\theta\colon \mathbb{Z}_5 \to 5\mathbb{Z}$ such that $\theta(x) = 0 \ \forall\ x \in \mathbb{Z}_5$, would be possible. In fact, only A1 recognized the trivial homomorphism would be a homomorphism without being prompted to consider it. He and other participants who successfully generated homomorphisms appeared to notice patterns in the orders of the groups, which allowed maps to be generated quickly. For example, when looking for a map from $\mathbb{Z}_3$ to $\mathbb{Z}_6$, B1 noticed the 0's should correspond and that $\{0,2,4\}$ acted just like $\mathbb{Z}_3$. Similarly, B2, who had found a homomorphism from $\mathbb{Z}_6 \to \mathbb{Z}_3$ before being asked about $\mathbb{Z}_5$ and $\mathbb{Z}_6$, noted a non-trivial homomorphism could not be created between them because "3 divides 6 right? So, like, it should have something important about mapping…."

Although most students attempted to use one of the strategies above first, they eventually resorted to trial and error to look for homomorphisms. Some students used pure trial and error techniques, such as B5, who attempted to map elements of $\mathbb{Z}_6$ to $\mathbb{Z}_3$ in seemingly random order

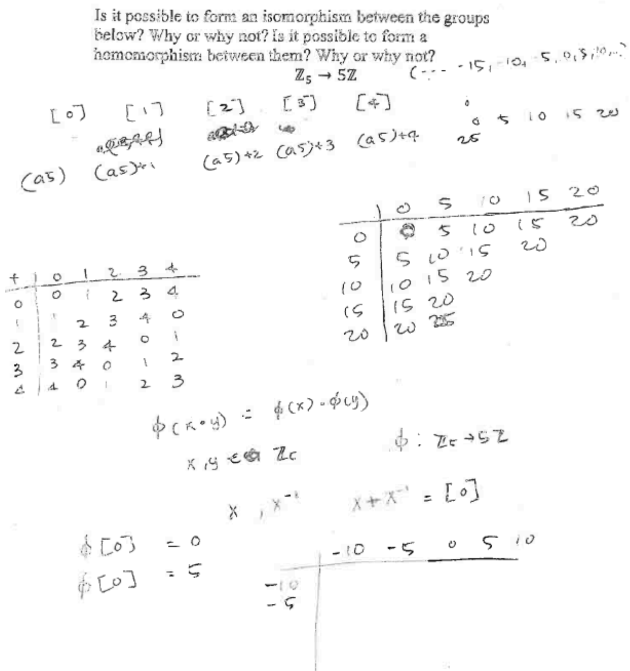

Figure 2. Work sample from B4 examining possible maps between $\mathbb{Z}_5$ and $5\mathbb{Z}$.

and then check if the homomorphism property was satisfied (i.e. mapping $\{0,3,4\} \rightarrow 0, \{1,2\} \rightarrow 1, \{5\} \rightarrow 2$). Both he and B3, users of this "random" approach, said they thought these problems were "trick questions" because there was no obvious technique to use. Participants who had more success finding suitable maps and ruling out incorrect maps tended to use knowledge of the orders of the groups to narrow possible choices, such as in B1's comparison of $\{0,2,4\}$ to $\mathbb{Z}_3$.

Stumbling blocks. A number of participants struggled to recall and utilize definitions effectively. Although most students defined an isomorphism as a bijective mapping or one-to-one and onto mapping that had the property $\phi(a * b) = \phi(a)\phi(b)$, some students struggled to unpack what "one-to-one" or "onto" meant. For example when B3 was asked what one-to-one meant, she first attempted to give the formal definition but could not recall it. When asked just to state what she thought about one-to-one and onto, she replied that in a one-to-one mapping "one [element] maps to one [element]" as she drew a set diagram illustrating a mapping. However, she still could not explain what onto meant, even in the context of her diagram. When asked to interpret the definition of homomorphism given in question 9, B2 claimed, "It should be abelian….Because you can switch these two, x and y, and then it just, isn't it automatically saying if you say yx, it'll just be y and x?" Additionally, students B2 and B5 attempted to map elements to multiple locations, thus violating the implicit function relationship in the definitions.

Although all participants tried to use formal definitions at times, some struggled to interpret them. Consider the following exchange after B4 was asked to give the definition of isomorphism.

B4: I don't even know if this is right. [Writes $(a \circ b) = a \circ b$.] I don't know what the circles are, but it's when it's preserved under the same something—I know it but I can't tell you.

I: Ok, well I feel like you're trying to give me the formal definition….Do you have just an intuitive sense of what it is?

B4: It's when two things are multiplied or something under a…say the mapping is α, if you do map of $a \cdot b$ is equal to map of $\alpha(a) \cdot \alpha(b)$ under, yeah, and it's onto and one-to-one, I think.

I: Ok. So you've given me a nice definition. Do you have any sense of, like in practical terms, what that might look like?

B4: No.

I: Ok, so if I asked you for an example you would say…

B4: Would probably give it to you in math terms. I don't know a real example. Yeah.

Some students also struggled to distinguish between the roles and the names of elements. This issue especially arose with the Cayley tables in question 10, when students often assumed they had to map element a to element a because it was the same letter rather than determining the identity of each group or using other techniques. This tendency to map elements with the same name to each other appeared in later problems too. For example, in question 13, every participant first tried to map $0 \to 0, \dots, 4 \to 4$, and all but A1 and B5 concluded that there could not be any homomorphism between the groups because the map matching similarly named elements did not work. Even when presented with the trivial homomorphism as a possible solution to question 13, B3 struggled to accept the mapping because she did not know what to do with the other elements in $\mathbb{Z}_6$ (i.e., 3+4=2 is mapped to 0, but $3+4 = 1$ in $\mathbb{Z}_6$ "isn't going anywhere").

Even when students identified the roles of elements in different groups, they did not always know how to create a mapping from this information. For instance, B2, who in response to question 5 had stated that creating Cayley tables could be useful in determining if an isomorphism existed between groups, struggled when presented with the tables of question 10. He successfully located the identity element of each group, but he was unsure what to do with this information until being prompted to consider mapping the identity elements to each other.

APOS Classification

In this section, a picture of each student is given through the lens of action-object theory. Students' perceived mental constructions are listed based on their problem solving approaches.

A1 was the strongest student in this study. Of all of the questions posed to him, he only struggled with determining if a homomorphism was possible on the Cayley table problem. Later, he observed that the trivial homomorphism is always a possible mapping between groups. He made use of the cardinalities of groups and the orders of elements, but also attended to whether the homomorphism property was satisfied while mapping. Furthermore, he had no problems with mapping from finite to countably infinite groups or between countably infinite groups. He was never explicitly asked to look for multiple isomorphisms, so it is difficult to tell whether he had constructed object level conceptions of isomorphism. However, he possessed at least process level conceptions of isomorphism, including for groups of infinite order. Because he eventually constructed mappings with non-trivial kernels, including both the trivial homomorphism and a homomorphism from $\mathbb{Z}_6 \to \mathbb{Z}_3$, he may have object level conceptions of homomorphism.

B1 was another strong student. She was comfortable working with countably infinite groups. She took the orders of groups into consideration when mapping, though she mostly based her isomorphism arguments on reversible or, as she said, "invertible" mappings. She generally would check the homomorphism property was satisfied whenever generating isomorphisms or homomorphisms, which allowed her to catch her own errors when her maps did not work. She was not asked to look for multiple isomorphisms, so it is only possible to say that she possessed at least a process conception of isomorphism. She possessed no greater than a process conception of homomorphism because she was unable to generate maps with non-trivial kernels. Although she quickly verified that the trivial homomorphism was a homomorphism when it was suggested, she did not create other non-trivial mappings, even in the $\mathbb{Z}_6 \to \mathbb{Z}_3$ problem.

B5 checked multiple elements worked before concluding his mappings were isomorphisms or homomorphisms. However, he would not check all elements and would not always happen to check the cases that failed, so he would claim a map satisfied the homomorphism property when it did not. He also was not always able to check the orders of elements; specifically, he believed that the order of each element was found by multiplying each element of a row by the identity element, thereby deciding that elements of orders 1,2,3, and 4 appeared in one of the Cayley tables. He was able to work with infinite groups without difficulty, however. Putting everything together, he had at best process level conceptions of isomorphism and homomorphism.

B4 did not make direct statements about the cardinalities of groups or elements in the context of isomorphism or homomorphism. However, she indirectly used cardinality by looking at the definition of one-to-one or by observing that the homomorphism property could not be satisfied when mapping similarly named elements to each other in groups of relatively prime order ($\mathbb{Z}_5 \rightarrow \mathbb{Z}_6$). She was always very attentive to definitions, though she did confuse the definitions of one-to-one and function. Because of her attention to definitions, she did not conclude isomorphisms and homomorphisms existed when they should not have. However, she struggled to get an intuitive sense of isomorphism and homomorphism, leading her to work very slowly. Because she was able to indirectly check cardinality and check the homomorphism property, she might have been at a process level; however, without more examples with equipotent groups that could not map easily based on the homomorphism property, it is difficult to tell if she possessed action or process conceptions of isomorphism and homomorphism. She never addressed any questions that addressed her conceptions of correspondences between infinite sets.

B2 was able to address problems when shown an issue and did recognize that he should attend to the identities of groups when mapping, but he struggled to know what to do with this information. At times, he checked the homomorphism property, but he placed more emphasis on using all of the elements of both groups, which led him to create maps that were not functions from $\mathbb{Z}_3 \rightarrow \mathbb{Z}_6$ and $\mathbb{Z} \rightarrow 2\mathbb{Z}$. Additionally, he had not taken analysis yet and struggled when asked if an isomorphism between $\mathbb{Z}$ and $2\mathbb{Z}$ could exist, as he assumed that $\mathbb{Z}$ was "larger" than $2\mathbb{Z}$. Overall, he appears to be at the action level for both homomorphism and isomorphism.

B3 struggled the most in this study. She occasionally checked the orders of elements and began to check the cardinalities of groups after she was given an interpretation of "one-to-one and onto". However, she struggled to recall and interpret definitions on her own and sometimes mapped elements at random. When looking for a homomorphism from $\mathbb{Z}_5 \rightarrow 5\mathbb{Z}$ she said, "I'm just mapping. I'm just picking" rather than checking whether her map would satisfy the property. At most, she displayed action conceptions of isomorphism and homomorphism.

Conceptual Metaphor

Students utilized a number of different metaphors and properties while defining and describing homomorphisms and isomorphisms. While all six metaphorical clusters were used by at least one person, the Mapping, Matching, and Traveling metaphors were used more commonly than the Machine, Input/Output, and Morphing clusters, both in terms of the number of participants using the clusters and the number of times each participant used the cluster. The metaphors and properties used by each student are given in Table 2 by map. Typical examples of each metaphor cluster are provided in Table 3. In addition to using metaphors, students also relied on certain properties that they either chose not to explain while using them or never explained in the interview. The properties used during explanations are also listed in Table 3.

The most successful solvers, those at the process level and above for homomorphism and isomorphism according to APOS theory, typically used Traveling metaphors. The exception was

B3, who also made use of Traveling metaphors a few times near the end of the interview. However, the interviewer made use of Traveling metaphors in some earlier explanations, so she may have simply adopted the interviewer's way of speaking. In addition, successful solvers typically integrated imagery and properties. A1, who had the most experience working with homomorphisms and isomorphisms, utilized three different metaphors while also making use of properties he had learned. The only time he struggled was when he failed to attend to properties and relied only on a Matching metaphor. Conversely, B4 struggled, especially early, when she focused almost exclusively on definitions and properties without interpretation as shown above.

Table 2
Students' Properties and Metaphorical Clusters by Mapping

Student	Homomorphism	Isomorphism
A1	C_{Map}, C_{Match}, C_{Tr}	C_{Map}, C_{Match}, C_{Tr}, P_{Gp}, $P_{1\text{-}1}$, P_{Onto}, P_{Hom}, P_{Card}
B1	C_{Map}, C_{Match}, C_{Tr}, C_{InOut}, P_{Image}	C_{Map}, C_{Match}, C_{Tr}, C_{Morph}, P_{Card}, P_{Bij}
B2	C_{InOut}, C_{Match}	$P_{1\text{-}1}$, P_{Onto}, P_{Bij}, P_{Gp}, C_{Match}, C_{Mach}
B3	C_{Map}, C_{Tr}	$P_{1\text{-}1}$, P_{Onto}, P_{Bij}, P_{Hom}, P_{Gp}, C_{Match}
B4	C_{InOut}, C_{Map}	C_{Match}, P_{Gp}, $P_{1\text{-}1}$, P_{Onto}
B5	C_{Match}, C_{Tr}	C_{Match}, $P_{1\text{-}1}$, P_{Onto}, P_{Gp}, P_{Card}, C_{Tr}

Table 3
Examples of Statements in Each Metaphorical Cluster

Name	Illustrative Example
Input/Output (InOut)	B4: "You have an equation or anything and *plug in* the value x, it would *output*, er, that *output* would be $\phi(x)$ so you *plug in* x in the group G into an equation or something of ϕ."
Traveling (Tr)	B3: "3 *goes to* 3 here, but $1 + 2 = 3$ won't *go anywhere*."
Morphing (Morph)	B1: "Say you try to add these two elements [in $\mathbb{Z}_5$]. You will get this one. Say you try to *transform* them in some way. You would have to do it $4 \to 5$, $1 \to 1$ or something else like that where you just plain don't get that when you add them [in $\mathbb{Z}_6$]."
Mapping (Map)	A1: "I don't know *what they map to* is the issue."
Machine (Mach)	B2: "I think my problem is I don't know *how this map goes* if I choose these two numbers."
Matching (Match)	B5: "The identities should be mapped *onto each other*."
Properties	One-to-one (1-1), Onto, Bijection (Bij), Homomorphism (Hom), Group (Gp), Cardinality/Order (Card), Image

B1 was striking in the variety of metaphors used. She utilized metaphors from five of the six clusters and was able to address most of the problems she was given effectively. Despite being unable to state the definition of homomorphism or isomorphism at the beginning of the study, when given the definitions, she immediately interpreted them using Mapping metaphors: "If you have any two elements, if you compose them before mapping, you get the same thing as if you compose…what their maps are for all of those elements. And here [in the isomorphism definition] it's basically that, plus you can do it backwards."

Additionally, while everyone used a Matching metaphor at some point, this image was not always helpful; in fact, it appeared to hinder some students' development. B3 was very focused on superficial sameness as she looked at Cayley tables, saying that if the groups in the Cayley tables were isomorphic, both tables would be the same; that is both should say "d,c,b,a" in the bottom row. While isomorphic groups could be relabeled in such a way as to make this happen, observing two Cayley tables of groups do not look identical is insufficient to conclude that the groups are not isomorphic. Even A1, who used the phrase "preserves structure" repeatedly and was able to address all isomorphism questions successfully, was sometimes hampered in his homomorphism efforts by trying to maintain the Matching metaphor for homomorphisms. His main problem occurred when trying to determine if a homomorphism could be established between the groups represented by the Cayley tables. Although he rapidly ascertained that no isomorphism could be formed between the groups in the Cayley tables, he confused himself by trying to continue his metaphor of "preserving structure" in the context of homomorphism. This led him to go back and forth between saying a homomorphism should not preserve the structure because that was what isomorphisms did, to saying the groups should "behave the same way" under a homomorphism. (When answering this question, he had not yet recalled that the trivial homomorphism could always be formed between groups.) He was so focused on his metaphor that he did not go back to his definition of isomorphism, in which he said that an isomorphism is a "homomorphism plus it's one-to-one and onto".

Discussion

From the problem solving approach analysis, we can see that students were more comfortable working with the bijective property than the homomorphism property, much like in Larsen et al. (2013). This seems plausible given that because the cardinality of a group can be determined rapidly, determining if a bijection exists between two groups is most likely not as difficult as determining if the homomorphism property holds for all pairs of elements of a group. Although the homomorphism property allows specific maps to be tested quickly, students had to rely on trial and error (albeit strategic trial and error) to create reasonable maps to be tested.

Additionally, students with limited concept images (Tall & Vinner, 1981) of one-to-one, onto, function, and homomorphism were at a disadvantage when creating homomorphisms and isomorphisms. Students A1 and B1, who had the most robust mental constructions of isomorphism and homomorphism, both utilized the concept of a mapping being reversible if it is an isomorphism and demonstrated the ability to use strategic trial and error to find homomorphisms quickly. These traits indicated a robust concept image of maps, much as the successful doctoral students utilized their knowledge of theorems strategically to write proofs (Weber, 2001). Like other studies, students considered the cardinalities of the groups to determine if they could be isomorphic (Dubinsky, et al., 1994; Leron, et al., 1995; Weber & Alcock, 2004; Weber, 2002). Despite literature indicating that comparing orders of elements of groups when trying to determine if a map is an isomorphism was a common technique (Leron, et al., 1995), only two participants utilized the technique in this study; however, this may be due to the limited number of questions in which both groups were finite and had the same cardinality.

From the APOS analysis, it is reasonable that students struggled more when asked to find homomorphisms from one group to another than when asked to determine whether groups were isomorphic because students need to coordinate an extra construction, namely determining the image of the homomorphism. In this study, students struggled far more when they could not map elements in the first group to distinct elements in the second group. Additionally, the "naïve" image of homomorphism is not as intuitive as the "sameness" associated with isomorphism. Because this image of homomorphism is tied to quotient groups, with which students famously struggle (Dubinsky, Dauterman, Leron, & Zazkis, 1997), students should not be expected to reach an object understanding of homomorphism until after quotient groups have been taught.

From the conceptual metaphor analysis, we see that collectively students used a variety of metaphors to describe mappings, though the most common type of metaphor was Matching. While one of the most successful solvers, B1, used a wide variety of metaphors, a better indicator of success was integrating properties with metaphors. Students who relied too heavily on properties at the expense of imagery struggled to move past computations and what they had memorized. Students who relied too heavily on word pictures at the expense of definitions could impute too many properties to their mapping (like B3 with the "same" Cayley tables) or could highlight the wrong properties (like A1 saying only isomorphisms "preserve structure").

By combining analyses, we are able to gain a characterization of what successful and struggling students might look like in abstract algebra. Successful students were able to utilize properties and definitions fluidly while also being able to characterize what was happening in a more intuitive way. By using their varied images and properties strategically, they were able to approach more problems with success (Weber, 2001). Students with limited ways of picturing mappings, who were tied to definitions and property statements, were still struggling to understand how each element would be mapped and were not in a position to create mental images of what all elements would do or how isomorphisms or homomorphisms should behave.

Future studies could use students more experienced with homomorphism and isomorphism to refine the genetic decomposition of homomorphism. Additionally, more questions with isomorphic groups should be explored to see if students utilize techniques like considering the orders of elements and creating reversible maps when faced with more groups of the same cardinality. Because of the dearth of studies on homomorphism, it would be illuminating to conduct teaching experiments examining how to enhance students' concept images of these mappings both by developing metaphorical descriptions and by grounding statements in formal properties. This might help students consider mapping elements that look different to one another despite elements of similar appearance being present in the other group (e.g., map $1 \to 2$ instead of $1 \to 1$ when generating a homomorphism from $\mathbb{Z}_3 \to \mathbb{Z}_6$). This study continues the work done by Zandieh et al. (2017) in examining students' conceptions of function in linear algebra by looking at students' conceptions in abstract algebra. Future studies could compare and contrast how students create and use mappings in other content areas, such as graph theory or analysis, generating insights into the role of mappings throughout mathematics.

Emerging Insights from the Evolving Framework of Structural Abstraction

Thorsten Scheiner
University of Hamburg, Germany

Márcia M. F. Pinto
Federal University of Rio de Janeiro, Brazil

Only recently 'abstraction from objects' has attracted attention in the literature as a form of abstraction that has the potential to take account of the complexity of students' knowing and learning processes compatible with their strategy of giving meaning. This paper draws attention to several emerging insights from the evolving framework of structural abstraction in students' knowing and learning of the limit concept of a sequence. Particular ideas are accentuated that we need to understand from a theoretical point of view since they reveal a new way of understanding knowing and learning advanced mathematical concepts.

Keywords: Limit Concept; Mathematical Cognition; Sense-Making; Structural Abstraction

Introduction

Theoretical and empirical research shows the existence of differences in knowing and learning concerning different kinds of knowledge (diSessa, 2002). A general framework on abstraction cannot encompass the whole complexity of knowing and learning processes in mathematics. Rather, in investigating the nature, form, and emergence of knowledge pieces, various local learning theories may be developed, which will be quite specific to particular mathematical concepts, individuals, and their respective sense-making strategies. As a consequence, the complexity of knowing and learning processes in mathematics cannot be described or explained by only one framework. Instead, we acknowledge that comprehensive understanding of cognition and learning in mathematics draws on a variety of theoretical frameworks on abstraction.

The literature demonstrates significant theoretical and empirical advancement in understanding 'abstraction-from-actions' approaches, particularly the cognitive processes of forming a (structural) concept from an (operational) process (Dubinsky, 1991; Gray & Tall, 1994; Sfard, 1991). Abstraction-from-actions approaches take account of a certain sense-making strategy, namely what Pinto (1998) described as 'extracting meaning'. However, only recently 'abstraction from objects' has attracted attention as a form of abstraction that provides a new way of seeing the complexity of knowing and learning processes compatible with students' strategy of what Pinto (1998) described as 'giving meaning'.

The purpose of this paper is to provide deeper meaning to a recently evolving framework of a particular kind of 'abstraction from objects': structural abstraction. The structural abstraction framework is evolving in the sense that the framework functions both as a tool for research and as an object of research (Scheiner & Pinto, 2016b). In more detail, we use the structural abstraction framework retrospectively as a lens through which we reinterpret a set of findings on students' knowing and learning of the limit concept of a sequence. This reinterpretation is an active one in the sense that the framework serves as a tool to analyze a set of data, while the framework is also refined and extended since the reinterpretation produces deeper insights about the framework itself. Especially, these more profound insights are what we need to understand from a theoretical point of view since they have relevance for significant issues in knowing and learning advanced mathematical concepts. Such a dynamic view that is aligned with an interpretative approach seems to be promising in responding to questions that evolve while the object of consideration is still under investigation.

We begin by providing an upshot of our synthesis of the literature on abstraction in knowing and learning mathematics. Our synthesis is to suggest an orientation toward the evolving framework of structural abstraction as an avenue to take account of an important area for consideration – that is, drawing attention to the complex knowing and learning processes compatible with students' 'giving meaning' strategy. The structural abstraction framework constitutes the foundation of the second part of the paper providing emerging insights in knowing and learning the limit concept of a sequence. These insights offer theoretical advancement of the framework and deepen our understanding of knowing and learning advanced mathematics.

Mapping the Terrain of Research on Abstraction in Mathematics Education

Abstraction seems to have gained a bad reputation after been questioned by the situated cognition (or situated learning) paradigm, and, as a consequence, has almost disappeared from recent research discourse. This criticism rests primarily on traditional approaches on knowledge transfer through abstraction that led to an understanding of abstraction as a process of decontextualization and a confusion of abstraction with generalization. The recent contribution by Fuchs et al. (2003) shows that such classical approaches to abstraction still exist:

> "To abstract a principle is to identify a generic quality or pattern across instances of the principle. In formulating an abstraction, an individual deletes details across exemplars, which are irrelevant to the abstract category […]. These abstractions […] avoid contextual specificity so they can be applied to other instances or across situations." (p. 294)

Though various images of abstraction in the mathematics education literature can be identified (see Scheiner & Pinto, 2016a), several scholars argued against the image of abstraction as decontextualization. Van Oers (1998, 2001), for instance, argued that removing context must impoverish a concept rather than enrich it. Several other scholars have reconsidered and advanced our understanding of abstraction in ways that account for the situated nature of knowing and learning in mathematics. Noss and Hoyles (1996) introduced the notion of *situated abstraction* to describe "how learners construct mathematical ideas by drawing on the webbing of a particular setting which, in turn, shapes the way the ideas are expressed" (p. 122). Webbing in this sense means "the presence of a structure that learners can draw up and reconstruct for support – in ways that they can choose as appropriate for their struggle to construct meaning for some mathematics (Noss & Hoyles, 1996, p. 108). Hershkowitz, Schwarz, and Dreyfus (2001) introduced the notion of *abstraction in context* that they presented as "an activity of vertically reorganizing previously constructed mathematics into new mathematical structure" (p. 202). They identify abstraction in context with what Treffers (1987) described as 'vertical mathematization' and propose entire mathematical activity as the unity of analysis. These contributions demonstrate that research on abstraction in knowing and learning mathematics has made significant progress in taking account of the context-sensitivity of knowledge.

Several other contributions shape the territory in mathematics education research on abstraction. Mitchelmore and White (2004) indicate a distinction between abstraction in mathematics and abstraction in mathematics learning. They proposed to include a new meaning in the later, which seemed to be missing in the debate on the notion of abstraction, related to "formation of concepts by empirical abstraction from physical and social experience" (p. 329). Articulated to this understanding, Scheiner (2016) proposed a distinction between two forms of abstraction, namely *abstraction from actions* and *abstraction from objects*. This distinction has been further refined in Scheiner and Pinto (2014) arguing that the focus of attention of each form of abstraction takes place on physical objects (referring to the real world) or mental objects (referring to the thought world) (see Fig. 1).

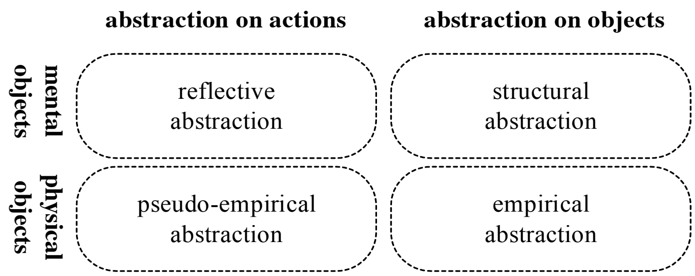

Fig. 1: A frame to capture various kinds of abstraction (reproduced from Scheiner & Pinto, 2014)

We consider this distinction as being productive in trying to capture some of the variety of images of abstraction in mathematics education (for details see Scheiner & Pinto, 2016a). It acknowledges Piaget's (1977/2001) three kinds of abstraction, including pseudo-empirical abstraction, empirical abstraction, and reflective abstraction, that served as critical points of departure in thinking about abstraction in learning mathematics. Research on abstraction in mathematics has long moved beyond classifying and categorizing approaches in cognition and learning, based on similarities of the individuals constructs. For instance, Mitchelmore and White (2007), in going beyond Piaget's empirical abstraction and in drawing on Skemp's (1986) conception of abstraction, described abstraction in learning elementary mathematics concerning seeing the underlying structure rather than the superficial characteristics. Abstraction in learning advanced mathematics, however, is almost always defined in terms of *encapsulation* (or *reification*) of processes into objects, originating in Piaget's (1977/2001) idea of *reflective abstraction*. Reflective abstraction is an abstraction from the subject's actions on objects, particularly from the coordination between these actions. The particular function of reflective abstraction is abstracting properties of an individual's action coordination. That is, reflective abstraction is a mechanism for the isolation of specific properties of a mathematical structure that allows the individual to construct new pieces of knowledge. Taking Piaget's reflective abstraction as a point of departure, Dubinsky and his colleagues (Dubinsky, 1991; Cottrill et al., 1996; Arnon et al., 2014) developed the APOS theory describing the construction of concepts through the encapsulation of processes. Similar to encapsulation is reification – the central tenet of Sfard's (1991) framework emphasizing the cognitive process of forming a (structural) concept from an (operational) process. In the same way, Gray and Tall (1994) described this issue as an overall progression from procedural thinking to proceptual thinking, whereas proceptual thinking means the ability to flexibly manipulate a mathematical symbol as both a process and a concept. Gray and Tall (1994) termed symbols that may be regarded as being a pivot between a process to compute or manipulate and a concept that may be thought of as a manipulable entity as procepts.

Scheiner (2016) revealed that the literature shows an unyielding bias toward *abstraction from actions* as the driving form of abstraction in knowing and learning advanced mathematics. This almost always exclusive view arises directly from the trajectory of our field's history; originating in Piaget's assumption that only reflective abstraction can be the source of any genuinely new construction of knowledge. While abstraction-on-actions approaches have served many purposes quite well, they cannot track detail of students' knowing and learning processes compatible with the strategy of giving meaning. The recently evolving framework of structural abstraction has attracted attention as a promising tool to shed light into the complexity of students' knowing and learning processes compatible with their strategy of 'giving meaning'.

The Evolving Framework of Structural Abstraction

The distinction between abstraction from actions and abstraction from objects reflects Tall's (2013) distinction between *operational abstraction* and *structural abstraction*. In contrast to Piaget (1977/2001) who dichotomized these two forms of abstraction, Tall (2013) argued that mathematical thinking emerges in these two forms: operational abstraction focusing on actions on objects and structural abstraction focusing on the properties (or structures) of objects. For instance, the development of geometry in the conceptual embodied world focuses mainly on structural thinking, the operational symbolic world blends both operational and structural thinking as new forms of number are introduced as extensional blends in algebra (see Tall, 2013). Obviously, mathematics education researchers used the term 'structural' in diverse ways, referring, for instance, to structural mathematics of axioms and definitions or to the properties of the structure of objects. In the following discussion, we departure from Scheiner's (2016) understanding of structural abstraction as focusing on "the richness of the particular [that] is embodied not in the concept as such but rather in the objects that falling under the concept […]. This view gives primacy of meaningful, richly contextualized forms of (mathematical) structure over formal (mathematical) structure" (p. 175). Here we focus the attention to several core assumptions that orient the evolving framework of structural abstraction (see Scheiner, 2016; Scheiner & Pinto, 2016b):

Concretizing through Contextualizing

Structural abstraction takes place on mental objects that, in Frege's (1892a) sense, fall under a particular concept. These objects may be either concrete or abstract. Concreteness and abstractness, however, are not considered as properties of an object but rather as properties of an individual's relatedness to an object in the sense of the richness of a person's representations, interactions, and connections with the object (Wilensky, 1991). From this point of view, rather than moving from the concrete to the abstract, individuals, in fact, begin their understanding of (advanced) mathematical concepts with the abstract (Davydov, 1972/1990). The ascending from the abstract to the concrete requires a *concretizing* process where the mathematical structure is particularized by looking at the object in relation with itself or with other objects that fall under the particular concept. The crucial aspect for concretizing is *contextualizing*, that is, setting the object(s) in different specific contexts. Different contexts may provide various senses (Frege, 1892b) of the concept of observation.

Complementizing through Recontextualizing

The central characteristic of the structural abstraction framework is that while, within the empiricist view, conceptual unity relies on the commonality of elements, it is the interrelatedness of diverse elements that creates unity within the approach of structural abstraction. The process of placing objects into different specific contexts allows specifying essential components. Structural abstraction, then, means attributing the particularized meaningful components of objects to the mathematical concept. Thus, the core of structural abstraction is *complementarity* rather than similarity. The meaning of advanced mathematical concepts is developed by complementizing diverse meaningful components of a variety of specific objects that have been contextualized and recontextualized in multiple situations. This perspective agrees with van Oers' (1998) view on abstraction as related to *re*contextualization instead of *de*contextualization.

Complexifying through Complementizing

The structural abstraction framework takes the view that knowledge is a complex system of many kinds of knowledge elements and structures. Complementizing implies a process of restructuring the system of knowledge pieces. These knowledge pieces have been constructed through the above-mentioned process or are already constructed elements coming from other concept images, which are essential for the new concept construction. The cognitive function of structural abstraction is to facilitate the assembly of more complex and compressed knowledge structures. Taking this perspective, we construe structural abstraction as moving *from simple to complex* knowledge structures, a movement with the aim to build coherent and compressed knowledge structures. In Thurston (1990)'s words, when the latter is achieved we "can file it away, recall it quickly and completely when you need it, and use it as just one step in some other mental process." (p. 847). From the structural abstraction perspective, abstraction is acknowledged as a movement across levels of complexity (Scheiner and Pinto, 2014).

Emerging Insights from the Structural Abstraction Framework

In this section, we summarize emerging insights we gained so far by using the evolving framework of structural abstraction retrospectively as a lens through which findings on students' (re-)construction of the limit concept of a sequence were reinterpreted. The study by Pinto (1998) provided the context in which she identified mathematics undergraduates' sense-making strategies of formal mathematics. From a cross-sectional analysis of three pairs of students, two prototypical strategies of making sense could be identified, namely 'extracting meaning' and 'giving meaning':

> "*Extracting meaning* involves working within the content, routinizing it, using it, and building its meaning as a formal construct. *Giving meaning* means taking one's personal concept imagery as a starting point to build new knowledge." (Pinto, 1998, pp. 298-299)

The literature on abstraction from actions provides several accounts of how students construct a mathematical concept compatible with their strategy of 'extracting meaning'.

For instance, dynamic views of the limit of a sequence and the genetic decomposition of the limit concept of a sequence are intensively investigated by Arnon et al.'s (2014) APOS theory to respond to how students may construct the concept through the process of reflective abstraction. To mention a few recent investigations supported by the same theory, and compatible with the strategy of 'extracting meaning', Martinez-Planell, Gonzalez, DiCristina, and Acevedo (2012) focused on students' understanding of series and investigated whether students saw series as a process without an end or as a sequence of partial sums, as stated by definition. They respond how students may construct the concept, by considering a distinction amongst their understandings of the concept of a sequence as a list of numbers or as a function defined in natural numbers (McDonald, Mathews, & Strobel, 2000), and concluded that even after formal training, students often think of sequences and series as an infinite, unending process.

However, there are almost no accounts of how students construct a concept compatible with their strategy of 'giving meaning', and the structural abstraction framework has shown to be enlightening with regard to this. Students who 'give meaning' seem to develop representations of the limit concept from their concept image and use them generically (see Yopp & Ely, 2016) for constructing and reconstructing the concept (see Pinto & Scheiner, 2016). This means, such representations are not always generic in the sense of Mason and Pimm (1984) though they are used as if they were of that nature. Moreover, such representations may be productive in some, though not all contexts, in which they are needed. In spite of the striking differences in the knowledge constructions in each case study, that are made explicit by the nature of the representations construed and their use, the three case studies presented in Pinto (1998) on students' strategy of giving meaning have in common a cohesion in their sense-making and in learning the formal mathematics concept (Pinto & Scheiner, 2016; Scheiner & Pinto, 2014). Pinto and Scheiner (2016) concluded that coherence amongst students' sense-making and their (re-)construction of the formal content had been proven to be a central characteristic of those students who 'give meaning'. This does not mean that the reconstructions a student made are configured in a "satisfactory reconstruction or accommodation" scenario (Vinner, 1991, p. 70); rather, that apart of the learning scenario, a student's sense making is coherent with her or his learning of a mathematical concept.

It is important to note that the evolving framework of structural abstraction is problem driven, that is, addressing the need for bringing light into the complexity of students' knowing and learning processes compatible with their strategy of 'giving meaning', rather than filling a theoretical gap just because it exists. The reinterpretation of empirical data on students' strategies of giving meaning in the light of the theoretical framework of structural abstraction proved to be particularly fruitful – not only to provide deeper insights into the strategy of giving meaning but also as a way to deepen our understanding of the phenomenon of structural abstraction that revealed new theoretical developments (Pinto & Scheiner, 2016; Scheiner & Pinto, 2014). In the following sections, we highlight the main theoretical advancements.

The idea of complementizing meaningful components underlying the structural abstraction framework reflects the idea that whether an individual has 'grasped' the meaning of a mathematical concept is situated in specific contexts where the objects falling under the specific mathematical concept have been placed in. In the case studies revisited, these contexts include the formal mathematics one, where mathematical objects are presented as formal definitions and their properties are deducted through formal proofs. Such a diversity of situated or contextualized meanings supports Skemp's (1986) viewpoint that "the subjective nature of understanding [...] is not [...] an all-or-nothing state" (p. 43). The reanalysis of the data indicates that the object of researchers' observation should be directed to students' *partial constructions* of the limit concept. These partial constructions may be specific and productive to particular contexts but may remain not fully connected and may be unproductive in other contexts (for instance, in making sense of the formal definition). The empirical data show that, in the case of the students who give meaning, several meaningful elements and relations in understanding the limit concept of a sequence are involved, although a few elements are missing (or distorted). However, some students are able to (re-)construct some meaningful components at need by making use of their partial constructions, while others are not able to do so.

Our reanalysis indicates that some students have developed *resources* that enable them to (re-)construct the limit concept of a sequence at need. Scheiner and Pinto (2014) focused on a case where a student developed a generic representation of the limit concept of a sequence that operates well in several, although not all, contexts and situations. This particular representation, however, allows the student to (re-)construct the limit concept in other contexts and situations. The reinterpretation of the data sheds light on the phenomenon that individuals may not 'have' all relevant, meaningful components, but, rather, they may have resources to generate some meaningful components and make sense of the context at need. In that sense, the ‘completeness’ of the complementizing process cannot ever be taken as absolute.

Several researchers suggested exposing learners to multiple contexts and situations. An important insight from using the structural abstraction framework retrospectively is that exposure to multiple contexts is at least important for particularizing meaningful components: various objects falling under a particular mathematical concept have to be set into different specific contexts in order to make visible the meaningful components or mathematical structure of these objects. In so doing, the objects may be ‘exemplified’ through a variety of representations, in which each representation has the same reference (the mathematical object); however, different representations may express different senses depending on the selected representation system (see Fig. 2).

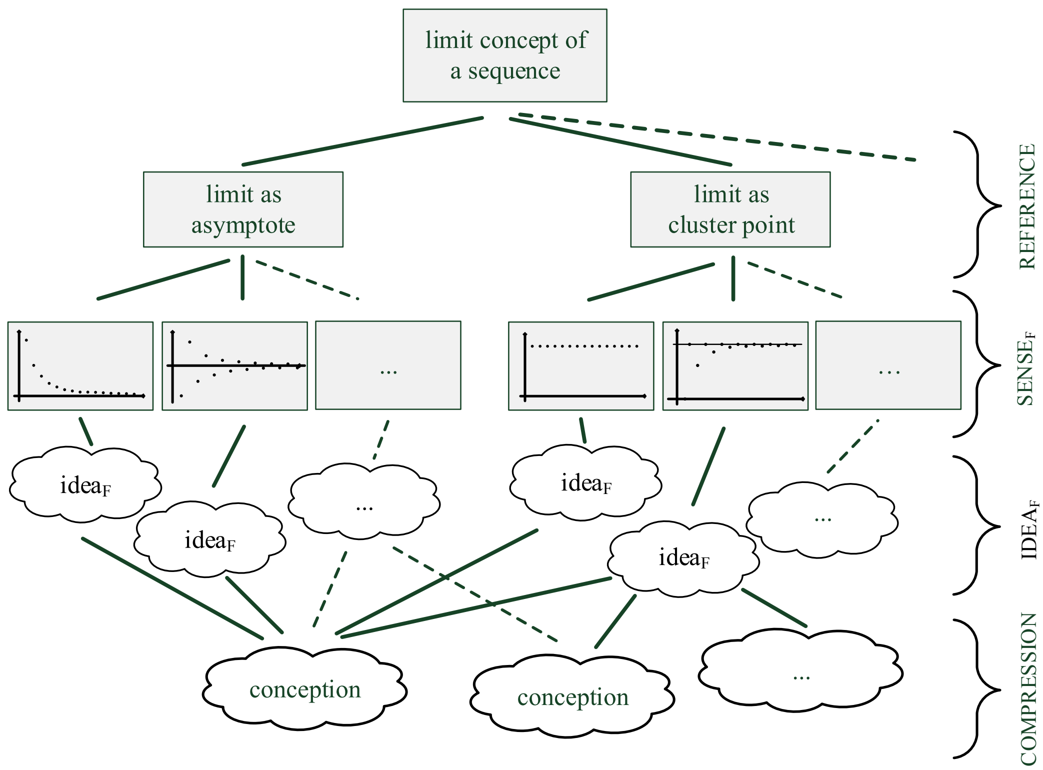

Fig. 2: Reference, sense, and idea

The distinction between *sense* and *reference* has been specified by Frege (1892b) in his work *Über Sinn und Bedeutung*, indicating both the sense and the reference as semantic functions of an expression (a name, sign, or description). In short, the former is the *way* that an expression refers to an object, whereas the latter is the *object* to which the expression refers. According to Frege (1892b), to each representation correspondents a sense; the latter may be connected with an *idea* that can differ within individuals since people might associate different senses with a given representation. Though multiple contexts and situations are needed, a new context that does not provide a new sense will unlikely be productive for concept construction.

Research also indicates that students may have difficulties with the *relationships* between the sense and the reference as well as difficulties in *maintaining* the reference as the sense changes (Duval, 1995, 2006). Thus, one might assume that these difficulties may (at least partly) be overcome by providing students a particular resource (such as a generic representation of the mathematical concept) that serves as a guiding tool in complementizing the meaningful components indicated in the different senses. From this perspective, a 'representation for' is a tool that provides theoretical structure in constructing the meaning of the concept of observation. It necessarily reflects essential aspects of a mathematical concept but can have different manifestations (Van den Heuvel-Panhuizen, 2003). Concerning the learning of the limit concept of a sequence, the reinterpretation of the data indicates that a slightly modified version of a student's representation (see Fig. 3) may support the complementizing process when the limit concept is recontextualized.

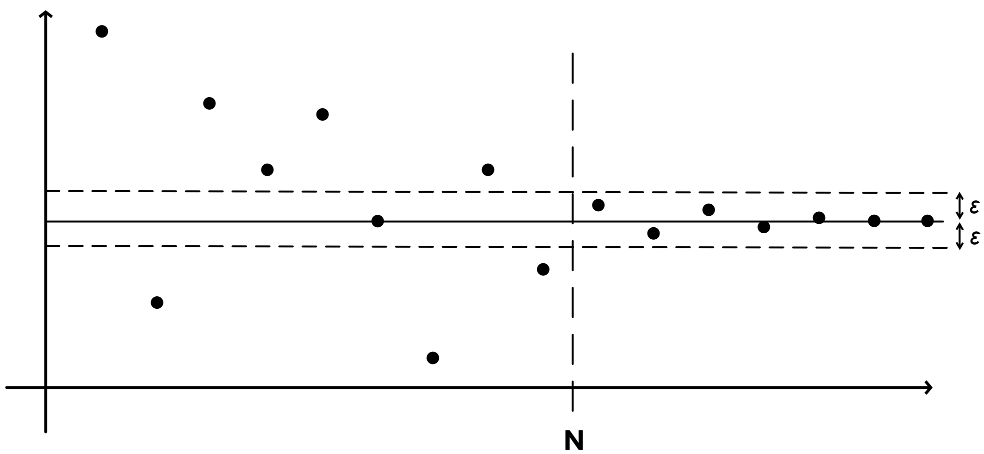

Fig. 3: A generic representation for learning the limit concept of a sequence

Notice that this generic representation for learning the limit concept of a sequence takes account of several students' common conceptions identified in the research literature, including those as (1) the limit is unreachable, (2) the limit has to be approached monotonically, and (3) the limit is a bound that cannot be crossed (see Cornu, 1991; Davis & Vinner, 1986; Przenioslo, 2004; Tall & Vinner, 1981; Williams, 1991).

The reanalysis of the empirical data gained from Pinto's (1998) study has shown that students who gave meaning built a representation of the concept and, at the same time, used it as a representation for recognizing and building up knowledge – the reconstruction of the formal concept definition, for instance. The analysis shows that these students consistently used *representations of* mathematical objects to create pieces of knowledge; or, in other words, the representations were actively taken as *representations for* emerging new knowledge and making sense of the context and situation. This shift from constituting a representation of the limit concept to using this representation as a representation for (re-)constructing the limit concept in other contexts can be described in terms of shifting from a *model of* to a *model for* (Streefland, 1985) – a shift from an *after*-image of a piece of given reality to a *pre*-image for a piece of reality to be created. Adopting this view, we may indicate variations in knowledge structures related to the possible explanations that are considered. Models may involve acceptance of other hypothesis through deduction, causality or analogy.

This mental shift from 'after-image' to 'pre-image' indicates a degree of awareness of the meaningful components and the complexity of knowledge structure that allows the transition from a 'representation of' as a result of various representations expressing specific objects set in different contexts to a 'representation for' constructing and reconstructing the limit concept, if inter alia, in formal mathematical reasoning. We suggest that a generic representation, as presented in Fig. 3, may provide an instructional tool that supports raising the awareness of meaningful components in learning the limit concept of a sequence. In other words, such a generic representation may direct students' perception of meaningful components although it does not enshrine mathematical knowledge.

A Comparison of Calculus, Transition-to-Proof, and Advanced Calculus Student Quantifications in Complex Mathematical Statements

Morgan E. Sellers	Kyeong Hah Roh	Erika J. David
Arizona State University	Arizona State University	Arizona State University

Abstract: This study investigates Calculus, Transition-to-Proof, and Advanced Calculus students' meanings for quantifiers in conditional statements involving multiple quantifiers. Three students from each course participated in clinical interviews. Students were presented with the Intermediate Value Theorem (IVT) and three other statements whose logical structure was similar to the IVT except for the order of both the quantifiers and their attached variables. The results reveal that Advanced Calculus and Transition-to-Proof students made distinctions between the different statements more often than Calculus students. Several student meanings for quantification were found to be necessary for making distinctions between each of the four statements. We also address student quantifications for hidden quantifiers in the statements.

Key words: Quantifiers, Student Interpretations of Mathematical Statements, Intermediate Value Theorem (IVT), Comparative Analysis, Undergraduate Students

The teaching and learning of Calculus is important for all STEM programs. Many studies have investigated STEM students' meanings for important Calculus concepts such as limits, differentiation, and integration, and how these concepts are presented to students (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Martin, 2013; Oehrtman, 2009; Orton, 1983; Thompson, 1994; Vinner & Dreyfus, 1989; White & Mitchelmore, 1996; Zandieh, 2000). Many Calculus concepts like the ones listed above are described in mathematical statements with multiple quantifiers. However, little attention has been paid to students' interpretations of the quantifiers used to express Calculus ideas.

In this paper, we focus on students' meanings for quantifiers in complex mathematical statements from Calculus. By complex mathematical statements, we mean statements that have both if-then structure and multiple quantifiers. The Intermediate Value Theorem (IVT) is one example of such a statement: "Suppose that f is continuous on the closed interval $[a, b]$ and let N be any number between $f(a)$ and $f(b)$, where $f(a) \neq f(b)$. Then, there exists a real number c in (a, b), such that $f(c)=N$" (Stewart, 2003, p. 131). Many Calculus definitions and theorems like the IVT can be classified as complex mathematical statements, even though the topic of quantification is not addressed in popular Calculus textbooks (Bittinger, 1996; Larson, 1998; Stewart, 2003).

Although some studies have investigated students' and teachers' treatment of quantifiers, these studies have dealt with a single quantifier in mathematical contexts or multiple quantifiers outside of a mathematical context (Dubinsky & Yiparaki, 2000; Piatek-Jiminez, 2010; Tabach et al., 2010; Tsamir et al., 2009). On the other hand, studies that have dealt with multiple quantifiers in mathematical contexts have placed more emphasis on Transition-to-Proof and Advanced Calculus students rather than Calculus students (Dawkins & Roh, 2011; Dawkins & Roh, 2016; Roh & Lee, 2011, 2015; Selden & Selden, 1995). This study explores the following questions for students who have completed either Calculus, Transition-to-Proof, or Advanced Calculus:

1. *How do students evaluate complex mathematical statements from Calculus?*

2. *What meanings do students at various mathematical levels have for quantifiers in complex mathematical statements from Calculus?*

Literature Review

Previous studies about student understanding of statements involving quantifiers focused on three issues as follows: students' understanding of statements with one quantifier, students' understanding of statements involving more than one quantifier, and students' understanding of statements in which quantifiers were not stated, but rather hidden.

Student Understanding of Single Quantifiers. Research in mathematics education points out that students may interpret quantifier words such as "for all" $(\forall)$, "there exists" $(\exists)$, and "there exists a unique" $(\exists!)$ differently than the mathematics community (Dawkins & Roh, 2016; Dubinsky & Yiparki, 2000; Epp, 1999, 2003). In turn, students' understanding of quantifiers in a statement plays a crucial role in their justification of a statement involving a quantifier. In particular, previous studies show that some students tended to suggest that a few examples are sufficient to show that a statement involving a single universal quantifier, in the form 'For all x, P(x),' where P(x) is a statement about x, is true (Bell, 1976; Healy & Hoyles, 2000; Moore, 1994; Selden & Selden, 1995). Some students even wished to examine additional examples even after seeing a generic proof of such a statement (Fischbein, 1982). On the other hand, when disproving a statement of the form 'For all x, P(x)', students often believed that only one counterexample is insufficient to disprove the statement (Balacheff, 1986; Galbraith, 1981) or they thought the statement must be still true as they viewed the counterexamples as outliers (Zaslavsky & Ron, 1998). In the case of a statement involving a single existential quantifier, in the form 'there exists x such that P(x),' students also rejected the notion that one example would suffice for proving such a statement (Selden & Selden, 1995). All of these issues may be rooted in the fact that students have different meanings for quantifiers other than the conventional mathematical uses of these quantifiers. Epp (2003) argues that some colloquial uses of quantifiers may influence students' use of quantifiers in mathematics. For example, the phrase "for all" in an English sentence often implies the existence of at least one element in a set. Based on such a colloquial use of the phrase "for all," students might interpret the universal quantifier in a mathematical statement as they interpret it in an English sentence whereas, in mathematics, a statement with a universal quantifier could be vacuously true. Shipman (2013) also found that students' conception of the unique existence in mathematics was not compatible with its meaning in mathematics but rather consistent with its colloquial meaning; in fact, students thought "unique" would mean *unequaled*.

Student Understanding of Multiple Quantifiers. Even if students appropriately interpret single quantifiers in mathematical contexts, they may not correctly interpret quantifiers if a statement involves multiple quantifiers. By multiple quantifiers we mean at least two quantifiers in a statement such as two quantifiers "for all N, there exists c" in the Intermediate Value Theorem. We refer to a statement of the form $\forall x(\exists y P(x,y))$ as an $\forall\exists$ statement and a statement of the form $\exists y(\forall x P(x,y))$ as an $\exists\forall$ statement. Previous studies showed that many students did not distinguish difference between $\forall\exists$ statements and $\exists\forall$ statements and more frequently misinterpreted $\exists\forall$ statements as $\forall\exists$ statements (Dubinsky & Yiparaki, 2000; Piatek-Jiminez, 2010). Other studies showed that some students switched the order of the variables attached to the quantifiers in a statement. For instance, in the case of the ε-N definition of the limit of a sequence, which is an $\forall\exists$ statement, students often considered the variable N before considering the variable ε, or determined the value of ε based on the value of N. In fact, these students did not necessitate the independence of the first variable ε and dependence of the second variable N in the statement (Dawkins & Roh, 2016; Roh & Lee, 2011, 2015).

Student Understanding of Implicit Quantifiers. Implicit (or hidden) quantifiers refer to the quantifiers that are not explicitly stated through direct phrasing such as "for all" and "there exists" (Durand-Guerrier, 2003; Shipman, 2016). The IVT, as stated in this paper, also has an implicit universal quantifier because it is a generalized conditional. The IVT is a generalized statement, and thus, "Suppose that f is a continuous function" implies that the statement has a hidden universal quantifier. Thus, f is often understood in mathematics as representing not a single continuous function, but *all* continuous functions. However, since the implicit universal quantifier is not explicitly stated in the statement, students may not take into account the arbitrariness of f. In fact, Selden and Selden (1995) found that undergraduate students in Transition-to-Proof courses were rarely able to explicitly interpret implicit quantifiers in statements in Calculus contexts. Likewise, several studies reported students' difficulties with reinterpreting a given statement with implicit quantifier into a statement including a statement that include explicit language for quantifiers, logical connectives, and structure (Durand-Gurrier, 2003; Selden & Selden, 1995).

Theoretical Perspective

In this study, we are trying to model individual students' meanings for quantifiers in mathematical statements. The discussion of meaning has permeated philosophy for centuries, particularly within the last century. Speaks (2014) discusses two major branches in theories of meaning: semantic theories and foundational theories. He claims that semantic theories specify "the meanings of the words and sentences of some symbol system" (p.2) and seek to answer the question, "What is the meaning of this or that expression?" (p.2) whereas foundational theories try "to explain what about some person or group gives the symbols of their language the meanings that they have" (p. 2). Foundational theories of meaning are more advantageous for our purposes than semantic theories in their recognition that meanings exist in the *minds* of students rather than on a page. However, foundational theories still do not address the need to analyze *individual* students who have had different individual experiences that led to their current meanings for quantifiers. In this study, we view thinking as a tool by which one constructs his meaning(s), and focus on meanings of individual*s* and not a collective group. Thus, we utilize a constructivist view of understanding and meaning throughout this paper (Glasersfeld, 1995; Thompson, 2013).

We distinguish between *understanding* and *meaning* throughout the rest of this paper. Thompson, Carlson, Byerly, and Hatfield (2014) use *understanding* to describe a student's assimilation to a scheme and a student's *meaning* to describe the mental actions or schemes that are easily triggered as a result of the understanding (assimilation). As the purpose of this study is to describe our best perception of each student's own meanings for quantifiers at different moments, we utilize the phrases *meaning* and *student meaning* throughout this paper the same way as Thompson et al. (ibid).

We utilize the phrase *student quantification* to refer to the process by which students quantify variables. Even in one student's quantification, different schemes of the student may be triggered by different tasks. Some student meanings may be stable, but other meanings may be "meaning(s) in the moment" (Thompson et al., 2014). Thompson et al. (2014) describe a meaning in a moment as "the space of implications existing at the moment of understanding" (p. 13), so students could be assimilating information in the moment and forming new meanings. A student's thoughts may begin to emerge or different meanings may be elicited in different moments. Thus, we consider several different moments and "meanings in the moment" (Thompson et al., ibid) because different moments may result in different types of student quantification.

Methods

Two-hour long clinical interviews (Clement, 2000) were conducted with nine undergraduate students during the spring and summer of 2016 at a large southwestern university in the United States. Students were placed in a category based on the highest course they had already completed. These students had various STEM majors and completed these courses with a variety of different instructors. Three students were selected from each mathematical level: Calculus I, Transition-to-Proof, and Advanced Calculus. Four researchers served in various roles for the data collection (as either interviewer, camera operator, or witness).

Interview Tasks. In the first half of the interview, students were asked to explain their understandings of the four statements shown in Table 1 and to evaluate the truth-values of each of the statements. (Only the statements in the left-hand column of Table 1 were presented to students.) The four statements in Table 1 exhaust all combinations for ordering explicit quantifiers and their attached variables. The symbolic representations of the explicit quantifiers found in the conclusion of each statement are also shown beside each statement in Table 1. Three of the statements are false. Statement 2 is the IVT and the only true statement. The variety of statements allowed us to analyze students' comparisons and contrasts among the explicit quantifiers.

Table 1
Statements Presented in Clinical Interviews

Statements	Symbolic Representations
Statement 1: Suppose that f is a continuous function on the closed interval $[a, b]$, where $f(a)\neq f(b)$. Then, for all real numbers c in (a, b), there exists a real number N between $f(a)$ and $f(b)$, such that $f(c)=N$.	$\forall c\exists N$ such that $f(c)=N$
Statement 2: Suppose that f is a continuous function on the closed interval $[a, b]$ where $f(a)\neq f(b)$. Then, for all real numbers N between $f(a)$ and $f(b)$, there exists a real number c in (a, b), such that $f(c)=N$.	$\forall N\exists c$ such that $f(c)=N$
Statement 3: Suppose that f is a continuous function on the closed interval $[a, b]$, where $f(a)\neq f(b)$. Then, there exists a real number N between $f(a)$ and $f(b)$, such that for all real numbers c in (a, b), $f(c)=N$.	$\exists N\forall c$ such that $f(c)=N$
Statement 4: Suppose that f is a continuous function on the closed interval $[a, b]$ where $f(a)\neq f(b)$. Then, there exists a real number c in (a, b), such that for all real numbers N between $f(a)$ and $f(b)$, $f(c)=N$.	$\exists c\forall N$ such that $f(c)=N$

We presented students with graphs in the second half of the interview. Students were asked to re-examine the four statements along with each of the graphs shown in Figure 1. The interviewer asked each student to explain why they a statement was true or false, in their opinion, by using these graphs.

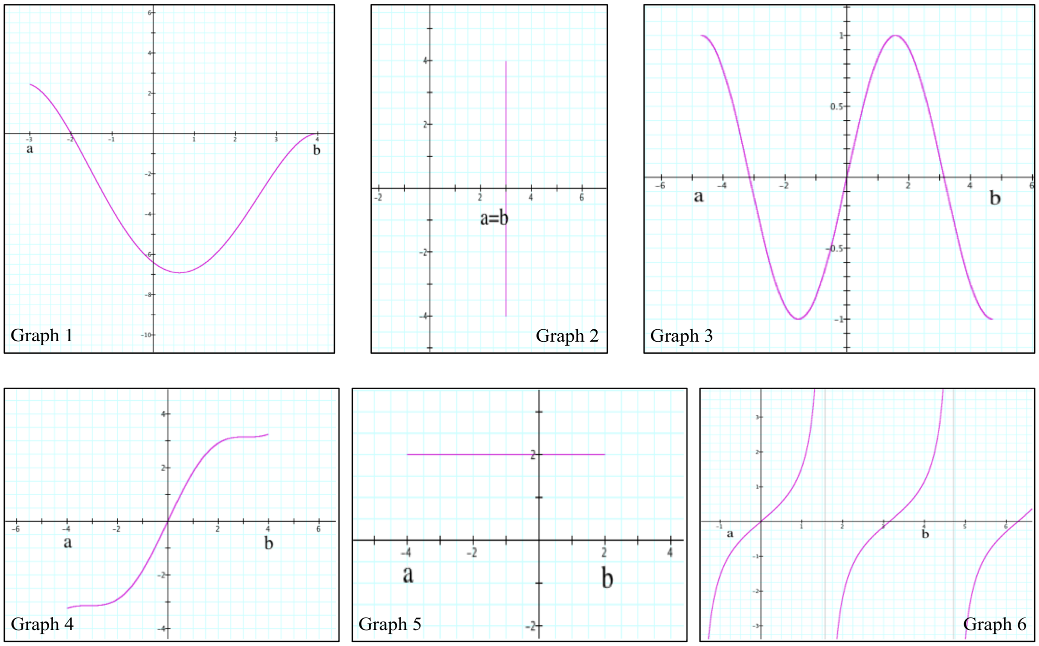

Figure 1. Graphs presented in second half of interview.

These graphs were all strategically chosen based on their properties as an example, non-example, or counterexample for each of the four statements. We used these graphs in the interview so that students could highlight the order in which they would select variables in a given statement and so that we could notice sweeping or pointing gestures that might indicate characteristics of their meanings for quantifiers.

Data Analysis. Our analysis was conducted in the spirit of grounded theory (Strauss & Corbin, 1998) using videos of the student interviews as well as the students' written work. Hence, the categories that describe students' meanings for quantifiers in this paper emerged from our data and not from previously created categories. Each interview was analyzed moment-by-moment to identify moments where distinctions could be made about a student's meanings for the quantifiers. A new moment began when a student was presented with a new question or task, changed their evaluation of a statement, or the student provided a new description of the quantifiers in a given statement. We used moments as our unit of analysis rather than students because students could exhibit various meanings for quantifiers in different moments of the interview. For example, in the second part of the interview, students were asked to explain why their evaluation was true or false given particular graphs. When students were analyzing the statements with these graphs, they would often change their evaluations of the statements or question their previous arguments.

We coded the data for characteristics of students' meanings for quantifiers. Once the difference in explicit and implicit quantifications was noticed, codes were organized and separated into one of these two categories. Categories emerged for types of student meanings for explicit and implicit quantifiers. In the final stage of data analysis, each interview was re-coded moment-by-moment for reliability. We then counted the number of moments that occurred in each category amongst all students. Some moments may not be useful for answering a particular research question. Other moments were found that lacked sufficient evidence for analysis. Thus, we only counted *relevant moments* in this study. By relevant moment, we mean any moment where sufficient evidence was available for answering a particular research question. Only relevant moments were considered in each phase of our analysis. For each research question, relevant moments were also tagged by the interviewee's mathematical level so that we could make comparisons about student meanings of quantifiers for each group.

Results

In this section, we first report how students evaluated the four statements provided (see Table 1 for the statements), and then further analyzed students' meanings for quantifiers in these statements. We also provide our comparative analysis on student meanings for quantifiers in these statements based on three different mathematical levels: Calculus, Transition-to-Proof, and Advanced Calculus.

Student Evaluations of Statements

All three groups of students correctly evaluated Statement 2 (the IVT) for more than half of all relevant moments. However, all three groups of students also incorrectly evaluated Statement 1 for more than half of all relevant moments, and Calculus students correctly evaluated Statements 3 & 4 ($\exists\forall$ statements) for less than a quarter of all relevant moments. Table 2 shows the percentage of relevant moments where students provided a truth-value for one of the statements. The unit of analysis was a moment, as detailed in the methods section. Only moments where students provided truth-values are shown in Table 2. Mathematically correct truth-values for each statement are shaded in Table 2.

Table 2
Student Evaluations for Statements 1-4 by Mathematical Level (by % of Relevant Moments)

	Calculus			Transition-to-Proof			Advanced Calculus		
	True	False	True/ False[1]	True	False	True/ False	True	False	True/ False
Statement 1 (S1): $\forall c \exists N$	6/8 (75%)	1/8 (12.5%)	1/8 (12.5%)	5/8 (62.5%)	3/8 (37.5%)	0/8 (0%)	4/9 (44.4%)	4/9 (44.4%)	1/9 (11.1%)
Statement 2[*] (S2): $\forall N \exists c$	6/9 (66.7%)	2/9 (22.2%)	1/9 (11.1%)	6/9 (66.7%)	3/9 (33.3%)	0/9 (0%)	8/9 (88.9%)	1/9 (11.1%)	0/9 (0%)
Statement 3 (S3): $\exists N \forall c$	6/9 (67%)	1/9 (11.1%)	2/9 (22.2%)	2/8 (25%)	6/8 (75%)	0/8 (0%)	0/8 (0%)	8/8 (100%)	0/8 (0%)
Statement 4 (S4): $\exists c \forall N$	8/11 (72.7%)	2/11 (18.2%)	1/11 (9.1%)	2/6 (33.3%)	3/6 (50%)	1/6 (16.7%)	0/8 (0%)	8/8 (100%)	0/8 (0%)

As shown in Table 2, while all three groups of students evaluated Statement 2 (IVT) correctly in more than 60% of relevant moments, this result does not imply that students understand the IVT properly because students' evaluations of the other three statements were often incorrect. For instance, Calculus students and Transition-to-Proof students incorrectly evaluated Statement 1 as a true statement in more than 70% and 60% of relevant moments,

[1] True/False indicates that student responses were "Sometimes True" and "Sometimes False."
[*] Statement 2 is the Intermediate Value Theorem.

respectively. Even Advanced Calculus students incorrectly evaluated Statement 1 as a true statement in more than 40% of relevant moments. We cannot claim that undergraduate students comprehend the quantification in the IVT if they cannot correctly evaluate these other statements. Also, this result indicates that even if students correctly evaluate Statement 2, they could reach a correct conclusion for the wrong reasons. We will now explain *why* these students' evaluations often differ from mathematical convention.

Student Meanings for Explicit Quantifiers

In order to understand *why* these students' evaluations of Statements 1, 3 and 4 were often incorrect, we further analyzed students' own interpretations of each of the four statements and compared whether they considered any of the four statements would have the same meaning. From this analysis process, we found that in all relevant moments throughout the interviews, Advanced Calculus students all concluded that none of the four statements have the same meaning. On the other hand, in some moments Transition-to-Proof and Calculus students said that some or all of the statements would have the same meaning. In particular, Calculus students often interpreted all four statements as Statement 1 although the order of quantifiers and the order of variables in each statement were all different from one another. We thus even further analyzed what meanings these students have for quantifiers in these statements. Three main factors emerged from this phase of data analysis that seemed to play a crucial role in and interpreting the four complex mathematical statements: (1) Having distinct meanings for single quantifiers, (2) having distinct meanings for the order of quantifiers, and (3) having distinct meanings for the order of variables attached to the quantifiers.

Distinguishing Single Quantifiers "For all" and "There exists." Some students exhibited distinct meanings that differed for each of the phrases "for all" and "there exists." Some moments involved student specification of the meanings of these phrases in their own words, such as describing "for all," as "for each one of these," or clarifying "there exists" as "I can find at least one." Other student moments were characterized by an interchange or alteration of the meanings for these phrases. Even though the phrases "for all" and "there exists" were used in the statements, students' explanations sometimes included using universal quantifier language such as "every," and "all" for the variable attached to the existential quantifier. Likewise, during some moments, students used phrases such as "I can find an" or "there is a" for the variable attached to the universal quantifier. Such student utterances indicate that in these moments, students did not have distinguishable meanings for the singular universal and existential quantifiers.

Hannah was a Calculus student who did not distinguish between "for all" and "there exists" in some moments. Hannah stated that Statement 4 ($\exists c \forall N$) had the same meaning as another previous statement. She also claimed in this moment, "anywhere you choose c to be, there is a value of N that's a real number because the function is continuous." Hannah said we could choose c-values *anywhere*, which indicates that she was treating the existential quantifier as if it were a universal quantifier. She also said that we could find *a* value of N, even though the statement says that we need to find a c that works for *all* values of N. This dialogue indicates that in this moment she was also treating the universal quantifier as if it were an existential quantifier.

Distinguishing Order of Quantifiers. Statement 1 ($\forall c \exists N$) and Statement 3 ($\exists N \forall c$) both have "there exists" with N and "for all" with c, but the order of these quantifiers is different. Statement 2 ($\forall N \exists c$) and Statement 4 ($\exists c \forall N$) also reorder in a similar fashion. Some student moments included explanations of why each statement in these pairs had a distinct meaning. Other student moments were classified by student views that these pairs were equivalent in meaning. Our findings are similar to those of Dubinsky and Yiparaki (2000), who showed that students may view reordering quantifiers, with variables attached, as inconsequential. Mike, a Transition-to-Proof student, explained why he thought Statement 1 and Statement 3 are similar:

> Mike: [Statement 3] and [Statement 1] are saying the same thing and [Statement 2] and [Statement 4] are saying the same thing. These two (*Statements 1 and 3*) are saying that there is only one output for all the inputs. But [for] Statement 1 and 3, I could assume this… for all real numbers c in the interval (a, b) I could assume that's true.

Mike acknowledged that he believed Statement 1 and Statement 3 are equivalent in meaning and Statement 2 and Statement 4 are equivalent in meaning. His classification insinuates that he did not distinguish between these quantifier distinctions. We have further evidence of his lack of distinction because he stated that both Statements 1 and 3 are about *one output* and *all* c's. Mike recognized that these pieces of the quantification are the same. However, since he emphasized the singular quantifiers and concluded that the statements are equivalent, we claim that he did not distinguish the difference in the order of the quantifiers in the statements.

Distinguishing Variable Order and Dependence. We also found a difference in how students treated the order of the variables c and N in their explanations of the statements. All but one student mentioned that the order of the variables was different in some of the statements. However, during some moments, students claimed that reordering the variables had no effect on the meanings of the statements. Zack, a Calculus student, explained why he thought Statement 2 ($\forall N \exists c$) was different, but equivalent, to Statement 1 ($\forall c \exists N$) in this moment:

> Zack: Um, so I mean obviously this [N] is now flipped with c, at least in [Statement 2]. I don't know how this [switch] necessarily affects [the statement]. So, when I explained it on the last one, I thought that N was a dependent value depending on what c is… Such that $f(c)$ is equal to N… I don't think that, I'm sorry. So it's like that… I'm interpreting [Statement 2] the same, that it's just saying that really for any real value of N's there exists a value of c, but c is still the value. Like… this (*points to c in f(c) in statement*) is the independent value versus this (*points to an N in the statement*) is the dependent value.

We claim that Zack recognized the variable order in Statement 2 in this moment, but he did not treat the first variable, N, as being chosen independently of the c-values. Zack mentioned that c is an independent variable and N is a dependent variable in the function in both statements. Zack appeared to choose c-values first because he thought that independent variables should be chosen first. However, he did not seem to connect the variable order in the quantification to his own choice for which variable should be held independent of the other.

Many student moments were different than Zack's moment; in these moments, students noticed the order of the variables and also displayed an understanding of the ramifications of this variable switch in different statements. Jay, an Advanced Calculus student, explained why Statement 1 ($\forall c \exists N$) and Statement 3 ($\exists N \forall c$) are different:

> Jay: For this one [Statement 1] all of the... like the values for individual c's can be different. So like given c, I give you an N, but that doesn't have to be the same N as some other c. But for here [Statement 3] that's not true. There exists a real... so I give you N before you give me c, meaning I know what the answer is before I even know what c is.

Jay was not only aware of the variable order in this moment, but how the variable order affects the statements' meanings. Jay contrasted the order in which the first person gave a c or N and the other person gave a variable in return. His contrast suggests that he thought of the first variable independently of the second variable. He also used the first variable's information to give him information about the second variable, which indicates that he considered that the second variable is dependent on the first variable.

Explicit Quantifier Distinctions Across Mathematical Levels. The four different meanings in Table 2 were more prevalent amongst the more advanced students interviewed. The results of this comparison of percentages from each of the three groups are shown in Table 3.

Table 3
Comparison of Students' Explicit Quantifier Meanings

Explicit Quantifier Meanings (by % of Relevant Moments)	Calculus	Transition-to-Proof	Advanced Calculus
Distinguished "for all" and "there exists"	4/17 (23.53%)	21/22 (95.45%)	17/17 (100%)
Distinguished "for all… there exists…" and "there exists… for all…"	0/8 (0%)	7/12 (58.33%)	6/6 (100%)
First Variable Independent & Second Variable Dependent	4/19 (21.05%)	14/15 (93.75%)	11/11 (100%)

Table 3 summarizes that higher-level mathematics undergraduates exhibit more moments with distinctive meanings for explicit quantifiers. The Advanced Calculus students had a greater percentage of moments where they exhibited each of these four meanings than Calculus students. Calculus student moments not only showed students' confounded meanings of "for all… there exists…" and "there exists… for all…," but they also revealed Calculus students' tendencies to confound the singular quantifiers "for all" and "there exists" as well. While the Transition-to-Proof students had a higher percentage of moments than Calculus students for distinctions between "for all" and "there exists," there were still several moments where they confounded meanings of "for all… there exists…" and "there exists… for all…" Calculus students may have recognized the change in variable order across statements, but the variable dependency moments revealed that this recognition was not associated with students' understanding for why variable ordering is important to statement meanings.

Students' Implicit Quantifications

Calculus students had fewer moments where they distinguished between different types of explicit quantifiers and their attached variables than their advanced peers. However, meanings for implicit quantifications varied amongst the groups. The phrase "Suppose f is a continuous function" elicited ambiguity in some student moments. All four statements in Table 1 are written with the intent that readers will apply each statement to *all* continuous functions. We found three ways that these students implicitly quantified f: universally, existentially, or case-by-case.

Universal Implicit Quantification. Some students did quantify the phrase "Suppose f is a continuous function" as intended. Students used words such as "arbitrary" or the phrase "*any* continuous function" to describe their meanings of the statements.

Case-by-case Implicit Quantification. Three students considered that some of the statements that we were giving them were not firmly true or false for some moments. They preferred to evaluate some statements as "sometimes true" or "sometimes false" instead of strictly true or false. Their reasoning for this choice was made apparent when we offered them graphs and they considered that the statement was true for some functions, and false for some functions. Zack claimed in one moment, “No, I still agree that this statement [Statement 1] would be sometimes true… because in my mind this graph (*points to what we would consider the counterexample graph*) proves it… proves that I can't say the statement is true one hundred percent of the time.” These students are classified as “Case-by-Case” because they were considering the if-then statement as having a variable truth-value instead of being firmly true or false. Our evidence supports Durand-Guerrier’s (2003) finding that students tend to think of a conditional as an open statement which may be true or false, depending on the case at hand.

Existential Implicit Quantification. Ron, a Transition-to-Proof student, interpreted the phrase “Suppose *f* is a continuous function” with an existential quantification. He described his lack of certainty about the intent of the statement, and described his conclusions in this moment:

> Ron: I am not sure if *f* is limited to there being an existence of a continuous function or it's “suppose that any function.” So because the wording is ambiguous in my mind I am not sure. I am just gonna keep it true for now because I am going to assume that “Suppose *f* is a continuous function” is going to be equivalent to the wording being “Suppose that *there is an existence* of a continuous function *f* on the closed interval *a* to *b*.”

Ron’s implicit quantification of “Suppose *f* is a continuous function” affected the rest of his arguments because he believed he only needed one function to make each statement true. He also thought that proving each statement false required exhausting all functions.

Implicit Quantification Across Mathematical Levels. The summary of all the students’ meanings in the moment for implicit quantifiers is shown in Table 4.

Table 4
Comparison of Students’ Quantifications for “Suppose f is a continuous function”

Implicit Quantifications (by % of Relevant Moments)	Calculus	Transition-to-Proof	Advanced Calculus
Universal	6/8 (75%)	4/8 (50%)	7/8 (87.5%)
Case-by-Case	2/8 (25%)	3/8 (37.5%)	1/8 (12.5%)
Existential	0/8 (0%)	1/8 (12.5%)	0/8 (0%)

As shown in Table 4, the majority of moments when students were implicitly quantifying *f* were distinguished by universal quantification in all three groups of students. However, there were some student moments from all three mathematical levels that exhibited a case-by-case quantification of “Suppose *f* is a continuous function.” Our only existential implicit quantification moments originated from one Transition-to-Proof student, Ron.

Discussion

This study indicates that students may correctly evaluate the IVT, but their meanings for the quantifiers in the IVT may be different than the intention of the theorem. Students who eventually evaluated all four statements correctly also provided thorough explanations of the statements and possessed distinct meanings for different types of quantifiers. These students articulated distinctions for single quantifier words "for all" and "there exists," as well as distinctions for the order of quantifiers "for all… there exists…" and "there exists… for all…" They also recognized and explained the importance of the order of c and N in the statements. On the other hand, students who incorrectly evaluated the truth values of at least one statement among the four statements often did not have distinct meanings for at least one of the three factors: single quantifiers, the quantifier order, and the variable order. There were also moments from students of all three levels who implicitly quantified "Suppose f is a continuous function" in different ways than the authors of the statements intended for the statements to be quantified.

The results of this study suggest what we may need to consider quantifiers more carefully when teaching complex mathematical statements. First of all, we may need to place more attention on students' meanings for quantifiers, the quantifier order, and the variable order in a complex mathematical statement. Calculus students in this study did not recognize the necessity of quantifiers in the statements. Compared to Calculus students, Transition-to-Proof and Advanced Calculus students had distinct meanings more frequently for different types of quantifiers. However, some Transition-to-Proof moments were characterized by a lack of distinction in quantifier order, and some of the students both Transition-to-Proof and Advanced Calculus also did not correctly interpret the implicit quantifiers in the statement. Having stable and coherent meanings for quantifiers is foundational to understanding complex mathematical statements, and we as mathematics teachers would need to reconsider how to help students recognize when variables are ordered differently across a set of statements before they focus on how this reordering alters the meanings of the statements. These results should be considered when making curriculum and instructional decisions for all mathematical courses, but particularly for Calculus and Transition-to-Proof courses.

We report a qualitative analysis of 14 undergraduate students' experience in a semester long introduction to proof course. Half were mathematics majors. Our research aims to characterize, conceptually and empirically, students' transition from a focus on computation to proof in mathematics. Our analysis focused on how students saw the course as different from prior courses, whether it required new or different learning activity, how they described their work in proof-writing, and how they saw their confidence and success in the course. This approach—targeting students' overall experience of the course—differs from prior research that has tracked students' challenges, focused on their work on specific proof problems, and explored how to support and improve their work (e.g., Selden & Selden, 2003). Our work has promise for informing the design of transition to proof courses and how those courses are organized and taught.

Keywords: Transition to Proof, Proof Reasoning, Students' Experience, Qualitative Analysis

The Transition to Proof and Proving

Many undergraduates experience difficulty in learning to prove mathematical propositions, including those who major in mathematics (Baker & Campbell, 2004; Moore, 1994; Selden, 2012). For many, experience with proof prior to college is quite limited (Anderson, 1994; Jones, 2000). Students' prior competence (and interest) in mathematics is typically centered on producing accurate answers to easily recognized tasks—"exercises" in Schoenfeld's terms (1992). That work involves recognizing specific types of mathematical tasks quickly and applying well-practiced procedures to solve them. These abilities do not support, and may interfere with students' work to conceptualize, write, or evaluate proofs. In addition to differences in the didactical contract between computation-heavy courses like calculus and proof-intensive courses, Selden (2012) reports that students encounter many difficulties, including mastering logic and definitions, generating and using examples and counterexamples, understanding concepts and theorems, and evaluating the arguments of others. In short, the transition to proof is complex and challenging, and much of students' prior ability appears inadequate, if not problematic for addressing these challenges.

Many mathematics departments have recognized this problem and experimented with different curricular and instructional approaches to support students' entry into proof, including dedicated "transition to proof" courses. These typically focus on precision of language and notation, reasoning, and proof and present sample accessible statements from numerous content domains to prove or disprove. But designing these courses is not a trivial task, and they have often shown limited positive effects (Selden & Selden, 2003; 2014). A crucial limitation affecting course design is that research has not systematically focused on the experience of students. Instead, course design and instructional decisions have often been shaped by assumptions about students, the kinds of challenges they face, and structures that productively support their learning. To begin to address this limitation, we explored how students describe their experiences in one such “transition to proof” course.

Conceptual Framework

The notion of a “transition” from one view and way of working in a school subject to another is as conceptually vague as it is intuitively sensible. What does a “transition” in students’ experience of mathematics mean?

To conceptualize the transition from computation to proof, we drew on prior work that conceptualized mathematical “experience” and “transition.” Smith and Star (2007) proposed that precollege students’ mathematical experience could be understood and studied as a composite of four dimensions: Achievement, disposition, differences between prior and current mathematics courses, and learning activity. *Achievement* was simply their grade performance in mathematics courses (not an assessment of what they learned to those courses). *Disposition* involved students’ attitudes toward mathematics and their beliefs about their own ability to learn it (self-efficacy). *Differences* captured students’ sense of what changed from prior mathematics courses to work in their present classroom; it embraced issues of curriculum, teaching, and assessment. *Learning activity* involved the actions that students took to learn mathematics, in and outside of class. Assessing change on these dimensions in turn supported grounded judgments of the significance/depth of students’ transitions.

In exploring students’ transition to proof, we first targeted how students saw the introduction to proof course as different from (and similar to) their prior mathematics courses (differences). We also sought to understand how students went about learning the content in the course, again both inside the classroom and outside (learning activity). Substantive differences in how students saw the introduction to proof course could drive substantial changes in how students went about their work. We narrowed the notion of disposition to self-efficacy and explored how students’ confidence to learn and achieve changed over the semester (confidence). Relative to achievement, we solicited their final grades, but also explored if and how they judged their success in the course in ways other than grades. Finally and centrally, because the transition to proof involves the development of new mathematical abilities, we explored how the students described their work in planning, writing, and evaluating proofs on assigned problems (proof reasoning).

More broadly, we approached our data collection and analysis with the constructivist focus. That perspective oriented our attention to how students used prior resources (elements of their prior mathematical success) to address the new challenges of proof writing, whether those resources proved useful and effective or not (e.g., Smith, diSessa, and Roschelle, 1993/94). For example, this perspective suggests that elements of prior competence in computing answers using practiced procedures would likely be recruited in proof writing (e.g., looking for ways to “proceduralize” the task), despite the numerous ways in which applying procedures and proving previously unknown statements differ. In a word, this general orientation expects substantial continuity in students’ thinking even as elements of prior competence “don’t work” in proof writing.

The Course & The Participants

The 14 participants in the study were all graduates of a multi-section semester course designed to introduce them—both mathematics majors and not—to proof and proving. The mathematics department hoped that the course would support greater success for both groups of students in upper-division courses that emphasize proof. The introduction to proof course focuses on appropriate syntax and notation, basic concepts in set theory and logic, and various proof methods before proving "entry-level" statements from various content domains (e.g., linear algebra, real analysis, and number theory). These methods were mathematical induction, proof by cases, working forward from definitions, contrapositive, and contradiction. The course pedagogy is not lecture-based. Instead instructors give short presentations and present proofs (or parts of proofs) before students spend substantial time working on proof tasks themselves, often in small groups. The course also includes elements of "flipped classrooms;" students read and answer basic comprehension questions prior to working on problems in class that draw on that content. Evaluation was primarily based on homework and exam grades (n = 3 before the final). Students were required to use LaTeX to post their solutions to homework tasks, but their solutions on all exams were hand-written.

We interviewed students in the summer after they completed the course in the prior spring semester. We invited all 110 enrolled students from that semester to participate; 17 (~15%) responded, and 14 (~13%) completed an hour-long interview about their experience. These interviews were audiotaped for analysis. Nine students were male and five were female; three were international students. The sample was diverse by major. Six were mathematics majors; two others were majoring in actuarial science. In addition, we interviewed students majoring in mechanical engineering, chemistry, packaging, biology, and economics. Two of those were pursuing dual majors. Most of the other "non-math" majors were pursuing minors in mathematics where the course was a requirement. That minor also requires subsequent courses that focus on proof. Table 1 provides an overview of the sample, including their final grades. Eight students received a 4.0, two received a 3.5, three received a 3.0, and one received a 2.5. Our sample was more successful than the average, relative to the course's grade distribution.

Table 1. Overview of Participants

Student	Gender	Home	Major(s)	Standing[a]	Minor[b]	Grade
1	F	US	Mathematics	1		3.0
2	M	US	Actuarial Science	2		3.5
3	M	US	Mechanical Engineering	4		4.0
4	M	US	Chemistry	3	Math	3.0
5	M	US	Actuarial Science	1	Math	4.0
6	M	Intl	Mechanical Engineering	3	Math	4.0
7	M	Intl	Computational Mathematics	3		4.0
8	F	US	Mathematics	1		3.0
9	F	US	Packaging	2	Math	2.5
10	F	US	Mathematics	2	Act Sci	3.0
11	M	US	Human Biology	3	Math	3.5
12	M	Intl	Mathematics	3		4.0
13	F	US	Economics & Statistics	2		4.0
14	M	US	Economics & Mathematics	2		4.0

[a] "Standing" reflects the amount of university coursework; in some cases, standing exceeds the number of years at the university. [b]S5 and S9 were strongly considering a mathematics minor but had not yet decided.

Our interview questions focused on understanding students' experience of the course in their terms, relative to their prior work in high school and college mathematics. We first secured basic information about them (e.g., major, standing, section/instructor, minor, and prior and intended math courses). Then we asked about their sense of the nature of the course (in contrast to their prior courses), their sense of success (or not) in it, what they did to be/become successful, and specifically how their view of and work on proof tasks may have changed in the course. As complement to seeking their verbal responses, we also asked them to graph their confidence in the course across the semester. These Confidence Graphs (Figure 1) often surfaced new information about our focal issues, as students explained the shape of their graphs and points during the semester when their confidence changed. We also asked about their sense of their instructor's view of the course, whether their course experience influenced their understanding of calculus (most had just completed that sequence), and whether they expected to be successful in subsequent math courses. Finally, we asked what they would tell incoming students about the course.

We also regularly observed (about twice per week) the classroom teaching and interactions in one section of the course for most of the semester—the section taught by the course coordinator. Observers took field notes in an observation template. These observations proved essential in preparing for the interviews, interpreting and responding to student responses, and in the analysis of the resulting data.

Figure 1. Confidence Graph (reduced in size). Each participant drew a graph of their confidence over the course of the semester. The X-axis represents time, from just before the course began through the final exam. The Y-axis represents their confidence in doing well in the course.

Analysis

Our analysis the interview data, both verbal and graphical, was qualitative, "bottom-up" (guided by our foci), and cyclical in nature. The results of initial analyses led to more detailed and focused rounds of analysis around specific issues. First, immediately after each interview, interviewers posted detailed summary descriptions of their interviewee's responses. All members of the research team then read carefully and discussed the similarities and differences evident in those summaries. Next, the audio records were transcribed verbatim and coded in the qualitative software *Dedoose* according to a coding scheme developed from the initial post-interview analyses and the categories suggested by our theoretical framework (achievement, disposition, differences between prior and current mathematics courses, and learning activity). This resulted in a coding scheme with the following top-level categories: (1) characterizing differences, (2) learning activities, (3) proof reasoning, (4) sense of success, and (5) prior mathematical experience. The coding scheme and a code book detailing criteria for assigning codes were refined through rounds of coding and discussion amongst members of the research team.

The Confidence Graphs that subjects produced were initially analyzed for their general graphical properties (e.g., initial sense of confidence and where slopes of sections were greatest, positively and negatively). A second round of analysis explored the relationship between the graphs students produced and their verbal explanations of that they drew. We paid particular attention to points in the semester when students' confidence changed and the reasons given for those changes.

Results

We report results in four main components. First, we present our summary of how the students described the course in comparison to prior mathematics courses. Second, we discuss one aspect of that comparison—how students used the terms "problem" and "answer" in describing their course work. Third, we characterize how students described their reasoning in solving proof tasks. Finally, we describe how the students viewed and evaluated their success in the course and the learning activities in which they engaged and also present the results of our Confidence Graphs analysis.

The Different Nature of the Course

Students were quite articulate about how the course differed from their prior mathematics course experiences, but their focus and emphasis varied. We found three main characterizations of difference: (a) the transition to proof course explained the mathematics, whereas prior math courses did not, (b) students' conceptions about proof and writing in mathematics changed, and most importantly, (c) the course emphasized explanation and reasoning, differing greatly from the computational and answer-focused nature of their work in past math courses. No student reported substantial prior experience with proof, in either high school or college; most reported no experience whatsoever. Those who did cite their experience with two-column proof in high school geometry were largely dismissive of that work as irrelevant.

First, students frequently stated that the course *explained* the mathematics, more so than in prior courses. Half said the course explained why mathematics is the way it is and how it came about. For example,

> *The past math courses have been a lot...you are given instructions and then you learn to kind of regurgitate them, whereas [this course] really made you think...why the rules are in place and coming up with your own rules* (S3).

Students noted that the course explained why procedures they had learned in previous mathematics worked. In particular, S8 and S6 cited limits, derivatives, and operations with matrices, respectively, as examples of this.

> *The difference is: when I learn matrices in differential equations, I only need to calculate multiplication, adding, or subtract[ing]. That's it. But [in this course], I have to know*

why is it possible to subtract two matrices. I have to show that. And that makes me to understand how's it come from when first it was invented (S6).

This pattern of response indicates that the course served an explanatory purpose for students, providing conceptual understanding over and above their learning about language, notation, and proof techniques. This is a central function of proof in mathematics (e.g., Thurston, 1994), but it was pleasing to hear students articulate it.

Second, half of the students (n = 7) talked explicitly about the new focus on proof and the dramatically increased focus on writing. S7 remarked that "calculus works with numbers and [this course] works with words," succinctly illustrating how students perceived a huge difference between these two types of courses. Students commented on changes in how they perceived mathematical writing (n = 5) and noted how much more writing was required in the course (n = 7). Some realized that proofs can include words, not just symbols (S12, S13); others came to new understandings about the importance of accurate grammar in writing compelling proofs (S2, S3). They saw that mathematical terms have much more specific meanings than do words in everyday language and communication and that that specificity was important. For example, S3 stated that "certain words mean different things in math as opposed to normal spoken English."

Last and perhaps most important, most students (n = 10) explicitly contrasted the computational, answer-focused nature of their work in prior courses (e.g., calculus) to the process- or argument-focused work in the introduction to proof course. As we note below, numerous students described the course in terms of what it was not: Writing proofs was not straightforward or step-by-step (S2-S5, S11) and did not involve applying formulas or solving equations (S6, S12, S14). Students discussed how they had to explain their thinking (n = 7), something they were not accustomed to doing in previous math courses. Nevertheless, students largely understood the rationale for the push for explanation.

Proof is actually more like explaining. So I learn how to generally explain some stuff...to justify your arguments or persuade others in order that they can understand what you wanna say (S6).

As a result, about a quarter of the sample expressed that the course valued the process of reasoning more than the answer.

Answers in proof work. As our constructivist perspective had suggested, students reused terms that were standard and relevant to computational work but seemed less appropriate to proof-writing work. All but one student used "answer" to describe products of their proof-writing work, and nine of them used that term to describe their work before the interviewer did. In some cases, students appeared to use "answer" to refer to the result to be proven (e.g., the consequent of an "if-then" statement). In other cases, "answer" appears to refer to the entire written proof. S10 explained,

Yeah but personally, me, I'm super neat so my homework I could have turned in [without conversion into LaTeX]. *But with the writing proofs you have all these ideas all over the place, and then you have one final answer where you put everything in order and it makes sense.*

S5 similarly used "answer" to refer to the general line of reasoning in his proofs. In contrast to S10, he did not seem to indicate the written details. We note the quick shift in his statement from "answer" to the more proof-consistent term "justification."

If you're struggling with a [introduction to proof] *problem, and you figure out that the answer is, that the justification by this road is extraordinarily complicated, my first instinct is not to think, oh, this is a complicated problem. My first instinct is to think* *there's an easier way to solve it.*

Overall, we found that students carried over linguistic resources (e.g., key descriptive terms) from mathematics work that focused on producing numerical and symbolic answers to proof-writing—a task that most of them saw as quite different from computational work.

Reasoning in Writing Proofs

One central goal of our work is to characterize how students see and carry out the reasoning required to produce acceptable proofs in the course. Though we did not ask participating students to solve and explain their reasoning on particular proof tasks, their responses to some interview questions produced more general views of how they came to view proof reasoning from their experience with assigned homework and exams. Most students (n = 10) provided relatively specific descriptions of their proof-writing work and thinking; more limited responses of four others left us unable to characterize their thinking. The ten students' responses emphasized five different features of proof reasoning: (a) applying proof methods, (b) looking for and using examples and models, (c) accommodating to problem solving, (d) understanding central concepts, and (e) reasoning backwards and forwards. Most students described multiple features, so our analysis is not one-to-one.

Applying proof methods. Six students (S5, S7, S9, S10, S11, S13) cited learning specific proof methods and/or described the process of applying them. That six of ten did is not surprising given the very limited prior experience with proof that students reported. Four (S7, S9, S10, S11) cited particular methods (e.g., proof by contradiction or induction). S10 indicated she saw class activity as learning proof methods and applying them to concepts she had learned in prior courses. S5, S7, S11, and S13 described proof construction as selecting an initial method and re-examining that approach if it did not work well. These students came to see that, relative to prior computational work, selecting an appropriate proof method was not a deterministic procedure; it involved judgment. For that reason, some students indicated that selecting an initial method was problematic. S9 stated that exam problems were more difficult for her than homework problems because the latter frequently included explicit hints or problem features (e.g., the phrase "for all N" in the statement) that cued specific methods (in this case, induction). Some students developed beliefs or expectations about the relationship between statements and methods. For S7, there was no shortcut to the best method for a given problem because search involved the analytic work of surveying and assessing methods. As quoted above, S5 expressed a different stance on this issue. When the solution via one method became complicated, he inferred that a simpler solution was possible via another method. By the end of the course, he judged that most all course problems could be matched to "one best proof method."

Searching for and using examples and models. Three students (S7, S11, S13) reported that they adapted examples from class or searched for proofs to homework problems outside of class. This orientation was clearly related to what had proven productive in their prior mathematics work. S13 said that the instructor gave full proofs as examples in class. She put those next to her when she worked on homework and looked for ways to adapt their features to the assigned problems. S11 indicated he searched for solutions to exact or similar problems on the internet and was frequently "successful" in finding them.

Accommodating to problem solving. Four students (S2, S7, S11, S12) explicitly stated that step-by-step procedures generally did not work in proof-writing and came to embrace the view that proving involved problem solving. S11 indicated,

> *I mean, doing like calculus, you might not know you're doing it right but at least you're going through the steps. It's like a step by step. And this* [work in the introduction to

proof course]*, there are no steps. You just kinda think about it, work your way around it and finish off. If that makes sense.*

Despite its vagueness, this statement shows S11 was coping with the essentially non-procedural nature of proof reasoning. For S2, the "problematic" nature of proof-writing followed from the greater variation proof problems compared to prior courses. He said,

> *They could still ask you the same question but like based upon like what formula they give you or what kind of function they give you,* [the proof] *could be completely different.*

Understanding central concepts. Four students (S4, S5, S6, and S12) emphasized the importance of understanding the concepts that appear the statements to be proven. They did not mean simply accurately recalling the definition; they emphasized using the definitions effectively in proof work. S4, S6, and S12 described the ways they used concepts in their proof reasoning. To prove a given statement, they needed to recall formal definitions and fit them together conceptually to support their proof writing. S4 emphasized rapid and accurate access to definitions,

> *That's like the heart of math is you have to have your definition in order to go. I kind of always forget about them in my mind when I work through it. So I know what I'm doing at this point, but just to keep them always in the back of my mind like right there, to like always have it to recall.*

He worked on homework problems with the relevant definitions at hand in pursuit of the goal of being able to recall them on exams when needed. S12 and S6 both said that they could solve all the problems in their calculus courses using only rote learning, but the introduction to proof course was different. S12 stated directly,

> *So you really have to understand what's going on and why we use it [the concept] and what, what can we apply for, yes. So it's more like understanding for memorizing concepts.....*

Reason backwards and forwards. Two students (S5 and S10) described their proof reasoning in spatial and directional terms, as reasoning backwards and forwards. S10 described her proof-writing work in stages. First she had to work forward to "the final answer"—that is, using the assumed properties in the statement to produce the desired result. Then she indicated she reversed the direction of her reasoning to write the proof.

> *This is what I think I do differently completely, is you write the proof backwards.... Because you know that it's the right answer, you just did all the math, and you can clearly see that it's the right thing. But you can't just turn that in; that is not a proof.*

S5, by contrast, described his high-level forward reasoning that told him if his selected proof method was going to work. He indicated,

> *If there's anything that I took away from this class, it's that you can usually see how the problem is gonna go prior to actually starting the problem.*

His ability to "see" forward a considerable distance in his reasoning may have contributed to his inference that one best proof method existed for most course problems.

Specific Challenges and Learning Activities

The interviews revealed three major loci of students' learning activities: (a) in-class work (e.g., mini-lectures, class discussion, group work), (b) out-of-class work that was required (e.g., completing homework sets and reading quizzes that prepared for and extended work done in class), and (c) out-of-class work that was optional such as attending the Mathematics Learning Center (MLC) and instructor or TA office hours. The students described aspects of these zones of activities that were new to the course and interesting connections between them. New expectations of students' activities in class (e.g., serious engagement of all students in group work) influenced their work outside of class (e.g., going to the MLC to work with peers they got to know in their in-class work). And as was intended in the course design, new requirements of students outside of class (e.g., completing reading quizzes before related work in class) had implications for the work done in class.

Most students described the work required to be successful in the course as more demanding than it had been in prior courses. Some were primed for challenge by characterizations offered by friends who had already taken it. Once in the course, they found that the homework carried substantial value in the grading scheme and that completing each weekly set took substantially more time than it did in prior courses—often much more time. Most students offered estimates of seven to ten hours for each set, compared to one to two hours in prior courses. This increased "time on task" combined with the students' descriptions what they did in their proof work on homework problems (above) indicates the importance of homework as a site for understanding and navigating the new work that was expected of them.

All but two students explained that they employed different practices in organizing and completing their homework than they had in prior courses. In response to the demands of frequent and challenging homework, most indicated that they responded by starting earlier in the week and/or distributing the work across days. Four communicated with peers via e-mail, worked with a classmate, or asked questions in class for the first time in mathematics. Twelve described the importance of using the MLC—many for the first time—in interesting and diverse ways. Some cited the availability of tutors to answer their questions; others simply sought a physical space to go and work alone; others emphasized collaborative work with other students in the space designated for this course. For some (e.g., S10), productive discussion and community building happened with students from other sections of the course. That said, this use of social and peer resources was not universal; some students (e.g., S5) simply worked on their own, even as they worked harder and longer.

Sense of Success and Confidence Graph

When we asked about students' sense of success in the course, most responded in terms of their final grade. Less frequently, they assessed their level of understanding the content or their sense of having mastered it. For example, S7 stated that he felt he mastered "90% of the course content." As Table 1 indicates, half of the students received final grades of 4.0, and only one student received a 2.5. S1 reported that her 3.0 grade missed being a 3.5 by a single point. So overall, despite the new demands of the course, most of the 14 students were successful by the traditional measure of final grades.

In analyzing the Confidence Graphs, five general patterns of graphical shapes emerged, with two outliers. The most common pattern (n = 4) was a "W" shape that showed an initial decrease in confidence relatively early in the semester followed by increase, then decrease again, and a final increase. An example (from S3) is given in Figure 2. Though all four graphs of this type followed this shape pattern, the distances between the peaks and valleys varied. The other groupings included two student graphs each and were characterized by (a) continuous increase, (b) concave up parabolic shaped graph, (c) initial increase followed by a sinusoidal wave for the rest of the semester, (d) initial increase followed by decrease, with a final confidence level that was lower than their initial level, and (e) other.

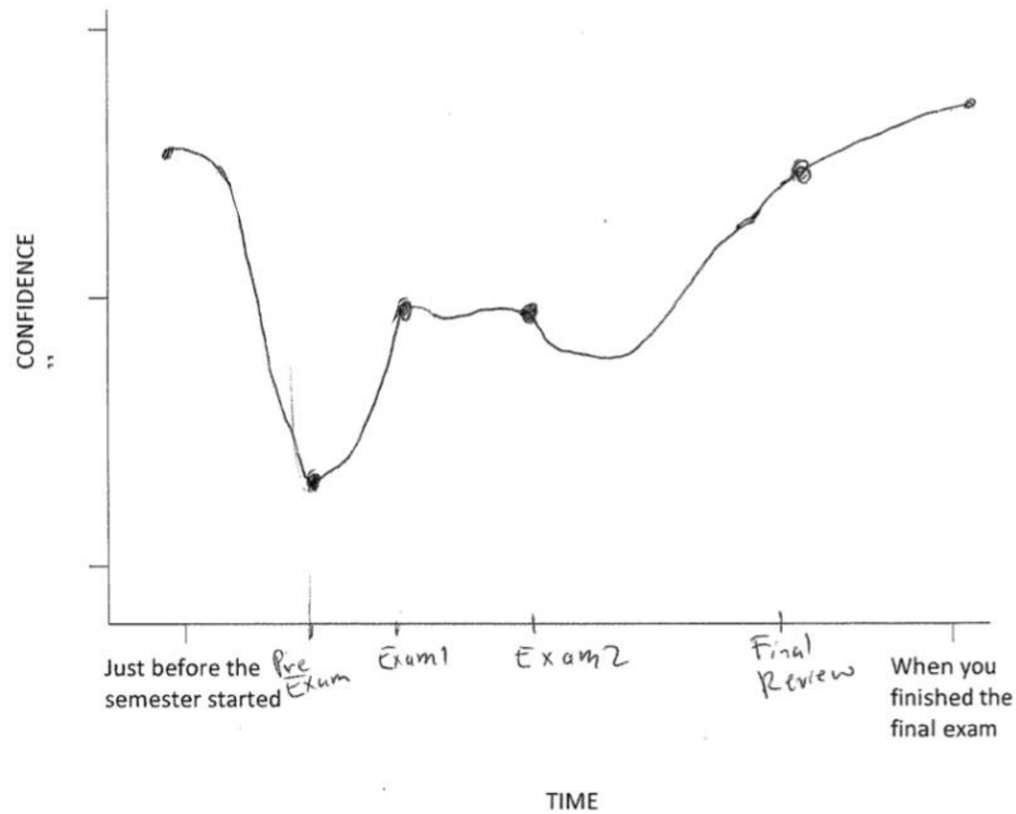

Figure 2. S3's Confidence Graph.

After analyzing the graphs by shape, we examined the drawings and the transcripts of students' descriptions of what they drew and tabulated the reasons given for initial confidence level and for factors that increased or decreased confidence thereafter. Consistent with how they described their sense of success in the course generally, most students (n = 12) identified grades (on homework and exams) as the principal causes of increases or decreases in their confidence. Many, like S3 above, located course exams as the X-coordinates of relative maxima or minima on their graphs. But when students explained what they had drawn, other factors emerged as important influences on confidence levels through our analysis of the transcripts.

Most students began at a confidence level near the middle marking on the y-axis, and described an uncertainty about what to expect in the course. Some who began at a low point or at y = 0 had heard the class was difficult. Some who started closer to the highest mark on the y-axis indicated either a strong belief in their mathematical ability or a favorable result in a prior course as orienting their initial confidence. The most commonly cited factors for increased confidence that were not grade-based were finding help in the MLC (n = 5), spending extra time studying and practicing (n = 4), and realizing a sense of understanding of the course content during the two weeks of review before the final exam (n = 4). For decreases, five students indicated that the real analysis portion of the course led them to feel less confident. Others alluded to personal reasons such as illness or missing classes, difficulty keeping up with the pace of the course, or proving in general as reasons for lowered confidence. Overall, their activity proved fruitful not only because it produced a representation of students' confidence over the duration of semester, but also because it then provided a visual focus for students to explain what aspects of the course and their work in it most affected their confidence.

Conclusions, Limitations, & Next Steps

Our research is ongoing, and we expect that subsequent steps will deepen and refine our understanding of students' experience in this course, and for those who enroll in more advanced courses, their further progress in the transition to proof. But the present analysis has been revealing, and in some unexpected ways. We first summarize our main findings.

First, we find substantial evidence that the transition to proof course "moved" students in two substantive and productive ways. It has placed them in the "space" of mathematical problem solving and thereby altered their views of competence in mathematics (augmenting, if not displacing a primarily computational view). Changing the nature of tasks from computing to proving substantially shifted mathematical work from "exercises" to real problems—that is, to tasks that for most students suggested no immediately obvious means of solution. In that sense, the course "successfully" created an environment where we could examine the birth of "new" (for students) forms of mathematical thinking and thereby students' sense of what is involved in that transition.

Second, in these initial steps to chart their transitions, we have identified aspects of cognitive continuity where students have reused or adapted aspects of their prior work in mathematics to work with proof. Many used prior computationally-oriented words to describe elements of their "new" mathematics work (e.g., "answer"), despite what many would see as strong differences in context. Some adapted prior patterns of finding solutions to work on proof tasks (e.g., finding or adapting examples and models). Many spoke to the difficulty of adjusting away from their past patterns of looking for a procedure or model solution to use to complete proof tasks on homework. These results are reminders that students try to extend the use of prior resources that have proven productive in the past even when they fit poorly or even forestall progress in mastering new challenges.

Third, where we found substantial commonality in how students saw the course as different from prior work in mathematics courses, we found considerable diversity their descriptions of their work to produce acceptable proofs. Some highlighted proof techniques (learning a set of generally-applicable proof methods); some focused on the necessary and productive focus on understanding the meaning of key concepts in the statement; some described a process of considering a top-level view of a series of steps in the proof—either forward or backward from the result. We do not suggest that course design and teaching should explicitly address one or another these top-level descriptions of proof reasoning, rather that course design and teaching practices can be usefully informed by them.

This study complements prior work that has focused on students' reasoning on specific problem-based tasks—typically proof construction and evaluation (Alcock & Weber, 2010; Selden & Selden, 2003). In targeting students' experience over the course of a semester, we have focused on more general issues, especially how students see their proof work and how they reorganize their learning to address the new challenge. These issues are important foci for all efforts to assist students in entering and succeeding in this fundamental new (for them) form of mathematical thinking. In particular, it informs the design of learning spaces that can support students' work outside of class (e.g., mathematics learning or help centers and how work is organized in these environments).

We see three main limitations in our work thus far, two of which concern our sample. Generally speaking, we do not know how well these fourteen students represent the range of experiences in the larger population of students who took the course that particular semester.

Second and more specifically, we are concerned that our sample was weighed too heavily toward successful students. Such students seemed to welcome the chance to describe their experience; less successful students, we think, are much less so. We need to find ways to reach those students—those who may have good reasons not to revisit a painful experience. Third, our interviews have sometimes posed questions that students have struggled to understand and respond to, for many reasons. The Confidence Graph activity and talk arising from it was a productive addition in that respect. It was accessible, reframed the issues under study, and produced many fluent explanations. We (and other researchers) should explore other such "stimuli" that may productively support students' efforts to recount their experience.

The most important next step in our research is to interview graduates of the course who are enrolled in subsequent proof-intensive courses, principally abstract algebra and real analysis. (An intervening linear algebra course mixes computational and proof-based work.) In the context of those two courses, we want to explore students' assessments of how well their introduction to proof course has supported their current proof writing work. We expect "mixed" and (we hope) rich stories of their continued journey as proof-writers and mathematical problem solvers. Second, we plan for more detailed analysis of the Confidence Graph data (graphical and verbal) in the goal of revealing more clearly how students experience and manage particular challenging events or periods of time in the course.

Knowledge about Student Understanding of Eigentheory: Information Gained from Multiple Choice Extended Assessment

Kevin Watson — Virginia Tech
Megan Wawro — Virginia Tech
Michelle Zandieh — Arizona State University
Sarah Kerrigan — Virginia Tech

Eigentheory is a conceptually complex idea whose application is widespread in mathematics and beyond. Herein we describe the development and use of an extended multiple choice assessment that gives us further insight into the ways students think about and understand eigenvectors, eigenvalues, and their related concepts.

Key words: linear algebra, eigenvector, eigenvalue, student understanding, assessment

The purpose of this report is to share results regarding student understanding of eigentheory that were gained from a multiple choice extended assessment instrument. We chose to focus on eigentheory because (a) it is a conceptually complex idea that builds from and relies upon student understanding of multiple key ideas in mathematics, and (b) its application is widespread in mathematics and beyond. Our aim to create an assessment instrument that captures nuances of students' conceptual understanding of eigentheory exists in tandem with our pursuit to frame what it might mean to have a deep understanding of eigentheory. As such, in this report we offer results both about student thinking and about possible affordances and constraints of various assessment instrument question formats.

Background and Literature

Research into people's understanding of eigenvectors and eigenvalues has had several different foci**,** such as: (a) using Tall's (2004) three worlds of mathematical thinking in conjunction with APOS theory (Dubinsky, 1991; Cottrill et al., 1996; Dubinsky & McDonald, 2001) to examine students' abilities to think about eigentheory in the embodied, symbolic, and formal worlds, and identify the various processes and objects students need to understand in eigentheory (Stewart & Thomas, 2006; Thomas & Stewart, 2011); (b) studying how mathematicians use gesture, time and motion to describe the concepts of eigenvector and eigenvalue (Sinclair & Gol Tabaghi, 2010); (c) examining how dynamic geometry software can encourage students to think geometrically about eigentheory (Gol Tabaghi & Sinclair, 2013); and (d) investigating the use of modeling problems and APOS theory to teach students the concepts of eigenvectors and eigenvalues (Salgado & Trigueros, 2015). Our current research into students' understanding of eigenvectors and eigenvalues has been influenced by the above work, but we endeavor to extend this growing body of knowledge in two ways. First, we hope to share further insights into how students think about and understand eigenvectors and eigenvalues that has not been reported on previously. Second, we are working towards the development of a framework for student understanding of eigentheory that both ties together the work others have done in this area of research, and adds our own insights on student understanding of eigentheory. We further discuss this framework within the next section.

Theoretical Framework

There exists a small collection of previous research into students' understanding of eigentheory that has worked towards developing a theoretical framework for what it means to have a deep understanding of eigenvectors and eigenvalues (Salgado & Trigueros, 2015; Thomas

& Stewart, 2011). These articles point out useful distinctions, including the processes, objects, and coordinations necessary for understanding eigentheory. As we refine our framework for student understanding of eigentheory, we aim to include the following ideas: (a) a distinction between the equations $A\boldsymbol{x} = \lambda\boldsymbol{x}$ and $(A - \lambda I)\boldsymbol{x} = \boldsymbol{0}$ and how these can influence the ways students think about and solve problems involving eigenvectors and eigenvalues; (b) the importance of eigenspaces, diagonalization, and their connection to the concepts of eigenvectors and eigenvalues; (c) how the concepts of eigentheory can be thought of within different modes of thinking (Sierpinska, 2000), modes of description (Hillel, 2000), or contexts (Zandieh, 2000); and (d) the various processes (e.g., matrix multiplication, scalar multiplication), entities (e.g., matrices, vectors), and theorems (e.g., the invertible matrix theorem) needed to understand eigentheory and the calculations involved therein. While this framework is still under development, it informed our decisions about the creation and refinement of the assessment instrument, and, cyclically, the results of the assessment continue to inform the development of the framework. We describe the assessment more fully in the following section.

Methods

In this section, we describe the development and format of our multiple choice extended (MCE) assessment instrument. We then describe the data collection and participants for this study, followed by a description of our analysis.

Instrument Development

The MCE assessment instrument for eigentheory development grows from our prior work in student understanding of span and linear independence in which we developed the MCE-style question format (Zandieh, Plaxco, Wawro, Rasmussen, Milbourne, & Czeranko, 2015). During this development, we considered literature on conceptually oriented assessment instruments in undergraduate mathematics and physics (Bradshaw, Izsak, Templin, J. & Jacobson, 2013; Carlson, Oehrtman, & Engelke, 2010; Epstein, 2013; Hestenes, Wells, & Swackhamer, 1992; Wilcox & Pollock, 2013). Questions written in an MCE style begin with a multiple choice element and then prompt students to justify their answer by selecting all statements that could support their choice, a format based on a concept inventory in Upper-division Electrostatics created by Wilcox and Pollock (2013).

To develop the assessment instrument questions for the Eigentheory MCE, we compiled a database of questions about eigenvectors, eigenvalues, and related concepts from literature on student understanding of eigenvectors and eigenvalues, online resources for clicker and classroom voting on linear algebra (Cline & Zullo, 2016), and previous linear algebra homework assignments, exams, and interview protocols used by research team members (e.g., Henderson, Rasmussen, Sweeney, Wawro, & Zandieh, 2010). The most promising questions that collectively addressed various aspects of our working framework were edited into the MCE format. The instrument has been administered in two sets of student interviews, as written homework, and as an in-class review activity, with subsequent refinements of the assessment after each administration. The most recent revision was also administered as written homework in Fall 2016. This current report relies on the administration of the assessment as an in-class review activity, described in further detail below.

Data Collection

We present data from written assessments collected from three introductory linear algebra classes taught by the same instructor at a large, research-intensive public university in the mid-Atlantic United States during Spring Semester 2016. The course utilized the Inquiry-Oriented Linear Algebra (IOLA) curricular materials. The materials, which are available at http://iola.math.vt.edu, contain three main units: Linear Independence and Span (Wawro, Rasmussen, Zandieh, Sweeney, & Larson, 2012), Matrices as Linear Transformations (Andrews-Larson, Wawro, & Zandieh (2017), and Change of Basis, Diagonalization, and Eigentheory (Zandieh, Wawro, & Rasmussen, 2017). The course also used Lay (2012) as its textbook.

Each class worked on one version of the MCE assessment (described in the following paragraph) during the last day of class as a review of eigentheory. Students took the assessment individually for 20-25 minutes, following which the instructor collected the assessments, and then held whole class discussions on the problems. This report focuses on the collected individual work.

All three versions of the MCE assessment consisted of the same six multiple choice question elements, with varying justification sections. Class 1 (27 students) received a version in which students indicated if each of six given justifications were true and relevant, true but not relevant, or false (see Figure 1a). Class 2 (29 students) received a version in which students only selected justification choices that were true and relevant (see Figure 1b). Lastly, Class 3 (28 students) received an open-ended version in which they wrote their own justification for their choice.

1. The matrix $A = \begin{bmatrix} -2 & 4 \\ 2 & 5 \end{bmatrix}$ has $\lambda = 6$ as one of its eigenvalues. Which of the following vectors is an eigenvector of A with corresponding eigenvalue $\lambda = 6$?

(a) $\boldsymbol{x} = \begin{bmatrix} 4 \\ -1 \end{bmatrix}$ **CORRECT→** (b) $\boldsymbol{x} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$

Because … (indicate if the choice is true and relevant, true but not relevant, or false)

True & relevant	True not relevant	False	Statement
			(i) This vector $\boldsymbol{x}$ makes $A\boldsymbol{x} = 6\boldsymbol{x}$ a true statement.
			(ii) This vector $\boldsymbol{x}$ is the only vector in $\mathbb{R}^2$ for which $A\boldsymbol{x} = 6\boldsymbol{x}$.
			(iii) This vector $\boldsymbol{x}$ makes $(A - 6I)\boldsymbol{x} = \boldsymbol{0}$ a true statement
			(iv) Subtracting 6 from the diagonal of A yields this vector $\boldsymbol{x}$ as a column vector of the resulting matrix.
			(v) The vector $A\boldsymbol{x}$ is 6 times the magnitude and in the same direction as this vector $\boldsymbol{x}$.
			(vi) The matrix A also has $\lambda = -3$ as an eigenvalue.

(a)

1. The matrix $A = \begin{bmatrix} -2 & 4 \\ 2 & 5 \end{bmatrix}$ has $\lambda = 6$ as one of its eigenvalues. Which of the following vectors is an eigenvector of A with corresponding eigenvalue $\lambda = 6$?

(a) $\boldsymbol{x} = \begin{bmatrix} 4 \\ -1 \end{bmatrix}$ **CORRECT→** (b) $\boldsymbol{x} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$

Because … (select ALL that could justify your choice)

(i) This vector $\boldsymbol{x}$ makes $A\boldsymbol{x} = 6\boldsymbol{x}$ a true statement.

(ii) This vector $\boldsymbol{x}$ is the only vector in $\mathbb{R}^2$ for which $A\boldsymbol{x} = 6\boldsymbol{x}$.

(iii) This vector $\boldsymbol{x}$ makes $(A - 6I)\boldsymbol{x} = \boldsymbol{0}$ a true statement

(iv) Subtracting 6 from the diagonal of A yields this vector $\boldsymbol{x}$ as a column vector of the resulting matrix.

(v) The vector $A\boldsymbol{x}$ is 6 times the magnitude and in the same direction as this vector $\boldsymbol{x}$.

(vi) The matrix A also has $\lambda = -3$ as an eigenvalue.

(b)

Figure 1. Comparison of (a) Class 1 MCE (3-Choice MCE) and (b) Class 2 MCE (Basic MCE).

By comparing performance on a measure independent of the items under investigation, namely the results of a class exam on eigentheory concepts given by the instructor (see Table 1), we can determine if the students in the three classes are of comparable ability. To do so, we ran a 1-way ANOVA looking for group variation on this data. The results of that analysis reveal there is no significant difference between the groups (F = 1.3075, p = .2761) and no post-hoc comparisons were necessary. Thus we can reasonably assume that the three sub-samples are of roughly equal ability and superior ability of a particular group will not bias the results in favor of one form of the 6-item assessment.

Table 1

Summary of Student Performance on a Class Exam on Eigentheory Material Given by Instructor (Independent of Researchers)

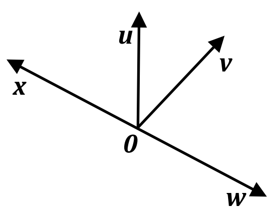
	Class 1	Class 2	Class 3	Overall
Average Score	*82.4*	75.9	80	79.4
Standard Deviation	*15.7*	13.7	16.3	15.5
Median Score	*88*	75.5	82.5	82

Analysis

After each class's written assessments were digitally scanned and grouped by question, spreadsheets were designed to enter the data from Class 1 and Class 2. Using the spreadsheets, the research group examined trends among student responses, which included looking for: (a) common sets of justifications that students selected or did not select; (b) how selecting certain justifications may have influenced students' multiple choice selection; and (c) instances where we would have expected students to select what we viewed as related justifications, but they did not. To help with comparisons and identifying these trends, some basic percentages were calculated for the justification choices of students in Classes 1 and 2.

2. Suppose the vector $\boldsymbol{x} \in \mathbb{R}^2$, in the two-dimensional sketch below, is an eigenvector of a 2x2 matrix M with real-valued eigenvalues. Which of the vectors $\boldsymbol{u}, \boldsymbol{v}$ or $\boldsymbol{w}$ illustrated below could be the result of the product $M\boldsymbol{x}$?

(a) $\boldsymbol{u}$
(b) $\boldsymbol{v}$
(c) $\boldsymbol{w}$ ←**CORRECT**
(d) Not enough information is given to know a possible result of the product $M\boldsymbol{x}$



Because … (select ALL that could justify your choice)

(i) This vector is on the same line as $\boldsymbol{x}$.

(ii) This vector and $\boldsymbol{x}$ form a linearly independent set.

(iii) This vector is in $span\{\boldsymbol{x}\}$.

(iv) This vector is a scalar multiple of $\boldsymbol{x}$.

(v) The matrix M needs to be known to determine what $M\boldsymbol{x}$ could be.

(vi) There exists a scalar c such that $M\boldsymbol{x} = c\boldsymbol{x}$.

3. Suppose A is a $n \times n$ matrix, and $\boldsymbol{y}$ and $\boldsymbol{z}$ are linearly independent eigenvectors of A with corresponding eigenvalue 2. Let $\boldsymbol{v} = 5\boldsymbol{y} + 5\boldsymbol{z}$. Is $\boldsymbol{v}$ an eigenvector of A?

(a) Yes, $\boldsymbol{v}$ is an eigenvector of A with eigenvalue 2. ←**CORRECT**
(b) Yes, $\boldsymbol{v}$ is an eigenvector of A with eigenvalue 5.
(c) No, $\boldsymbol{v}$ is not an eigenvector of A.

Because … (select ALL that could justify your choice)

(i) $\boldsymbol{v}$ is a linear combination of eigenvectors that have the same eigenvalue.

(ii) The set $\{\boldsymbol{v}, \boldsymbol{y}, \boldsymbol{z}\}$ is linearly dependent.

(iii) A linear combination of eigenvectors does not result in another eigenvector

(iv) $A\boldsymbol{v} = A(5\boldsymbol{y} + 5\boldsymbol{z}) = 5A\boldsymbol{y} + 5A\boldsymbol{z} = 5 \cdot 2\boldsymbol{y} + 5 \cdot 2\boldsymbol{z} = 2(5\boldsymbol{y} + 5\boldsymbol{z}) = 2\boldsymbol{v}$.

(v) $\boldsymbol{v}$ is an element of the eigenspace created by the vectors $\boldsymbol{y}$ and $\boldsymbol{z}$.

(vi) $A\boldsymbol{v} = A(5\boldsymbol{y} + 5\boldsymbol{z}) = 5A\boldsymbol{y} + 5A\boldsymbol{z} = 5 \cdot 2\boldsymbol{y} + 5 \cdot 2\boldsymbol{z} = 5(2\boldsymbol{y} + 2\boldsymbol{z}) = 5\boldsymbol{v}$.

Figure 2. Questions 2 and 3 of the Eigentheory MCE.

The open-ended data were analyzed through multiple iterations of open coding. First, each team member individually summarized the key aspects of each student's justification process. Next, the team came together to develop a coding scheme for the student work to be used in the second iteration of coding. Each team member then individually coded the student responses with the new coding scheme before collectively determining a set of codes for each student. Lastly, the larger themes from the finalized coding were identified by examining common patterns across multiple students' solutions and justifications.

Based upon the patterns and trends found in Classes 1 and 2, as well as common student justifications in Class 3, the next step of our analysis involved the creation of a type of “conditional table” for all three classes on specific justification and multiple choice comparisons. We give further explanation of these tables in the results below as they facilitate making comparisons across classes. In this report, we focus on the first three questions from the assessment (see Figures 1 and 2), with plans to analyze all six later.

Results

Table 2 shows the general performance of the three classes on the multiple choice portion of the three questions. We make a few observations. First, classes performed similarly on all three questions, further supporting the reasonableness of comparing across them. Second, Question 1 and Question 2 may seem somewhat uninformative because a majority of the students chose the correct answer. However, in the results and discussion to follow, we share how the MCE gives more information about student thinking through the justification portion of each question. Third, as evidenced by the results on Question 3, linear combinations of eigenvectors with the same eigenvalue, in other words, elements of an eigenspace, is a difficult topic. We first share insights into students’ thinking about eigentheory we gained from each individual question, and then explain some of the overarching insights gained by looking across questions in the discussion.

Table 2
Class Percentages for Answers Chosen on the Multiple Choice Portion

		Class 1 Judgment MCE (27 Students)	Class 2 Original MCE (29 Students)	Class 3 Open-Ended (28 Students)	Overall (84 Students)
Question 1	*Choice (a)*	14.8 (4)	24.1 (7)	7.1 (2)	15.5 (13)
	Choice (b)	81.5 (22)	75.9 (22)	92.9 (26)	83.3 (70)
	No Answer	3.7 (1)	0.0	0.0	1.2 (1)
Question 2	*Choice (a)*	0.0	0.0	0.0	0.0
	Choice (b)	0.0	6.9	0.0	2.4 (2)
	Choice (c)	92.6 (25)	82.8 (24)	96.4 (27)	90.5 (76)
	Choice (d)	3.7 (1)	10.3 (3)	3.6 (1)	6.0 (5)
	No Answer	3.7 (1)	0.0	0.0	1.2 (1)
Question 3	*Choice (a)*	25.9 (7)	48.3 (14)	21.4 (6)	32.1 (27)
	Choice (b)	3.7 (1)	6.9 (2)	17.9 (5)	9.5 (8)
	Choice (c)	55.6 (15)	31.0 (9)	57.1 (16)	47.6 (40)
	No Answer	14.8 (4)	13.8 (4)	3.6 (1)	10.7 (9)

NOTE: Correct answers are shaded. Grey numbers in parentheses are the number of students.

Question 1

Recall that the main prompt for Question 1 required students to determine which given vector was an eigenvector for $\lambda = 6$ for a given matrix A (Figure 1). From among the provided justifications that support a correct answer, students were able to choose “(i) this vector makes $A\boldsymbol{x} = 6\boldsymbol{x}$ a true statement” or “(iii) this vector makes $(A - 6I)\boldsymbol{x} = \boldsymbol{0}$ a true statement.” First, we consider the open-ended responses to Question 1 from Class 3 to determine if students, of their own accord, explicitly wrote some form of $A\boldsymbol{x} = 6\boldsymbol{x}$ or $(A - 6I)\boldsymbol{x} = \boldsymbol{0}$ within their justifications. In Figure 3, we provide three examples of student responses: one that included both equations (Figure 3(a)), one that utilized $A\boldsymbol{x} = \lambda\boldsymbol{x}$ to arrive at the solution (Figure 3(b)), and one that utilized $(A - \lambda I)\boldsymbol{x} = \boldsymbol{0}$ to arrive at the solution (Figure 3(c)). In Figure 3(a), the student’s response explained how solving for $\boldsymbol{x}$ in $(A - \lambda I)\boldsymbol{x} = \boldsymbol{0}$ could be derived from $A\boldsymbol{x} = \lambda\boldsymbol{x}$, and the goal is to find the $\boldsymbol{x}$ that makes that equation true. The approach in Figure 3(b) started with $A\boldsymbol{x} = \lambda\boldsymbol{x}$, substituted in the provided matrix A and the two options for the eigenvector $\boldsymbol{x}$, and carried out the computations to determine that the vector in option (b) was an eigenvector of A associated with the eigenvalue 6. The response in Figure 3(c) began with $(A - \lambda I)\boldsymbol{x} = 0$, converted it to an augmented matrix, found a general solution of $x_1 = 0.5x_2$, and determined that the vector in option (b) satisfied that relationship. We offer these examples as prototypes for the kinds of justifications students gave of their own accord in response to this problem, as well as illustrations of students' use of different solution strategies in conjunction with the eigen-equation they wrote down.

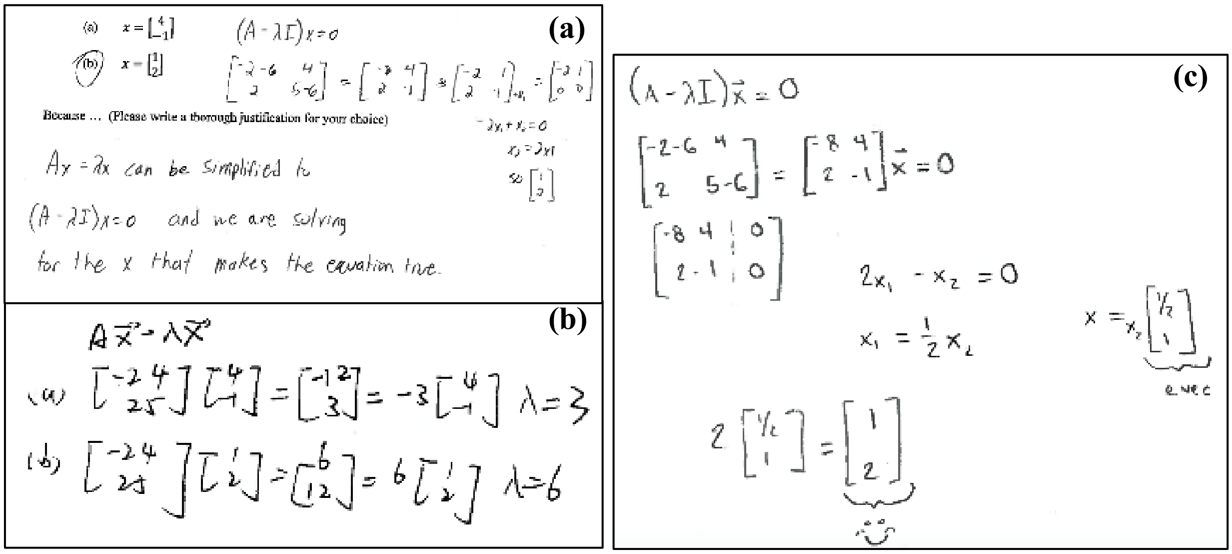


Figure 3. Three examples of open-ended justifications for Question 1.

Next, we analyze student responses from Class 1 and Class 2 in regard to their selection of justifications (i) and (iii), along with the eigen-equations Class 3 students explicitly wrote in their justifications**.** We organize this information in a format consistent with conditional tables in Figure 4, and we reuse this format throughout the paper in Figures 5, 7-9, and 11. We explain Figure 4 in detail here to familiarize the reader with the information contained in these conditional tables. Across the top of Figure 4 is justification (iii), and down the left side is justification (i). Every cell within the tables indicates the number of students who fall in that category (bold number), and gives a breakdown of their multiple choice answers (correct answer italicized). The leftmost section of Figure 4 provides information about the number of students in Class 2 that chose either, both, or neither of statements (i) and (iii). The cell in the first column and first row indicates that 23 students selected both statements as supportive of their conclusion, with 19 of them correctly choosing (b) as the solution to the main problem; 4 students selected (iii) but did not select (i), of which 1 correctly chose (b); one selected (i) but not (iii) and correctly chose (b); and one chose neither (i) nor (iii) and correctly chose (b).

(iii) This vector $\boldsymbol{x}$ makes $(A - 6I)\boldsymbol{x} = \boldsymbol{0}$ a true statement

(i) This vector $\boldsymbol{x}$ makes $A\boldsymbol{x} = 6\boldsymbol{x}$ a true statement

Figure 4. Comparing students' distinction between $A\boldsymbol{x} = 6\boldsymbol{x}$ and $(A - 6I)\boldsymbol{x} = \boldsymbol{0}$ on Question 1.

The center section of Figure 4 provides information about the number of students in Class 1 that thought statements (i) and (iii) were true and relevant, true but not relevant, or false in terms of supporting their conclusion to the main problem. The cell in the first column and first row indicates that 23 students selected both statements as true and relevant, with 19 of them correctly choosing (b) as the solution to the main problem; 3 students indicated that statement (iii) was true but not relevant and statement (i) was true and relevant in supporting their solution, with all 3 correctly choosing (b); and 1 student indicated that (iii) was true and relevant, statement (i) was true but not relevant, and correctly chose (b).

Finally, the rightmost section of Figure 4 provides information about the number of students in Class 3 that explicitly wrote within their justifications either, both, or neither of the equations $(A-6I)\boldsymbol{x}=\boldsymbol{0}$ (indicated across the column) or $A\boldsymbol{x}=6\boldsymbol{x}$ (indicated across the row) in some form. The cell in the first column and first row indicates that 4 students wrote forms of both equations, with 3 correctly choosing (b) as the solution to the main problem; 10 students wrote an equation of the form $(A-6I)\boldsymbol{x}=\boldsymbol{0}$ but not $A\boldsymbol{x}=6\boldsymbol{x}$, with all 10 correctly choosing (b); 4 students wrote an equation of the form $A\boldsymbol{x}=6\boldsymbol{x}$ but not $(A-6I)\boldsymbol{x}=\boldsymbol{0}$, with all 4 correctly choosing (b); and ten students did not explicitly write some form of either equation, with 9 correctly choosing (b). We recognize, however, that students may have been thinking about one or both equations without explicitly including them in their written justification.

Comparing across the three classes produces an interesting insight. When students are asked to write their own justification (Class 3), a majority explicitly write only one of the eigen-equations, and quite a few write neither. However, when students are forced to consider the truth and relevance of the two equations contained in justifications (i) and (iii), the large majority are able to see both as true and relevant. Thus, it seems most students understand the importance and relevance of the two equivalent eigen-equations. Furthermore, the versions of the MCE that give students closed-ended justification choices (Basic MCE and 3-Choice MCE) might actually give more insight into students' understanding of eigentheory than the open-ended justification version.

(v) The vector $A\boldsymbol{x}$ is 6 times the magnitude and in the same direction as this vector $\boldsymbol{x}$

(i) This vector $\boldsymbol{x}$ makes $A\boldsymbol{x}=6\boldsymbol{x}$ a true statement OR (iii) This vector $\boldsymbol{x}$ makes $(A-6I)\boldsymbol{x}=\boldsymbol{0}$ a true statement

Figure 5. Comparing students' Algebraic vs. Geometric Justifications on Question 1.

We now look at students' judgment of the truth and relevance of geometric justifications on Question 1. Looking at the rows in Figure 5, we see that a large majority of students selected or wrote at least one of the eigen-equations, a compilation of the results from Figure 4. However, looking across the columns in Class 1 and Class 2, we see that a large number of students did not see the geometric justification (v) as relevant to answering Question 1 (15/29 students in Class 2, and 9/27 students in Class 1); indeed, there were even five students in Class 1 who said this justification was false. Even more striking, no students in Class 3 wrote anything geometric in their justifications. This might indicate students tend to think about eigenvectors and eigenvalues symbolically more than geometrically, or students may see symbolic reasoning as the more acceptable justification to the teacher or the broader math community.

Question 2

Students' geometric understanding of eigentheory was further explored in the results of Question 2. When looking at open-ended justifications from Class 3, two of the most common justifications students gave mentioned the result of the product being on the same line as the eigenvector $\boldsymbol{x}$, or being a scalar multiple of $\boldsymbol{x}$. We share three prototypical examples of students' justifications in Figure 6. The student in Figure 6(a) stated that the product should be a scalar

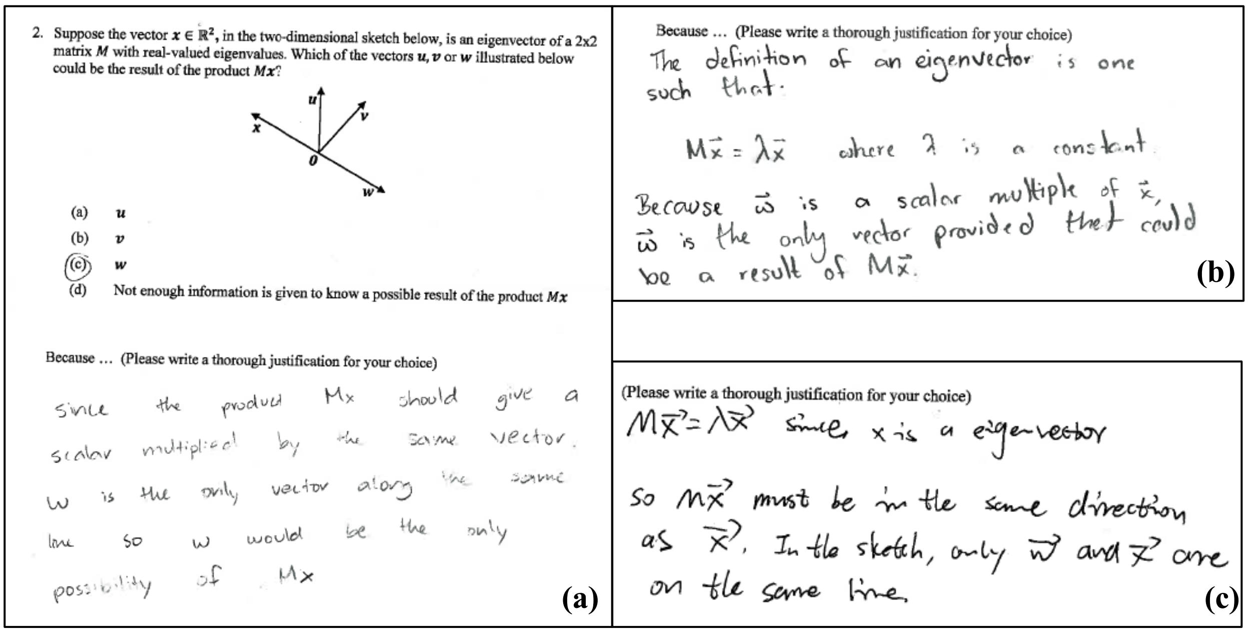

Figure 6. Example of three students' open-ended justifications for Question 2

multiple of the eigenvector, as well as on the same line; the student in 6(b) used the equation $\boldsymbol{Mx} = \lambda\boldsymbol{x}$ to argue why the product would need to be a scalar multiple of $\boldsymbol{x}$; and the student in Figure 6(c) explained how the product should be in the same direction and on the same line as the eigenvector $\boldsymbol{x}$. When we consider how students selected the related justifications (i) and (iv) on the Basic MCE and 3-Choice MCE (see Figure 7), it becomes clear that these ideas of the result being on the same line as $\boldsymbol{x}$ or a scalar multiple of $\boldsymbol{x}$ were seen by students as particularly relevant; more specifically, a majority of students in all classes selected or wrote at least one of these ideas, and in Classes 1 and 2, most students selected both justifications (i) and (iv) as true

(iv) This vector is a scalar multiple of $\boldsymbol{x}$

(i) This vector is on the same line as $\boldsymbol{x}$

Figure 7. Student justifications that included "scalar multiple" or "on the same line" for Q2.

and relevant. These results indicate the importance of having these justifications on the MCE instrument. Furthermore, we again wish to point out that when students write their own justifications, a large majority do not write down both ideas; but, when students are forced to consider the truth and relevance of these ideas, most select both as true and relevant. Hence, we are able to see deeper into students' understanding of eigentheory through the MCE instrument than we would through only the open-ended assessment.

An eigentheory expert might expect a similar majority of students to also select justification choice (iii) "This vector is in span$\{\boldsymbol{x}\}$" as true and relevant, since justifications (i), (iii), and (iv) could be seen as closely related. However, the results from the three classes tell a different story (see Figure 8). Looking at Class 3, we see that this concept was not something students readily volunteered as a justification, as only two students mentioned anything about span in their open-ended response. In Class 2, 16 of the 29 students did not select justification choice (iii) as true and relevant, but we cannot be sure why they did not select it. Did they think it was false, or just not relevant? The results from Class 1 may be the most illuminating, as no student said that justification choice (iii) was false, showing they understand that the result would be in span$\{\boldsymbol{x}\}$, but 10 of the 28 students said it was not relevant. Hence, although an expert might see justifications (i), (iii), and (iv) as closely related, for some students span was not relevant to answering this particular eigentheory question.

(iii) This vector is in span$\{\boldsymbol{x}\}$

(i) This vector is on the same line as $\boldsymbol{x}$

Question 3

As mentioned previously, students' response to Question 3 varied greatly across all three classes, suggesting this question was more difficult for students than the first two. Because of the varied response on the multiple choice portion, we looked at the relationship between students' multiple choice selection and particular justification choices. In Figure 9, we examine the relationship between students' multiple choice selection and justification (iv) "$A(5\boldsymbol{y}+5\boldsymbol{z}) = 5A\boldsymbol{y}+5A\boldsymbol{z} = 5\cdot 2\boldsymbol{y}+5\cdot 2\boldsymbol{z} = 2(5\boldsymbol{y}+5\boldsymbol{z}) = 2\boldsymbol{v}$". For Class 1 and Class 2, students who

Multiple Choice Answer

(iv) $A(5\boldsymbol{y}+5\boldsymbol{z}) = 5A\boldsymbol{y}+5A\boldsymbol{z} = 5\cdot 2\boldsymbol{y} + 5\cdot 2\boldsymbol{z} = 2(5\boldsymbol{y}+5\boldsymbol{z}) = 2\boldsymbol{v}$

Figure 9. Comparing students' multiple choice response to selection of justification (iv)

selected justification (iv) as true and relevant were more likely to select the correct multiple choice answer *A*. We note that in the open-ended responses, this was not the case; in fact, the majority of students in Class 3 did not write anything algebraic. Furthermore, Class 3 had the lowest percentage get the multiple-choice stem correct. From this result, there is a real possibility that having a correct string of algebra provided as a justification choice led the students in Classes 1 and 2 to the correct multiple choice answer. However, in some sense, it might be considered a good thing that students were able to recognize the algebraic string as correct and understand how this supports selecting the correct multiple choice answer. Considerations will need to be made on whether or not this justification is too leading for future use on the Eigentheory MCE.

To further explore why this question was particularly difficult for students, we examined the open-ended student responses to Question 3, where students used the concepts of linear combination and eigenspace in support of both correct and incorrect multiple choice answers. In Figure 10, we share examples of students using these concepts in their justification, but arriving at different conclusions. The two leftmost students both mentioned $\boldsymbol{v}$ being a linear combination of eigenvectors, but arrived at opposite answers, with one saying $\boldsymbol{v}$ would be an eigenvector, and the other saying $\boldsymbol{v}$ would not. Similarly, the two rightmost students both gave justifications that could be seen as involving eigenspace, but came to opposite conclusions, with the student on the far right mentioning that an infinite number of eigenvectors "doesn't make sense."

v is a linear combination of y and z which have the same eigenvalue.	No, because v is a linear combination of the two vectors.	v is in the eigenspace of both y and z	Multiplying the linearly independent eigenvectors by 5 makes them linearly dependent technically you could multiply the eigenvectors by any number and if you did so and another eigenvector was achieved there would be a possibility for infinite eigenvectors which doesn't make sense
Linear Combination Correctly chose (*A*)	Linear Combination Incorrectly chose (*C*)	Eigenspace Correctly chose (*A*)	Eigenspace Incorrectly chose (*C*)

NOTE: Typed versions are used here to improve readability of students' handwritten justifications

Figure 10. Example of four students' open-ended justifications for Question 3

Students' difficulty with these concepts is further supported when comparing their selection of justifications (i) and (v) found in Figure 11. Classes 1 and 2 each had a majority of students select at least one justification as true and relevant; however, students used these same justifications in support of different multiple choice answers. From Class 3, we notice that this is

(v) $\boldsymbol{v}$ is an element of the eigenspace created by the vectors $\boldsymbol{y}$ and $\boldsymbol{z}$

(i) $\boldsymbol{v}$ is a linear combo of eigenvectors that have the same eigenvalue

	Selected	Not selected

Class 3 (open-ended, 28 students)

NOTE: Four students in Classes 1 and 2 and one student in Class 3 did not answer. Two students in Class 1 did not select either justification. These students are not included in the tables above.

Figure 11. Student use of linear combination and eigenspace for varying answers.

also the case for students that only wrote about linear combination and not eigenspace; of the 18 students that used linear combination in their justification, all three multiple choice answers were chosen, with a majority actually choosing the incorrect answer. Furthermore, in comparison to the first two questions, there is overall wider variation in students' selections for justifications (i) and (v) in Class 1 and 2. Generally, the results from this question demonstrate how the concepts of linear combinations of eigenvectors and eigenspaces are especially challenging for students.

Discussion

In this section we share insights into students' understanding of eigentheory that come from looking across the data for all three questions and how these relate to previous research on students' understanding of eigentheory. We then discuss the strengths and weaknesses of the three different MCE versions and considerations for future use of the assessments.

Insights from Looking Across Questions and Connections to Previous Research

First, there are some indications that students favor algebraic reasoning over geometric reasoning when justifying their answers to eigentheory questions, even though the class used the IOLA curriculum which specifically introduces eigenvectors and eigenvalues geometrically. As a particular example, the proportions of students who selected the algebraic justification (iv) (or wrote something similar) on the geometrically-oriented Question 2 were higher than the proportions of students who selected the geometric justification (v) (or wrote something similar) on the algebraically-oriented Question 1 (see Table 3). This may be seen as corroborating the work of Thomas and Stewart (2011), who found that "students tend to think about the concepts of eigenvalue and eigenvector in a primarily symbolic-world way" (p. 294), even after two years of linear algebra instruction. However, it should be noted that a majority of these students were able to answer the multiple choice stem of Questions 1 and 2 correctly, demonstrating some ability to reason both algebraically and geometrically about eigenvectors and eigenvalues. This is good, as many have advocated the importance of understanding eigentheory from geometric or embodied perspectives in addition to algebraic or symbolic ones (Gol Tabaghi & Sinclair, 2013, Salgado & Trigueros, 2015, Sinclair & Gol Tabaghi, 2010, Stewart & Thomas, 2006; Thomas & Stewart, 2011) and others have explained the significance of fluently translating between different modes of description (Hillel, 2000), modes of thinking (Sierpinska, 2000), or worlds of mathematics (Tall, 2004), to understanding linear algebra in general.

Table 3
Evidence of Students' Preference for Algebraic Justifications over Geometric

	Class 1	Class 2	Class 3
Proportion of students who selected the geometric justification (v) The vector $\boldsymbol{Ax}$ **is** 6 times the magnitude and in the same direction as this vector on Question 1, or wrote something similar	12/27	14/29	0/28
Proportion of students who selected algebraic justification (iv) There exists a scalar c such that $M\boldsymbol{x} = c\boldsymbol{x}$ on Question 2, or wrote something similar	17/27	18/29	12/28

Second, there is some evidence that the ways students think about and solve problems involving eigenvectors and eigenvalues are influenced by their reliance on or preference for one of the two equations $A\boldsymbol{x} = \lambda\boldsymbol{x}$ and $(A - \lambda I)\boldsymbol{x} = \boldsymbol{0}$. While we agree in the importance of students understanding both of these equations and the relationship between them, as suggested by previous research (Salgado & Trigueros, 2015; Thomas & Stewart, 2011), our results go beyond this by suggesting that the particular eigen-equation a student thinks about in the problem solving process can actually result in different ways to think about the same problem.

Some evidence for the idea of students relying on or preferring a particular equation can be seen in Class 3's results on Question 1, where 14 of the 28 students only wrote one of the two equations, suggesting students may have a "go to" equation when thinking about and solving eigentheory problems. Furthermore, as an example of a student's thinking or solution strategy being potentially influenced by one of the two eigen-equations, consider Figure 12. In this figure, we share open-ended work on Question 1 and Question 3 from a student who shows some reliance on or preference for the homogeneous equation $(A - \lambda I)\boldsymbol{x} = \boldsymbol{0}$. On Question 1, we can infer this student first found the matrix $(A - \lambda I)$, multiplied each vector by it, and chose the vector that was mapped to the zero vector. Then, on Question 3, although what he actually writes is not mathematically sound, we can infer he was still reasoning similarly with the homogeneous equation, imagining the vectors $\boldsymbol{y}$ and $\boldsymbol{z}$ being mapped to the zero vector by the matrix $(A - \lambda I)$, and therefore the vector $\boldsymbol{v}$ would also map to the zero vector. We recognize this is only one example, but we hope it illustrates how students' thinking and reasoning about eigentheory problems can be driven by the particular eigen-equation they adhere to at any given time. Future research plans of ours include exploring this idea further.

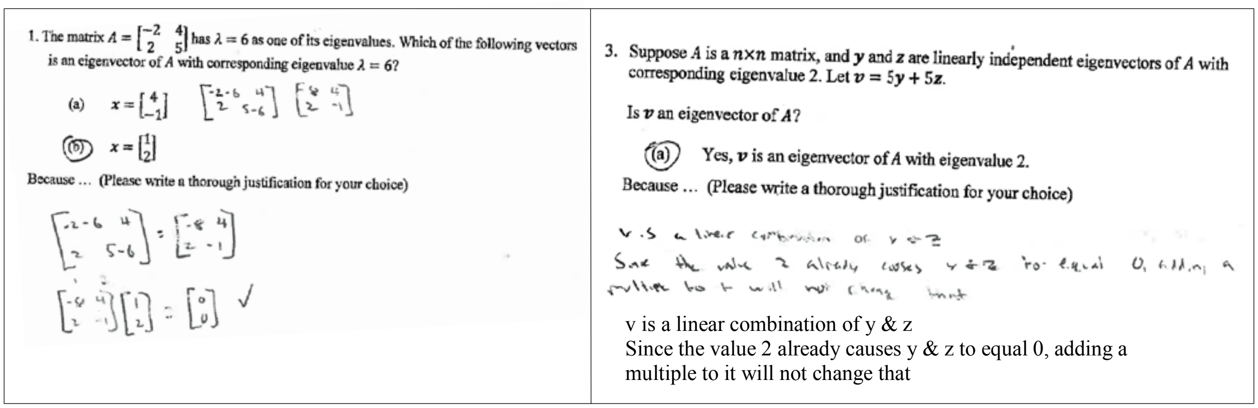

Figure 12. Evidence of student B66's Preference for Homogeneous Equation $(A - \lambda I)\boldsymbol{x} = \boldsymbol{0}$

Third, the concept of eigenspace is particularly difficult for students to understand, as evidenced in the results from Question 3. This corroborates the results of Salgado and Trigueros (2015) who suggested this might be due to difficulties students have "in understanding the concepts of spanning set, basis, and space spanned, and also to the difficulties involved in comparing different geometrical objects in a three dimensional space" (p. 118). Our results go a bit further in two ways. First, Class 2's results on Question 2 above, where no student said justification (iii) "This vector is in span$\{\boldsymbol{x}\}$" was false, shows the students do have some understanding of the concept of span (at least one-dimensional span). Second, from Class 1 and Class 2's (56 students total) results on Question 3, 13 of the students said justification choice (v) "$\boldsymbol{v}$ is an element of the eigenspace created by the vectors $\boldsymbol{y}$ and $\boldsymbol{z}$" was true, but selected (c) "No, $\boldsymbol{v}$ is not an eigenvector of A." This suggests students might not understand that any vector belonging to the span of a set of eigenvectors with the same eigenvalue (i.e., elements of the eigenspace) are themselves eigenvectors with that same eigenvalue. We suggest, along with Salgado and Trigueros (2015), further research specifically look at students' understanding of eigenspaces, and ways we might better teach this difficult concept.

Comparing the Three MCE Formats

One might be tempted to think that the open-ended version of the MCE would be the most helpful or appropriate for eliciting the ways students think about eigentheory. However, we have shown here that forcing students to think about other justifications can lead to interesting results, and gives us further insights into students' understanding of eigentheory. The question arises, which assessment (3-Choice MCE or Basic MCE) should be pursued further? We explore three considerations, namely time and cognitive demands, information gained, and scoring issues.

As both the Basic MCE and the 3-Choice MCE have a student read through six justification choices for each multiple choice question, the MCE is considerably more time consuming than a simple multiple choice assessment. This significantly affects the number of questions that can be asked using this format, and is one reason our instrument was limited to six questions. In reality, those six questions could be thought of as six multiple choice questions with 36 true-or-false sub questions. The MCE can also be cognitively taxing, as students must ponder on each individual justification choice to determine if it is true and relevant. Thus, mental fatigue is a real concern by the time students reach the end of the assessment. Furthermore, the 3-Choice MCE is more demanding in both time and cognition than the Basic MCE, because a student has to make a choice for each justification, not just circle those that are true and relevant.

On the other hand, when it comes to information gained from the assessment, the 3-Choice MCE gives more information about students' thinking than the Basic MCE. When students do not select a justification choice on the Basic MCE, we cannot know if they thought it was false, or just not relevant to answering the question. With the 3-Choice MCE, we are able to see this difference and gain better insight into their understanding of particular eigentheory concepts that the justifications are aimed towards.

Lastly, scoring of these assessments can be particularly troublesome. For example, what score is given to a student who selects all of the true and relevant justifications correctly, but chooses the wrong multiple choice answer? Or, what score is given for the exact opposite, choosing the correct multiple choice but none of the justifications correctly? (In fact, both situations have come up with the data we have). As we explore various scoring options, the question remains as to what these scores would actually mean, and how they should be interpreted or used to inform us about students' understanding.

It seems promising to focus on the use of this instrument as either a formative assessment to give instructors a general idea of their students' understanding and help inform further instruction, or a research instrument used to examine students' understanding of multifaceted concepts (such as eigentheory) similar to what we did in this current paper. Still, it would be useful if there were a more succinct way to look at individual students' results and quickly ascertain where a student's current understanding is. To this end, we hope to align a method of scoring the eigentheory MCE with our solidified framework for student understanding of eigentheory in the future. This scoring would hopefully give a summary of a student's understanding (e.g., reliance on a particular eigen-equation, ability to reason geometrically, algebraically, etc.) that would be helpful to teachers and education researchers of linear algebra.

Conclusion

In this paper we have presented insights into students' understanding of eigentheory that were obtained through the use of the Multiple Choice Extended assessment on eigentheory that we developed. These insights include students' use of the two eigen-equations and how they may influence students' solution strategies, students' tendency towards algebraic justifications when working on eigentheory problems, and the difficulty of the concept of eigenspace. We have also shown how the MCE gives us rich information about students' understanding of eigentheory. We hope that further refinement and use of the MCE, as well as developing possible scoring systems, will continue to broaden and deepen the mathematical community's understanding of the ways students reason and think about eigentheory.

Meta-Representational Competence with Linear Algebra in Quantum Mechanics

Megan Wawro
Virginia Tech

Kevin Watson
Virginia Tech

Warren Christensen
North Dakota State University

In this report we share analysis regarding students' meta-representational competence (MRC) that is expressed as they engage in solving quantum mechanics problems that involve linear algebra concepts. The particular characteristic of MRC that is the focus of this analysis is students' critiquing and comparing the adequacy of representations, specifically matrix notation and Dirac notation, and judging their suitability for various tasks (diSessa, 2004). With data from semi-structured individual interviews, we created categories of types of MRC elicited during students' work on an expectation value problem. We provide detail on two students who serve as paradigmatic examples of a student's power and flexibility in thinking in and using different notation systems. This work lends credence to and inspires our preliminary conjecture that strong meta-representational competence (MRC) is necessary not only to be fluent and proficient in the mathematics involved in solving quantum mechanics problems but also to develop a robust understanding of the quantum mechanics content.

Key words: *linear algebra, physics, matrix notation, Dirac notation, symbolizing*

The National Research Council's (2012) report, which charges the U.S. to improve its undergraduate STEM education, specifically recommends "interdisciplinary studies of cross-cutting concepts and cognitive processes" (p. 3) in undergraduate STEM courses. It further states that "gaps remain in the understanding of student learning in upper division courses" (p. 199), and that interdisciplinary studies "could help to increase the coherence of students' learning experience across disciplines … and could facilitate an understanding of how to promote the transfer of knowledge from one setting to another" (p. 202). Our work contributes towards this national need for basic research by investigating students' understanding, symbolization, and interpretation of eigentheory and related key ideas from linear algebra in quantum physics. One overarching research question for this work is: What are the various ways in which students reason about and symbolize concepts related to eigentheory in quantum physics?

As we examined data from individual interviews at the end of the course, one student's work in solving quantum mechanics problems was particularly striking to us because of the ease with which he moved between and explicitly discussed different notations, namely Dirac notation and matrix notation. After reviewing research literature on students' understanding of symbols, notations, and representations, we decided to align our analysis with the framework of meta-representational competence (diSessa, Hammer, Sherin, & Kolpakowski, 1991), as well as the delineation of structural features of algebraic quantum notations offered by Gire and Price (2015) which we explain further in the following section. This framing helped narrow our focus to the following sub-question: What aspects of Meta-Representational Competence exist in students' reflections on and comparisons of matrix notation and Dirac notation in quantum mechanics? In this report we share analysis of two students' reflections on explicit symbolization choices made while solving quantum mechanics problems that involve linear algebra. In particular, we inspect data of these two students solving an expectation value problem and analyze their reasons for how and why they chose a specific symbol system – either Dirac notation or matrix notation – for that particular situation. Our aim is to demonstrate how each student's rich understanding of linear algebra and quantum mechanics includes and is aided by their understanding and flexible use of different notational systems.

Background and Theoretical Framework

In this section, we give an overview of research conducted on student understanding of symbols and representations in mathematics and physics, as well as our theoretical orientation. We conclude with a brief introduction to eigentheory in Quantum Mechanics and Dirac notation.

Student Understanding of Symbols and Representations

The recognition of the importance of students having an understanding of the symbols used in mathematics and physics has grown over the past few decades. Arcavi (1994, 2005) coined this as "symbol sense," which includes (a) being "friendly" with symbols, (b) reading through symbols, (c) engineering symbolic expressions, (d) understanding different meanings based on equivalent expressions, (e) choosing which aspects of a mathematical situation to symbolize, (f) using symbolic manipulations flexibly, (g) recognizing meaning within symbols at any step in the solution process, and (h) sensing the different roles symbols can play in various contexts. Other research along this vein include: an explication of how different perspectives, such as cognitivist, situationist, and social-psychological, provide vastly different ways to understand how students make sense of and use inscriptions and symbols (Kaput, 1998); a study of how students mathematize their language from a Vygotskian perspective (Van Oers, 2002); and an exploration of how notational systems can serve as a mediational tool which triggers and sustains mathematical activity (Meira, 2002).

Research into students' competence with symbols, inscriptions, and representations is not limited to K-12 studies. For example, Harel and Kaput (2002) describe how mathematical notations play a key role in forming conceptual entities in higher mathematics. Additionally, in linear algebra research, Hillel (2000) described three modes of description (abstract, algebraic, and geometric) of the basic objects and operations in linear algebra and pointed out that "the ability to understand how vectors and transformation in one mode are differently represented, either within the same mode, or across modes is essential in coping with linear algebra" (p. 199). Thomas and Stewart (2011) found that students struggle to coordinate the two mathematical processes captured in $A\boldsymbol{x} = \lambda\boldsymbol{x}$, where A is an n x n matrix, $\boldsymbol{x}$ is a vector in $\mathbb{R}^n$, and λ is a scalar, to make sense of equality as "yielding the same result." This interpretation of the "equals" symbol is often novel and nontrivial for students (Harel, 2000). Harel also posits that the interpretation of "solution" in this setting, the set of all vectors $\boldsymbol{x}$ that make the equation true, entails a new level of complexity than does solving equations such as $cx = d$, with each taking values from the reals. Thomas and Stewart (2011) conjecture that this complexity may prevent students from progressing symbolically from $A\boldsymbol{x} = \lambda\boldsymbol{x}$ to $(A - \lambda I)\boldsymbol{x} = \boldsymbol{0}$, which is particularly useful when solving for the eigenvalues and eigenvectors of a matrix A.

Relatedly, diSessa et al. (1991) identified students having a great deal of knowledge about what good representations are and how they are able to critique and refine them, which the authors defined as Meta-Representational Competence (MRC). In (2004), diSessa commented on the choice of term used, stating:

> In using the prefix *meta*- we do not mean to invoke the idea of metacognition. Instead, meta is used generically as it is in metascience or metaphysics (and also metacognition), purviews that transcend the mere practice of science or of physics, or, in this case, purviews that transcend the mere production and use of representations. (p. 294)

diSessa and Sherin (2000) explained that MRC includes inventing and designing new representations, judging and comparing the quality of representations, understanding the general and specific functions of representations, and quickly learning to use and understand new representations. diSessa (2002, 2004) expound upon these ideas by offering a list of critical resources students possess as part of their MRC for judging the strength of representations, such as compactness, parsimony, and conventionality. Two particular resources encompassed by MRC that we focus on in our data are "critique and compare the adequacy of representations and judge their suitability for various tasks," and "understand the purposes of representations generally and in particular contexts and understand how representations do the work they do for us (diSessa, 2004, p. 94). In this study, we align ourselves with the theory that representations are a sense-making tool, in that "the construction of representations on paper during problem solving mediates and organizes one's understanding of mathematical concepts" (Meira, 2002, p. 101). We couple this with a framing of MRC, specific to two notational systems, to investigate student reflections on their own notational preferences in quantum mechanics and what that may reveal about their understanding of change of basis and eigentheory in that context.

Extending even further, research into students' understanding in quantum mechanics has looked at how students make sense of and use a novel notation, called Dirac notation (explained in the subsequent section). Singh and Marshman (2013) showed that even after graduate level instruction in quantum mechanics, students still struggle with Dirac notation, showing inconsistencies in its use among contexts and problems. More closely related with this current study, Gire and Price (2015) looked at four structural features of three different notation systems used in quantum mechanics (Dirac, matrix, and wave function) and how students' reasoning interacts with these features. The features identified by the authors are: (a) individuation, or "the degree to which important features are represented as separate and elemental" (p. 5); (b) externalization, or "the degree to which elements and features are externalized with markings included in the representation" (p. 7); (c) compactness; and (d) symbolic support for computation. Using problem-solving interviews with students as insight into these features, Gire and Price found that students readily used Dirac notation, and that the structural features vary across the different notations as well as among several contexts within quantum mechanics.

From an expert's perspective, Gire and Price have highlighted features that could also be identifiable by a student, and articulation of some of these ideas would fit well within diSessa's framework of MRC. The work presented here attempts to develop a coding scheme that can be used to identify MRC as students discuss, describe and use matrix and Dirac notation to solve quantum mechanics problems.

Brief Introduction to Eigentheory in Quantum Mechanics and Dirac Notation

In quantum mechanics, certain physical systems are modeled and made sense of using eigentheory. To a physical system we associate a Hilbert space (such as $\mathbb{C}^2$), to every possible state of the physical system we associate a vector in the Hilbert space, and to every possible observable (i.e., measurable physical quantity) we associate a Hermitian operator (usually given in its matrix form). The only possible result of a measurement is an eigenvalue of the operator, and after the measurement the system will be found in the corresponding eigenstate.

Dirac notation, also known as bra-ket or just ket notation, is a commonly used notational system in quantum mechanics. A vector representing a possible state is symbolized with a ket, such as $|\psi\rangle$. Mathematically, kets behave like column vectors, such as $|\psi\rangle \doteq \begin{bmatrix} a_1 \\ a_2 \end{bmatrix}$, $a_1, a_2 \in \mathbb{C}$, and are usually normalized. The complex conjugate transpose of a ket is called a *bra*, which behaves mathematically like a row vector, such as $\langle\psi| \doteq [a_1^* \quad a_2^*]$. In addition, the eigenvalue equations for observables are central to many calculations. For instance, the eigenvalue equations for S_x (the operator measuring the x-component of intrinsic angular momentum) of a spin-½ particle are $S_x|+\rangle = \frac{\hbar}{2}|+\rangle$ and $S_x|-\rangle = -\frac{\hbar}{2}|-\rangle$, where $|+\rangle$ and $|-\rangle$ are orthonormal eigenvectors of S_x and $\pm\frac{\hbar}{2}$ are the two possible measurement results of the observable. When symbolized in terms of this eigenbasis, the matrix representation of S_x is $\begin{bmatrix} \hbar/2 & 0 \\ 0 & -\hbar/2 \end{bmatrix}$.

One can also measure spin along other directions, such as z; similarly, the eigenvalue equations are $S_z|\pm\rangle = \pm\frac{\hbar}{2}|\pm\rangle$ (it is common for no subscript to be used for the z-direction). Thus, "within its own basis," the matrix representation of S_z would be identical to the aforementioned diagonal one for S_x. It is often beneficial to change between bases; for example, $|+\rangle_x = \frac{1}{\sqrt{2}}|+\rangle + \frac{1}{\sqrt{2}}|-\rangle$ and $|-\rangle_x = \frac{1}{\sqrt{2}}|+\rangle - \frac{1}{\sqrt{2}}|-\rangle$, so S_x "in the z-basis" is $\begin{bmatrix} 0 & \hbar/2 \\ \hbar/2 & 0 \end{bmatrix}$.

An elegant use of Dirac notation involves change of basis; because the eigenvectors of one operator are often well known in terms of another, such as along the z-direction of a spin-½ particle, Dirac notation is seen to make basis change calculations efficient. Finally, inner products are involved in computing the expectation value of observable A for state psi, $\langle\psi|A|\psi\rangle$. These calculations require the bra and ket expansion to be in the same eigenbasis as the matrix representation of A. Because of the orthonormality of eigenvectors of Hermitian operators, the relevant inner products yield $\langle+|+\rangle = 1, \langle-|-\rangle = 1$, and $\langle\mp|\pm\rangle = 0$. As such, expectation value problems present a rich setting for investigating students' symbolizing of eigentheory and change of basis in a physics context.

Methods

Participants for this study were junior physics majors at a large, public, research-intensive university in the Pacific Northwestern United States. They were drawn on a volunteer basis from a class of 35 students in a Spin and Quantum Measurements course; this course met for 7 class-hours per week for three weeks and involved many student-centered activities and discussions. In addition to videotaping each class session, we conducted individual, semi-structured interviews (Bernard, 1988) with 8-13 students at the beginning and end of the course. This particular report draws on data gathered during the end-of-course interview, in which 8 students participated. The goals of the interview questions were to learn how students reasoned about linear algebra concepts (e.g., normalization, basis, and especially eigentheory), how they reasoned with these concepts as they discussed quantum mechanics concepts and solved quantum mechanics problems, and how they symbolized their work.

To begin our analysis, we viewed the videos and observed how students navigated the interview problems, while we kept in mind the overarching research questions regarding students' reasoning about and symbolizing eigentheory in quantum physics. Throughout our viewing, we noticed some students were particularly fluent in how they talked about and worked with both matrix and Dirac notations. This compelled us to investigate the literature about student use of symbols and notations, the most relevant of which were discussed above. As such, we began an analysis drawing on the work of diSessa and colleagues (diSessa et al., 1991; diSessa 2002, 2004), and Gire and Price (2015). In particular, we coded for instances of students mentioning structural features of the mathematics or students making explicit meta-commentary on the representations they chose to use. This allowed us to integrate our analysis of students'

MRC with Gire and Price's types of structural features in a way novel to the physics and mathematics education fields.

We now explain how the students for this report were chosen. One student who fluidly worked with both matrix and ket notations was student A25, and this fluidity was especially evident within his solution of an expectation value problem. Because this problem seemed to be conducive to eliciting students' understanding, critiques, and comparisons of both notations, we identified all students who had engaged in the expectation value problem in their end-of-course interview, resulting in a pool of four students to study. The second author then read the transcript or watched the video of the entire interview for all four students, indicating instances in which the student explicitly talked about either or both notations. These instances were then collated into a single document with all student identifiers removed. Using this document, each author individually coded the sections, specifically attending to ideas related to MRC (diSessa, 2002, 2004) and the characteristics of matrix and Dirac notation identified by Gire and Price (2015). We then met collectively to share our codes and decide on a final set of codes for each transcript section. After the codes were finalized, we began axial coding, placing our collective codes into categories of features and characteristics of Dirac and matrix notations students were attuned to.

In this particular report, we focus on the end-of-course interview with two students: Milan and Buzz (both names are pseudonyms). Milan was a double major in math and physics who had completed one 10-week course in linear algebra and was concurrently enrolled in a second linear algebra course, and Buzz was a double major in physics and nuclear engineering who had completed two 10-week courses in linear algebra. The purpose of focusing on Milan and Buzz was their demonstrated ability to articulate their thinking. More specifically, during the interview, they demonstrated flexibility in reasoning about the concepts we were probing, and a great deal of MRC was visible and analyzable through their explanations.

Results

Our coding of the data produced three main categories of codes: (A) Preference based on a value judgment, (B), Preference based on the problem or context, and (C) Awareness of the purposes of representations and the work they do for us. Each category is composed of 5, 6, and 4 subcodes, respectively (see Figure 1). Category (A) comprises MRC statements related to preferences students expressed related to some overarching value; statements were similar to sentiments such as one notation being preferred because it is faster to write than another [A2], more familiar to work with [A3], or easier to write than another [A5]. The MRC codes in Category (B) comprise statements students made that are more intrinsically tied to particular problems or contexts; statements were similar to sentiments such as one notation being preferred or chosen in a particular problem because of the format of the question statement (e.g., "sometimes the ket notation is nicer…if you already know the eigenvalues and you just are multiplying by operators." We note that aspects of [B1] and [B2] are consistent with Gire and Price's structural feature of "symbolic support for calculation." We also purposefully use their other three structural features as our codes for [B4], [B5], and [B6] because we saw evidence of them in our data. We do note that which main category these codes best belong in could be open for discussion. Finally, Category (C) derives its name from one of diSessa's (2004) stated functions of MRC as an overarching awareness of representations and what they do for us. Again, student statements consistent with all four (C) codes existed in our data and gave rise to the codes. We note that these codes in particular have a compatibility with Arcavi's (1994) characteristics of symbol sense but stand out as novel because of its use with MRC.

A. Preference based on a value judgment	B. Preference based on the problem or context
1. Clarity 2. Speed 3. Familiarity 4. “Likeability” 5. Ease of writing	1. Useful in calculations 2. Makes more direct use of given relationships 3. Needs less information 4. Compactness 5. Individuation 6. Externalization
C. Awareness of the purposes of representations and the work they do for us	
1. Has freedom to choose symbols 2. Has an ease with notation, writes symbols to mean what is personally desired 3. Aware of one’s own progress in notation use 4. Able to “step back” and weigh options to decide which notation system is best	

Figure 1. The list of categories of MRC that resulted from our data analysis.

We organize the remainder of our results section according to excerpts from Buzz and Milan, including aspects of their responses that particularly point to and illustrate their MRC.

Buzz

In the beginning of the interview, Buzz volunteered that he sometimes explicitly chooses between doing calculations in matrix notation or in Dirac notation:

I: So how do you feel like, using eigenvectors and eigenvalues, in spins has been similar to and different from how you've experienced those in other classes?

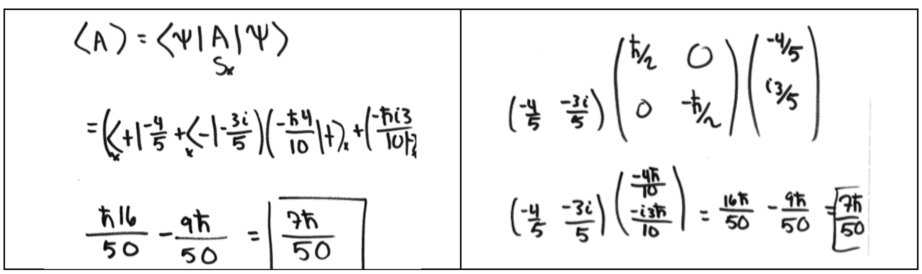
Buzz: Uh, well, it's very similar because you're doing a lot of the same math …the difference especially in physics, you're looking at kets. In, in at first it was kind of jarring, like to- to try to do the math in kets. But now, it's kinda- it's kinda easier, there's problems, there certain problems…where there's two ways to do them, they're kind of parallel, you can do it and you can expand the- the- the state in- in like as a- and expand them as- as kets in a different basis, or you can write that state as a- as a, as a vector, in that basis, and you can either do the matrix math for the like expectation values for example, you can do the matrix math or you can do the ket math, and sometimes it's, I'm finding that I, rather expand something in the ket.

From the transcript we see that Buzz was aware that there exist multiple legitimate ways to solve the problem, seemingly understanding the various mathematical nuances and implications of his notational choices. His brief explanation highlights sentiments that are consistent with Arcavi’s characteristics of symbol sense, such as being “friendly” with symbols and using them flexibly. We add, however, a metacognitive aspect of symbol sense here, noting that A25 was engaged in self-reflection rather than a researcher analyzing Buzz’s engagement with symbols. Thus, we code this as “[C4] able to “step back” and weigh options to decide which notation system is best.” We also note that Buzz was aware of his own progress, commenting that it was “it first kind of jarring…to try to do math in kets,” but that now it is “kinda easier.” We code this as “[C3] aware of one’s own progress in notation use.”

Because Buzz volunteered expectation value problems as a situation in which he could use either notation, the interviewer had him work on such a problem right away, even though it was prepared to be at the end of the interview: “Consider the state $|\psi\rangle = -\frac{4}{5}|+\rangle_x + i\frac{3}{5}|-\rangle_x$ in a spin-1/2 system. Calculate the expectation value for the measurement of S_x.” Buzz immediately worked on the problem within Dirac notation, saying, “basically to find the expectation value…

it's like denoted that way [writes $\langle A \rangle$] but really what you're doing is you're taking the, the bra of the state, and then you're putting the operator [writes $= \langle \psi | A | \psi \rangle$] in the middle of the inner product…" He continued to explain his work as he went, arriving at the correct answer of $7\hbar/50$ (see Figure 2a). Note that his work in Figure 2a involved the state's expansion and use of eigenvector equations for S_x in ket notation. In addition, this notation was first introduced to the students during this course; as such, Buzz was clearly quick to use and understand this representation (a additional quality of MRC, diSessa & Sherin, 2000).

After discussing his work and solution, the interviewer asked: "Before you were telling about bra-ket versus matrix notation, you brought up an expectation value as an example of like, either or both, so can you, now that you had this problem, kinda revisit that?" Buzz immediately solved the problem completely within matrix notation (see Figure 2b), explaining his steps. For instance, in line 1 in Figure 2b, he wrote the complex conjugate transpose of the vector representation of the state in the x basis, the matrix representation of the S_x operator in the x basis, and the vector representation of the state in the x basis. He also stated his process for computing the matrix times the column vector before he did the computation, and again in line 2 he explained "then I do it again, so, um, this time you're gonna get a number out," meaning he anticipated that a row vector times a column vector would be a number. We see this as flexibly using symbolic manipulations (Arcavi, 1995) and an anticipation of results.



(a) (b)

Figure 2. Buzz's expectation value problem, in ket notation (a) and matrix notation (b).

The interviewer then asked Buzz to reflect on his preference between the two notations:

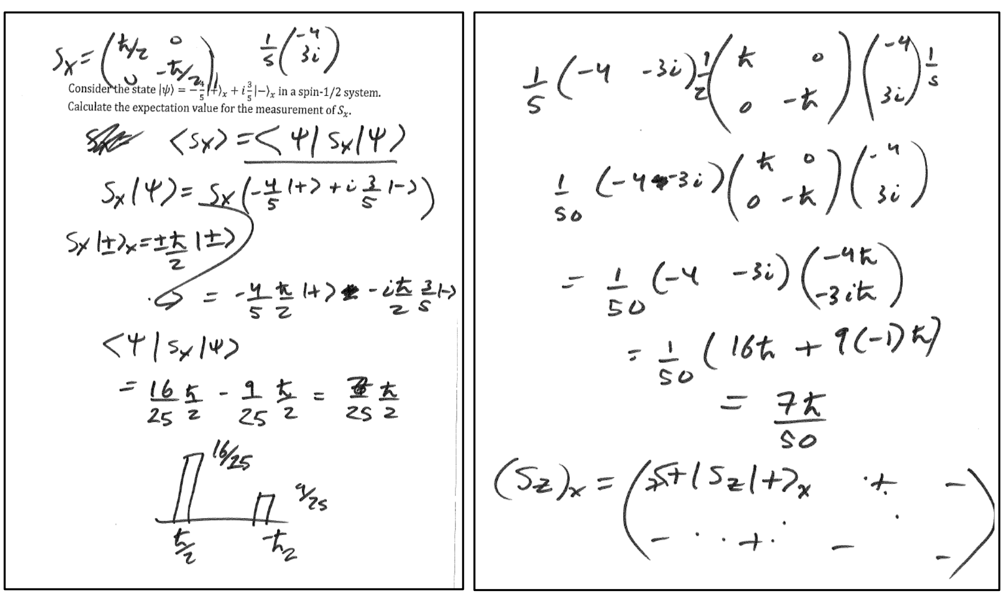
Buzz: Uh...To be honest, I don't really, I don't really know why I prefer this [Figure 2a], I think it's just because, um, I like this notation. This- this specific notation [Figure 2a line 1] like this to me is like a cleaner way of writing that [Figure 2b line 1] because that- I mean this and that [touching lines 1 in both figures] I feel like are your starting points, so you, you start here with this nice, like, looking thing [traces his finger under $\langle \psi | A | \psi \rangle$], or you start here with this big array of numbers [puts open hands around Figure 2b], and I prefer this [Figure 2a line 1], even though you have to expand this into basically the same amount of information [Figure 2a line 2]. And also, the nice thing about, about this [Figure 2a line 1], is it—actually this is really why it's better—is because you can, you can say ok S_x works- acts directly on these kets, you can just get rid of the matrix altogether...

This excerpt begins with two value statements: that Buzz prefers Dirac notation because he likes it [A4] and because it provides a cleaner way of writing the desired information [A1]. We see his use of "nice looking thing" and "big array of numbers" in comparison to one another are an example of compactness [B4]. He also compares line 1 in 2(a) and line 2 in 2(b) regarding the "amount" of information they convey, which involves reflection on the physical and mathematical content expressed in the compared notations. Finally, acting directly on the expansion in terms of the eigenstates of the operator allow him to forego the matrix calculation entirely, which speaks to Buzz's view of the utility of notation for calculation in a specific problem [B1] and his preference for Dirac in a situation that allows him to make a more direct use of the given relationships [B2].

When asked about his notation preferences if the basis expansion of a given state vector and the operator "didn't match," Buzz recalled a problem from their last homework that was "actually easier…to do the matrix multiplication," stating "you don't want to have to change these kets into different bases all over the place 'cause they're already all written in the same basis and you know what the operator is in that basis so you might as well just, do the matrix multiplication." This speaks to his awareness of using given relationships directly [B2] as well as being able to choose which notation system is best for a certain situation [C4].. Finally, when asked if the notions of basis or eigenvectors/eigenvalues come up more in one notation than the other, Buzz stated, "certainly…every time you write down a ket you're, you're very conscious of what basis you're in. In this one [points to Figure 2(b)] it's just kinda implied…all this [is] in the same basis, so you're just, you're just writing out numbers, an arrays of numbers, but here [in Figure 2(a)] you're thinking ok, this is the S_x operator, this is the x plus ket, this is the x minus bra…so I think that you're definitely more aware of what basis you're in when you're using this, because you have to be." This explanation is consistent with Gire and Price's (2015) notion of externalization [B6], in that the ket notation allows features of the problem, namely basis, to be externalized in a way that the matrix notation did not provide for Buzz.

Milan

We focus our examples of Milan's MRC on his work with the Expectation Value Problem. Like Buzz, he first completed the problem in Dirac notation but then, prompted by the interviewer because of a comment Milan had made, correctly completed the problem using matrix notation (see Figure 3).



(a) (b)

Figure 3. Milan's work on the Expectation Value problem.

Milan: So, this is very convenient because it's in the S_x basis. Um, so, basically all we need to do is put S_x in some matrix representation as — well, do we need to do matrix representation? I don't think we do. So, let's not worry about that. So, the expectation value of S_x is defined as this ψ, and the S_x, and ψ. And we're just going to include the ψ's in this — We're just going to drop the x subscript and just assume that it's, um, the x-basis….

Int: When you first started, you almost started using matrix notation, and then you decided not to. Can you talk more about that?

Milan: So, ket — because you know this eigenvalue equation, ket notation just skips all that. Um, if you wanted to, you could have written this out as, uh, 1/5(-4 3i), But, you can see that's more confusing to go through — and then you have to look at S_x and, where you can write it as ħ/2, -ħ/2, 0, 0, and you have to do matrix multiplication. Um, actually, that might be quicker, honestly…Which is, the exact same answer we got before, and it was substantially quicker. And in — I mean, I guess it depends how good you were with this kind of notation 'Cause, this is, I learned two and a half weeks ago, and this I learned almost a year ago.

As Milan began his work on this problem, he thought out loud about his approach, first stating he would put S_x in a matrix form but then deciding he did not need to do so. We coded this as [C4], an ability to "step back" and weigh options to decide which notation system is best. Once he decided to solve the problem within Dirac notation, he decided to drop the "x" subscript from the expansion of the state ψ in terms of the x basis (see lines 2, 3, and 5 in Figure 3a). This indicates Milan's ease with notation in that he can write and engineer symbols to mean what he personally desired [code C2].

After 4 minutes of work in which Milan explains his steps to correctly solve the expectation value problem (Figure 3a), the interviewer asked him to comment more on his rather explicit choice to not use matrix notation. We coded his statement, "Because you know this eigenvalue equation, ket notation just skips all that" as [B2] because of his preference for Dirac nation based on his perception that it made more direct use of the eigenvalue equations $S_x|\pm\rangle_x = \pm\frac{\hbar}{2}|\pm\rangle_x$. He also stated that one could have written the vector form of the given ψ, which is another example of his awareness of his choice in notation system [C4]. He continued by explaining how that would be more confusing in this situation [code A1, preference based on clarity] and summarized the matrix symbols and operations that would be necessary to complete. Milan then reflected out loud, saying that the matrix notation approach may actually be faster for him in this problem [code A2, preference based on value judgment of speed]. The interviewer prompted him to "do it that way," and after one minute of work (see Figure 3b), Milan concluded he got the same answer as before but substantially quicker. He then spontaneously reflected a bit more about the two notation options, noting aspects of familiarity with matrix notation [code A3] and that it takes time to make progress in using the new-to-them Dirac notation system [code C3].

Conclusion

In this report we shared our analysis of the meta-representational competence of two students as they engaged in solving a quantum mechanics problem involving linear algebra. To coalesce the ideas shared herein, we offer three reasons why this work is important to mathematics and physics educators. First, similar to one of the purposes of the work of diSessa et al. (1991), our report acts as a counter narrative to a number of articles in physics education that focus on students' difficulties or misconceptions in learning quantum mechanics (Johnston, Crawford, & Fletcher, 1998; Singh, 2001; Styer, 1996), and more specifically with the notations used in quantum mechanics (Singh & Marshman, 2013, 2016). We have shown students' abilities to critique and understand the general purposes of the various notations used within quantum mechanics, and how their meta-representational competence can even include some ideas about strengths and weaknesses of the notations that align with expert determined structural aspects of quantum representations (Gire & Price, 2015). Hence, instead of only focusing on students' difficulties with notation, educators might examine how they can build upon the meta-representational competence students already have to help deepen and strengthen their understanding of quantum mechanical and mathematical representations.

Second, as mentioned by diSessa (2004), educational research is always looking for ways we can help students develop deeper understanding of science and mathematics, and an important piece of this deeper understanding includes knowing "not only how to operate scientific apparatus (from strategies that solve problems, to representations and concepts), but also understanding how and why they work, and even being able to generate and judge alternative means" (p. 299). Thus, helping students develop deep understanding of quantum mechanics and linear algebra should include providing opportunities for students to use and improve their meta-representational competence. In fact, we noticed that the strongest students within our study in regards to their understanding of linear algebra and quantum mechanics concepts were also the students who demonstrated particularly articulate and thoughtful MRC. This begs the question, does a deep understanding of the physical and mathematical concepts create a conducive environment for developing stronger MRC, or does MRC help students develop a rich understanding of physical and mathematical concepts? We hypothesize that there is actually a cyclical relationship between MRC and physical and mathematical understanding, with development in one influencing the development of the other. For example, a student's understanding of eigentheory would influence the aspects of MRC they could attend to when using the different notations in quantum mechanics. In turn, the MRC in regard to quantum mechanical notations that student develops might strengthen their understanding of eigentheory concepts. Future research could examine and explore this cyclical relationship in greater detail, and how instructors might take advantage of it in helping students develop deep understanding of physical and mathematical concepts.

Third, we have presented codes we have used for identifying and analyzing students' MRC in their talk about eigentheory and quantum mechanics, as well as general categories for the types of MRC these codes indicate students demonstrate. This coding scheme still has the potential to be expanded, extended, and refined, especially as students' MRC within quantum mechanics and linear algebra are further explored, and as students' MRC is studied within other mathematical and physical contexts. Our hope is this coding scheme will facilitate analysis of students' understanding of representations within mathematics and physics, and gaining insight into the richness of their overall understanding of mathematical and physical concepts. Furthermore, we hope the identification of particularly useful and powerful elements of MRC, such as those found in analyzing experts or strong students, will help educators know the types of thinking and reasoning to emphasize and cultivate in teaching their students. Education researchers could then search for teaching methods, questions, and curricular materials that would support students in developing their MRC in these productive ways.

In our own future research, we plan to analyze the rest of the students from the current data set, as well as interviews with students in a Junior-level quantum mechanics course at a public university in the Northeastern United States. The latter interviews should be particularly useful for further refinement of our MRC coding scheme as we were more explicit in designing questions that might elicit students' MRC when writing the interview prompts. This analysis may also begin to give us further insight into the cyclical relationship between students' MRC and their understanding of physics and mathematics, as well as ways researchers and educators might elicit and cultivate students' MRC.

Corequisite Remediation and Math Pathways in Oklahoma

Matthew Wilson
Oklahoma State University

Michael Oehrtman
Oklahoma State University

We examine multiple data sources to assess the current progress of implementing corequisite remediation and multiple math pathways in the state of Oklahoma. We begin by analyzing trends in national reform efforts and contrasting them with the status of current challenges and efforts in Oklahoma. We then present preliminary data from pilot sections of a corequisite College Algebra course and a new math pathway for degrees that require significant quantitative literacy but do not require engineering calculus. Finally, we consider statewide data on student course-taking patterns, degree requirements, and existing institutional efforts that will inform upcoming state-level decisions on these reforms.

Key words: corequisite remediation, mathematics pathways, reform

Introduction

The state of Oklahoma is currently in the process of reforming introductory post-secondary mathematics options and curriculum across all 27 public higher education institutions with the goal of increasing success in college mathematics courses and therefore increasing degree attainment across the state. To accomplish these goals the Oklahoma State Regents for Higher Education, the governing body for all public higher education institutions in Oklahoma, adopted the Complete College America agenda (Complete College America, 2013). The main focus of the state reforms are 1) supplementing the current system of remedial courses with a corequisite model and 2) creating multiple introductory mathematics pathways better aligned to diverse degree programs.

Traditionally, to ensure preparation of entering students, colleges assess students using various criteria (e.g. SAT scores, ALEKS, high school math GPA, etc.) then place them into college courses using these measures. Under-prepared students are placed in a remedial course sequence designed to fill in deficiencies from secondary mathematics and prepare these students for college-level courses. Once a student completes the remedial course sequence, they are allowed to take credit-bearing math courses required for a degree. This remedial system, however, often fails in its ultimate goal. In 2010, Bailey et al. (2010) found that only 31% of community college students referred to a remedial courses sequence in mathematics completed it. Only half of the students completing the remedial course sequence enrolled in the subsequent college-level course. Ultimately, only 15% of students referred to remediation passed the subsequent college credit-bearing course, which is significant as 58% of entering community college students enrolled in a remedial mathematics course (Attewell et al., 2006). Overall, 28% of college students from two or four-year colleges enroll in remediation (Attewell et al., 2006). Furthermore, delaying enrollment in college-level courses in favor of remedial courses has the consequence of extending students' time to degree, meaning both an increased cost and decreased persistence toward a degree (Complete College America, 2011).

Alternatively, in corequisite remediation, underprepared students are placed directly in college-level courses with targeted assistance. The aim of the model is to allow under-prepared students to earn college credit upon entering while still providing the students with necessary perquisite material, thereby eliminating often multiple semesters of remedial courses and enabling students to progress to through their degree programs. Corequisite remediation has been successful in several pilot programs across the country, which will be briefly discussed in the next section.

The second focus of the reforms are creating mathematics pathways beyond the standard College Algebra/Calculus sequence. Creating additional pathways provides students in non-STEM disciplines basic mathematics courses more relevant to their interests and needs. The reforms seek to increase collaboration between math departments, other academic degree programs, and employers as to the necessary mathematical knowledge and skills for students in their chosen field. For many, courses in statistics, quantitative reasoning, or mathematical modeling are more applicable to future collegiate and career needs than College Algebra. The need for increasing such diverse mathematical competencies has been highlighted by several reports from professional associations including: the *Common Vision 2025* report by the Mathematical Association and America (Saxe et al, 2015), the *Guidelines for Assessment and Instruction in Statistics Education (GAISE): College Report* endorsed by the America Statistical Association (Aliaga, 2005), and the *Beyond Crossroads* Report of the American Mathematical Association of Two-Year Colleges (Foley, 2007). Additionally, by creating clearly defined mathematics pathways at the state level, Oklahoma is aiming to increase transferability of mathematics courses between public institutions.

In this paper, we address the following research questions:

1. What are the primary national trends and lessons in corequisite remediation and math pathways relevant to the goals and structures of the Oklahoma higher education system?
2. What are the primary obstacles in implementing corequisite remediation and math pathways in Oklahoma, and what factors can local and state leaders influence to address these challenges?

A National Perspective of the Reforms

Several states have either implemented or are in the process of implementing the reforms outlined above. We briefly describe progress in two of the states to lead these reform efforts, Georgia and Tennessee.

Currently, Georgia has two pathways: the traditional College Algebra/Calculus pathway and a non-algebra pathway which focuses on either quantitative reasoning or modeling. In Fall of 2014, Georgia piloted corequisite remediation for both pathways. 67% of the 2919 students in the non-corequisite sections passed the gateway course. In the corequisite sections, there was a total 1,132 students 64% of whom passed. Comparably, only 21% of students referred to remedial education in 2010 passed their gateway course within two years (Complete College America, 2015).

Beginning in Fall of 2014, Tennessee conducted a pilot corequisite program for an introductory statistics course with 1,019 students at 9 different campuses. Tennessee saw similar results to Georgia, 63.3% of students assessed as being underprepared passed introductory statistics whereas under the previous remediation model only 12.3% completed the introductory statistics course.

Similar results can been see in other states (Complete College America, 2016). We will continue to examine the progress and challenges of the reforms across the country and how their efforts can inform the reforms in Oklahoma.

Traditional Remediation at Oklahoma Institutions

Consistent with the national picture, a large percentage of students at each of the public institutions in Oklahoma are referred to remediation. In many of the state community colleges, over 60% of the entering students are referred to some type of remediation, be it English, math, or both. Figure 1 gives the percentages of student's referred to remediation at each of the public two institutions. With stricter admissions criteria at four-year initiations, the rate at which students are placed into remedial courses when entering is lower, however, still over 40% of entering students are placed into remediation. Remedial courses have a number of effects on students who are enrolled. Remedial students pay both tuition and additional remediation fees for courses which confer no college credit. Furthermore, taking remedial courses increases the number of mathematics courses a student must take thereby increasing the potential "drop-out" points. These "drop-out" points include potential failure in the remedial courses, but also include failure to enroll in either the subsequent remedial course or the gateway course after passing the initial course. The high remediation rates are particular troubling when one considers the success of this as measured by the completion of the college gateway course as shown in Figures 1-4.

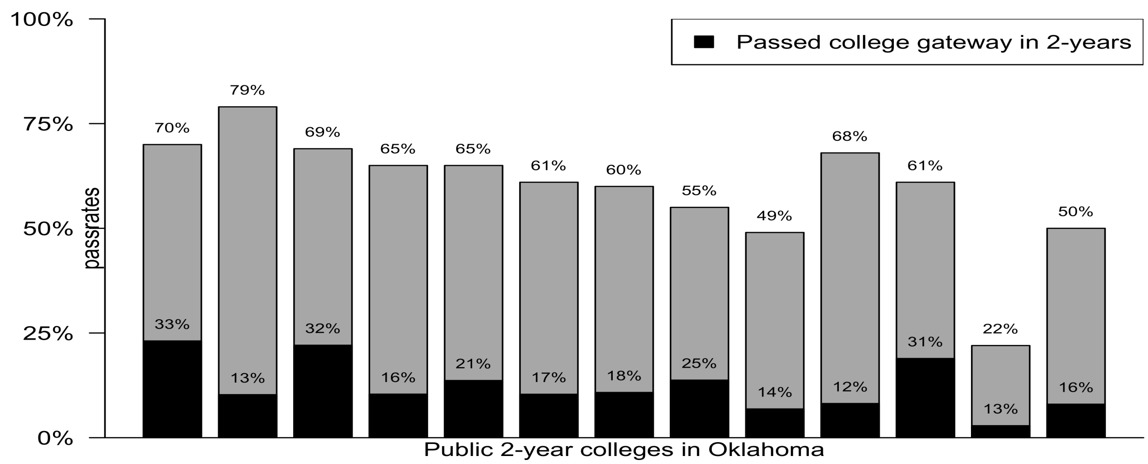

Figure 1. Entering students taking any remedial sequence.

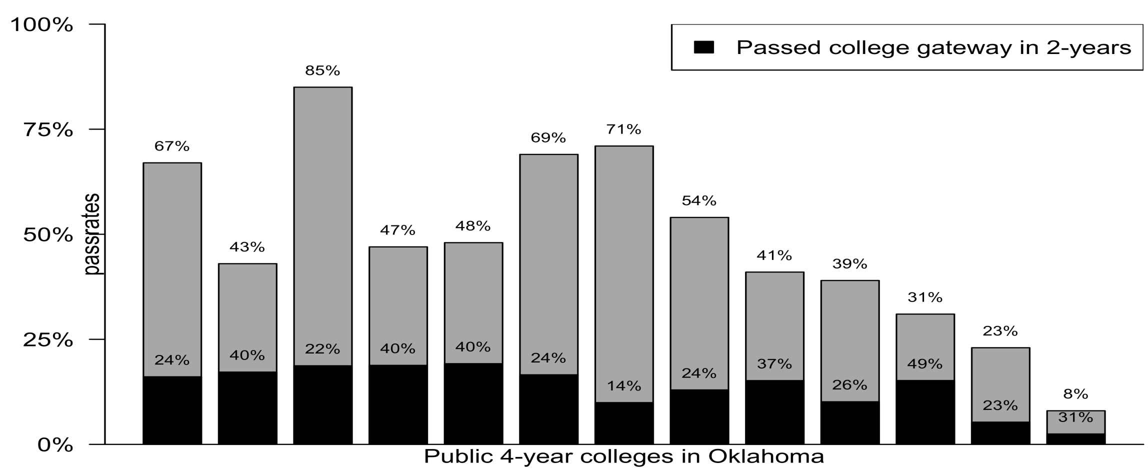

Figure 2. Entering students taking any remedial sequence.

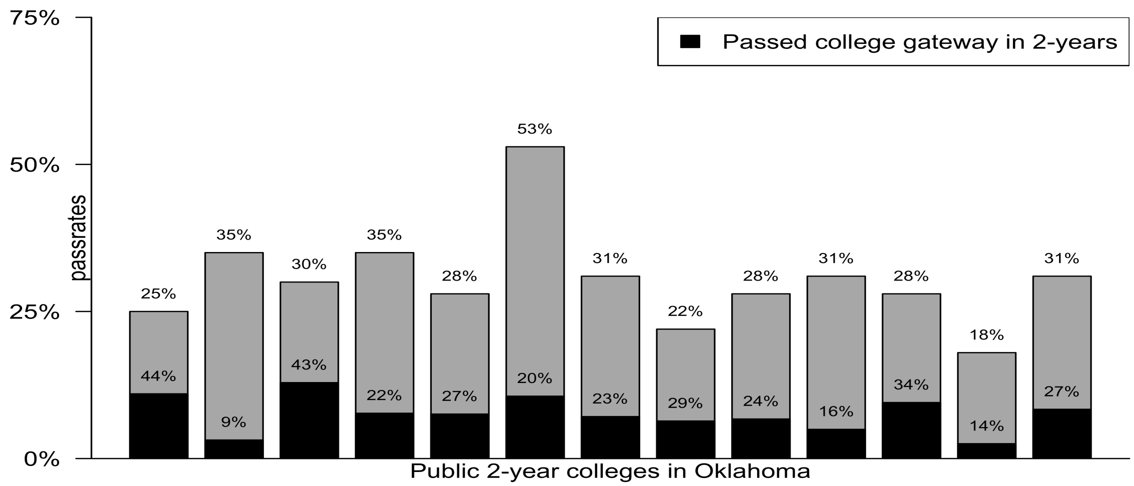

Figure 3. Entering students taking only a remedial mathematics sequence.

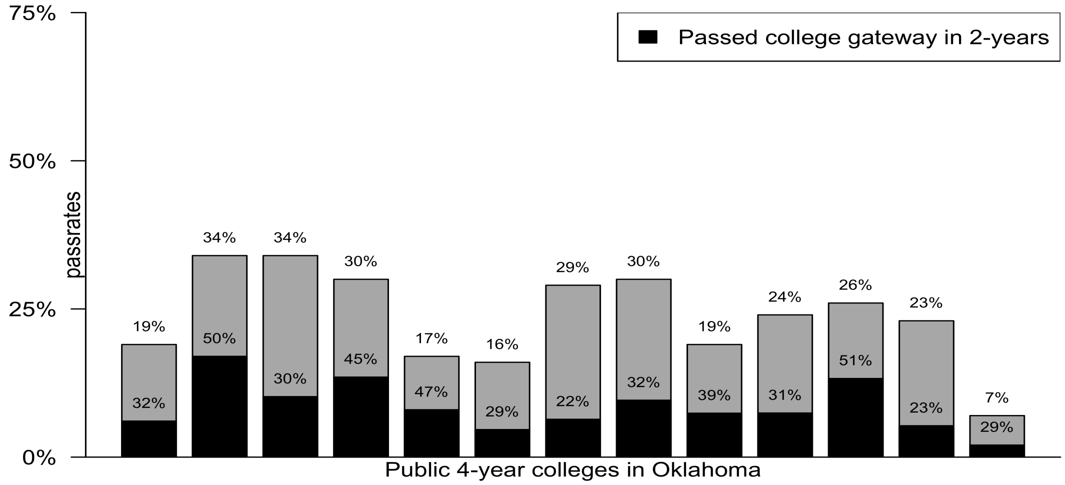

Figure 4. Entering students taking only a remedial mathematics sequence.

Figures 1-4 show that less than 35% of the students who begin college in remediation at the two-year colleges were able to complete the college gateway course within two years. The success rates improve slightly when looking at the students that besides mathematics were assessed as "college ready." Again the success rates are higher for students entering a four-year institution, but at most of the intuitions, less than half of the students pass the gateway course within two years.

As the gateway course is a degree requirement, students must pass the course in order to graduate. This is particularly relevant to the two-year colleges, as the success rate in completing the college gateway course within two-years is an upper bound for the graduation rate for these students at their starting institution. However, the possibility remains that students can transfer to another institutions to complete the college gateway course after completing the remedial sequence.

Progress in Oklahoma

Corequisite Remediation

To address these completion rates, the state of Oklahoma is in the process of implementing corequisite remediation. Several institutions have started running pilot sections, and are doubling or tripling previous success rates. In this section we report the data from the pilot sections at one of our institutions.

In fall of 2015, Oklahoma State University began piloting corequisite courses. The ALEKS PPL test is used to assess entering student college readiness. Normally, to place into College Algebra a score of 45 out of 100 is required. The pilot sections consisted of students with scores from 30 to 44 on the ALEKS test. That is, students who would ordinarily have to take a remedial course sequence were included in the pilot. The students in the corequisite sections attended class five days a week as opposed to three days in the regular course sections. Of these five days, three days were dedicated to regular instruction. During the other two days, an undergraduate learning assistant engaged students in active learning sessions designed by an experienced course coordinator to improve students' prerequisite knowledge. The learning assistants are mathematics education majors selected by the department. Students in the corequisite sections completed the same homework and took the same exams as students in regular College Algebra sections. Figure 5 shows the percentage of the students in these courses earning a D or F or withdrawing (D/F/W rate).

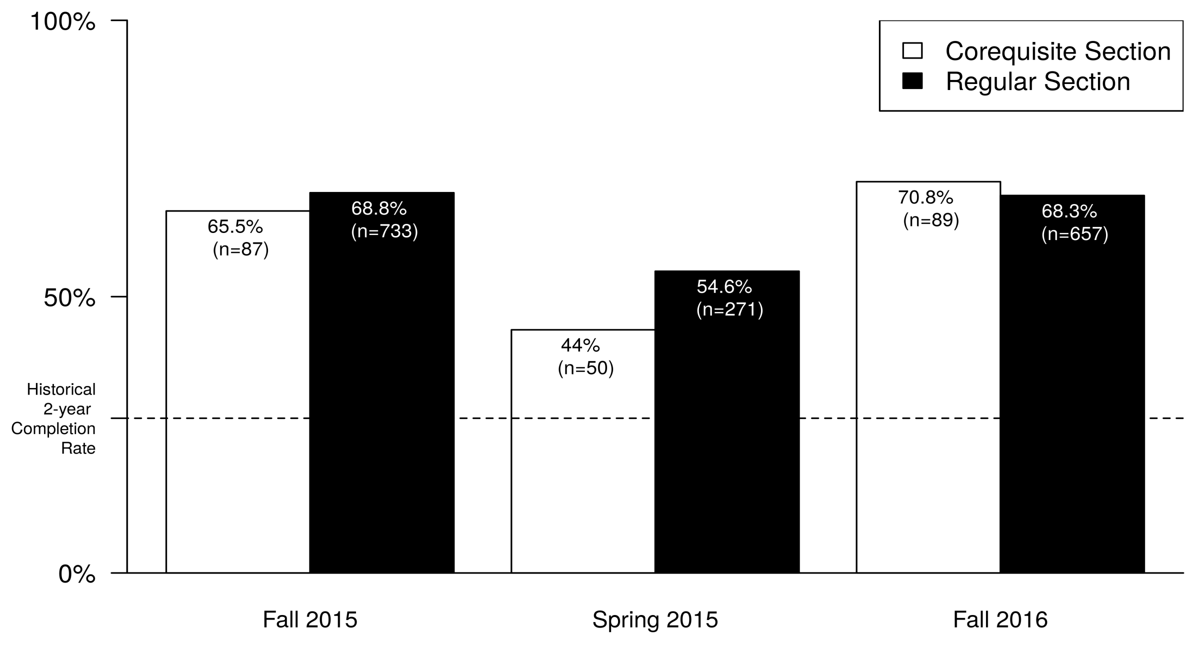

Figure 5. College Algebra Passrates.

While the success rates of the students in the pilot sections in both fall 2015 and spring 2015 were lower than the students in the regular sections, the improvement is noticeable when compared to the historic two-year completion rate in college algebra for these students. Moreover, the corequisite students have succeeded in a single semester as opposed to the minimum of two semesters that would have been normally required. Equally important is student persistence to and success in subsequent mathematics or statistics courses which is shown in Figure 6 for the Fall 2015 corequisite College Algebra cohort.

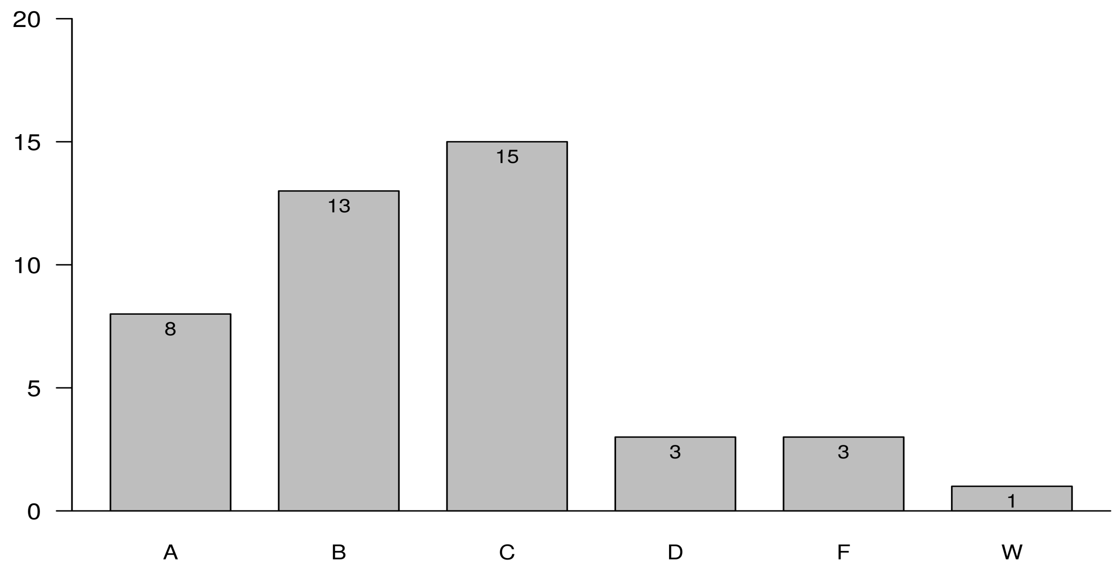

Figure 6. Fall 2015 corequisite students' grades in subsequent mathematics or statistics courses.

Half of the corequisite cohort students enrolled in a subsequent mathematics course, and over 83% of those students passed. (For reference, the typical success rates for students in these subsequent courses are around 70%.)

With regard to the statewide reforms, we have collected surveys from all public institutions in the state on their implementation of corequisite courses. We are in the process of analyzing this data, which will provide a useful baseline for comparison as the state reforms unfold.

Math Pathways

In the Common Vision 2025 (Saxe et al, 2015) the authors called for a "broader range of entry-level courses and pathways into and through curricula" (pg. 13). Of particular interest to us are moving degree programs that do not require engineering calculus away from College Algebra which is intended to prepare students for calculus. The goal is to increase relevance to students' courses of study.

Oklahoma State University has created a course *Mathematical Functions and Their Uses* (MATH 1483) which is being offered as an alternative to College Algebra for many business, social science, health, and agriculture degrees that do not require an engineering calculus course. The course emphasizes quantitative reasoning by modeling data with a calculator and/or excel and serves as an equally successful preparation for Business Calculus as College Algebra. The D/F/W rates are typically 15% and 25% for the fall and spring respectively. As degree requirements shift away from college algebra, we are in the process of analyzing D/F/W rates from subsequent gateway courses. Moreover, the shift to functions has led to an increased success in College Algebra. Additionally, in Fall 2016, the university began piloting a corequisite section of the functions course allowing traditionally underprepared students another pathway to earn college credit upon entering. The success rate in the pilot section was 86.2%, although we are hesitant to make comparisons between this pilot section and the regular sections as content and assessments were not consistent across the two.

Statewide, we collected detailed information on the mathematics requirements for every major at all 27 state public institutions and complete statewide data for student enrollment and success in math courses by major. The aim is to better understand the current math pathway options available and clusters of majors that might benefit from shifts to new math pathways.

A preliminary review identified 530 majors (out of 1790) that require college algebra but not engineering calculus. By analyzing the degree sheets for these majors we identified, 94 programs that have a path for which college algebra is not a prerequisite. The most common courses required for these majors for which college algebra is a perquisite are physics (37 programs), chemistry (100), statistics (45 programs), and trigonometry. In Oklahoma, outside of STEM degrees, college algebra is the most commonly taken mathematics course.

Discussion

Early corequisite remediation and new math pathways reforms in Oklahoma are showing promising results enabling dramatically more students to complete credit bearing gateway courses. Moreover, this data shows that these students are able to succeed in subsequent college mathematics and statistics courses. While the gains are promising, these results are preliminary. As the ultimate goal is to increase student success in college, what remains to be seen is how these efforts will affect graduation and degree completion rates. As we continue our data analysis, we have been be conducting interviews with individuals involved in the reforms in Oklahoma and individuals involved in the national reforms to better understand the data and process.

Using Intuitive Examples from Women of Color to Reveal Nuances about Basis

Aditya P. Adiredja
University of Arizona

Michelle Zandieh
Arizona State University

Research and surveys continue to perpetuate deficit narratives about women of color, particularly regarding their participation in and contribution to mathematics. Following the broader call for more research concerning STEM learning experiences of women of color, this study focuses on the sense making of eight women of color regarding their understanding of basis in linear algebra. We documented diverse ways that these women creatively explained the concept of basis using intuitive ideas from their everyday lives. These examples revealed important nuances and aspects of understanding of basis that are rarely discussed in instruction. These students' ideas can also serve as potentially productive avenues to access the topic. Our results also challenge the existing broader narrative about academic underachievement of women of color in mathematics.

Key words: student thinking, basis, linear algebra, equity

Most areas of science, technology, engineering and mathematics (STEM) continue to be unsupportive spaces for women of color, and people of color more generally. One indicator of this issue is the high attrition rates in mathematics among Black,[1] Latinx,[2] Native Alaskan, Hawaiian, and Native American students (NSF SEI, 2014). One way the education community has studied this problem is by exploring differences in achievement outcomes between groups of students. Outcomes of students from underrepresented groups are often compared with those of the dominant groups (e.g., White and male students). More recently, some scholars have shifted their focus to understanding ways that students are racialized and gendered in their educational experience (Martin, 2009). That is, research has begun to investigate the impact of racism on students of color, particularly Black students (e.g., McGee & Martin, 2009), and the impact of sexism on women (e.g., Herzig, 2004). Women of color as a group experience both racism and sexism, which has motivated the idea of *intersectional* feminism (Crenshaw, 1991). Ong and colleagues' (2011) literature review pointed out the dearth of intersectional research that focuses on experiences of women of color in STEM.

In this paper we operationalize racism, sexism and their intersection through social narratives (Nasir and Shah, 2011; Nasir, Snyder, Shah, & Ross, 2012). Nasir and colleagues (2012) used the term racial storyline (narrative) to describe established and shared narratives about a particular race that are enacted in social interaction in different social contexts. Existing narratives on women of color in mathematics typically frame students, particularly Black and Latinx students, as persistently underachieving and academically inferior to their White/Asian

[1] Berry (2015) uses the term "Black" to acknowledge the Black Diaspora, and to highlight the common way that Black learners, regardless of their origin are racialized in the U.S.
[2] "Latinx" is gender-neutral term to describe to describe people with Hispanic and/or Latin American origins. The term deemphasizes implicit gender binaries in "Latina/Latino," and hence more inclusive of transgender and other non-binary gender identities. Ramirez and Blay (2016) discuss the origin and different perspectives on the use of "Latinx" in scholarship, activism and journalism.

counterparts. Nasir and colleagues (2013) found that racial storylines, as an example of social narratives, limited access to educational opportunities (e.g., who gets called on in class, or who gets advised into honors classes) and added cognitive burdens for students while learning.

These deficit narratives about women of color are also supported by the dominant method to study inequities in education: achievement gap studies and comparison studies. Most comparison studies and achievement gap studies perpetuate the narrative that students (and women) of color are always lagging behind their White/Asian counterparts (Gutiérrez, 2008; Gutierrez & Dixon-Roman, 2011). Gutierrez (2008) has emphasized that comparison studies and achievement gap studies treat dominant students as the standard against which to measure. She also critiqued the implicit assumption that the validity of research on underserved populations rests on their comparison with the dominant group. Harper (2010) has also highlighted the prevalence of a deficit narrative in higher education research that discusses the participation of students of color in STEM. He found that research questions often positioned students as personally and solely responsible for their underachievement, thus positioning their underachievement as a result of personal failure and lack of motivation.

Deficit narratives about women of color intersect with deficit narratives about students' understanding and learning of mathematics. Deficit narratives about student thinking as generally naïve, full of misconceptions, and unrefined reciprocally support the narrative of academic inferiority of students (and women) of color in mathematics (Adiredja, under review). Some of these narratives about students' knowledge became more established as a result of the popular misconceptions research in the mid to late 1970's (diSessa, 2006; Smith, diSessa, & Rochelle, 1993). Nowadays, challenging the prevalence of deficit narratives about mathematical learning has been highlighted in research commentaries about equitable teaching (Bartell et al., 2017) and position statements about social justice in mathematics education (NCSM & TODOS, 2016). Thus, constructing counter-narratives about how women of color learn mathematics can help challenge the deficit narrative about women of color. This calls for researchers to be intentional about selecting research subjects and adopting an anti-deficit perspective (Adiredja, under review).

A group of Black scholars have recognized the broader deficit narratives regarding Black students, and have been intentional in shifting the narratives of research about Black students. Instead of fixating on comparing Black students to White or Asian students, scholars have focused on understanding Black students' learning experiences and offering counter-narratives about these students (e.g., Berry III, Thunder, & McClain, 2011). In the context of undergraduate mathematics, some scholars have focused instead on the experiences of successful Black mathematics and STEM majors (Ellington & Frederick, 2011; Larnel, 2016; Martin & McGee, 2009). This type of research has been able to offer counter-narratives by sharing stories of academically successful Black students in STEM. Additionally, it has revealed the resourcefulness and resilience of these students in navigating the additional burdens and obstacles embedded within the academic institution for these students. The study presented in this paper takes a similar approach in subject selection and in the way that it seeks to uncover resourcefulness of women of color in learning mathematics without comparing them to the dominant culture.

In this paper we focus on learning of women of color regarding the Linear Algebra concept of basis. The focus of this study was partly motivated by a need for more research about students' understanding of this topic. We were able to find only one study reporting on students' understanding of basis, which is an important topic in Linear Algebra. Stewart and Thomas

(2010) reported that students in their study struggled in making meaning of basis, and tended to explain it in terms of procedures. The authors also found that students struggled in explaining span and linear independence, two related concepts. In this study we explore the following questions:

1. How did the women of color in the study explain the concept of basis using ideas from their everyday lives?
2. What did their explanations reveal about nuances in the concept of basis?

These questions support the two complementary goals for this study. First, the study aims to construct a counter narrative about women of color by investigating their sense making of mathematics from an anti-deficit perspective. Second, it seeks to investigate the structure of understanding of the concept of basis in Linear Algebra. Our focus on explanations rooted in students' everyday experiences was motivated by some of the theoretical frameworks, which we turn to now.

Conceptual and Theoretical Frameworks

Sociopolitical Perspective

The design and analysis of this study are broadly guided by a sociopolitical perspective in mathematics education research (Gutiérrez, 2013, Valero, 2004). Gutiérrez (2013) explains that adopting a sociopolitical perspective involves investigating the relationship between knowledge, power, identity, and social discourses. She argues,

> [K]nowledge and power are inextricably linked. That is, because the production of knowledge reflects the society in which it is created, it brings with it the power relations that are part of society. What counts as knowledge, how we come to "know" things, and who is privileged in the process are all part and parcel of issues of power. Here, power is not a possession but it is circulated in and through discourses (p. 44).

Social discourses establish particular power relations from a sociopolitical perspective. Discourses include "institutions, actions, words, and taken-for-granted ways of interacting and operating" (Gutiérrez, 2013, p. 43). These discourses structure the world by producing "truths" about individuals and groups of people. Gutiérrez highlighted the power of discourses in deciding what counts as productive mathematical knowledge and who can be a successful mathematics student, that is, the politics of knowledge (Apple, 1992; Nasir, Hand, & Taylor, 2008).

This paper focuses on narratives as part of social discourses. The Oxford English Dictionary defines a narrative as a particular telling of a story that "reflects an overarching set of aims or values." The narrator establishes these aims and values, and they position people within the narratives. The positioning that results from these aims and values is the impact of the power that gets exercised through narratives.

Knowledge in Pieces (KiP)

Knowledge in Pieces (KiP) (diSessa, 1993) is a cognitive framework that explicitly emphasizes anti-deficit perspectives on students' knowledge and learning. KiP models knowledge as a complex system of elements. KiP rejects oversimplified deficit models of students' misconceptions, and typical efforts to replace persistent misconceptions (Smith, diSessa & Roschelle, 1993). The perspective that students have persistent misconceptions perpetuates narratives about students as unskilled, lacking resources and prone to mistakes. Instead, KiP focuses on the productivity of students' knowledge and the foundational role their prior knowledge plays in learning. KiP recognizes productivity of knowledge (elements) through its principle of *context sensitivity* (Smith et al., 1993). Misconceptions are seen as overgeneralizations of a productive use of a knowledge element in a new context.

Studies using KiP focus on understanding a student's own way of reasoning about a topic instead of assessing its correctness with respect to a normative standard (diSessa, Sherin, & Levin, 2016). More broadly, KiP is more interested in understanding aspects of the current context that might have led students to cue particular knowledge elements than in deciding if the cueing is "correct." KiP does not assume that productive knowledge has to be encoded in normative academic language. In fact, it is common for studies using this framework to uncover productive sense making in students' use of non-normative language (e.g., Campbell, 2011; diSessa, 2014).

Knowledge Analysis (KA) (diSessa, Sherin, & Levin, 2016) is a method associated with KiP that focuses on studying knowledge elements and how they are used. KA focuses on intuitive knowledge as a target of study, and assumes that forms of naïve knowledge are diverse and generative. Intuitive knowledge is seen as knowledge stemming from students' observation of their everyday experiences in engaging with the physical world. Some studies have shown the utility of intuitive knowledge in mathematics (Campbell, 2011; Pratt & Noss, 2002). This theoretical assumption motivates asking students about basis using everyday ideas.

Understanding Basis

In the same way that KiP motivated the focus of our study on students' everyday examples and our attention on students' intuitive knowledge, other frameworks motivate our organizing our study around different ways in which students understand the notion of basis.

By analyzing student understanding of a particular mathematical concept, we are following from a tradition in the mathematics education research literature of analyzing how students think about particular mathematical ideas. At the undergraduate level these include function (e.g., Sfard,1992; Oehrtman, Carlson & Thompson, 2008), limit (e.g., Williams, 1991; Roh, 2008; Swinyard & Larsen, 2012), and derivative (e.g., Zandieh, 2000).

In thinking about the various aspects involved in understanding a particular mathematical idea, we start with the notion of concept image. The term concept image has been used to refer to the "set of all mental pictures associated in the student's mind with the concept name, together with all the properties characterizing them" (Vinner & Dreyfus, 1989, p. 356). Tall and Vinner (1981) describe a person's concept image for a particular concept as "the total cognitive structure that is associated with the concept" (p. 152). A longer term goal of our work is to create a framework for describing the details of the cognitive structure involved in understanding the notion of basis. This paper provides a first step towards describing in more detail the various aspects of students' concept images of basis.

One tradition for delineating student understanding of a particular mathematical concept is the notion of conceptual metaphor (Lakoff & Núñez, 2000). In the undergraduate mathematics education literature conceptual metaphor has been used to examine student understanding of a number of concepts including function (e.g., Zandieh, Ellis, and Rasmussen, 2017), limit (e.g., Oehrtman, 2009), and derivative (e.g., Zandieh & Knapp, 2006).

Conceptual metaphors may be used without reflection or without even awareness that a metaphor is involved. In our study we ask students to create everyday examples that may or may not be able to serve more broadly as conceptual metaphors for basis. Our intention for the purpose of this paper is to consider students' everyday examples as potential conceptual metaphors that allow insight into nuances of understanding involved in a particular student's concept image of basis and more generally into delineating a framework for what it means to understand this mathematical construct.

Methods

Data Collection

Given the desired depth and detail of analysis, this study favored the use of a small number of research subjects and videotaped individual interviews (diSessa, Sherin, & Levin, 2016). Participants were 8 undergraduate women of color at a large public research university. We invited women of color with the help of the university's mathematics advising center and by leveraging our personal contacts with students. We reached out to mathematics majors and minors who had completed an introductory linear algebra course.

The breakdown of racial and ethnic backgrounds and their past mathematics courses are presented in Table 1. This information was drawn from a student background survey that was administered at the end of the interview. All information was self-reported. The "Other Mathematics Courses" column are courses taken by the student prior to linear algebra. By the time of the interview in late Spring 2016 some students had completed additional mathematics courses post linear algebra. With the exception of Morgan, a Biomedical Engineering major, all the other students were mathematics majors or minors. Pseudonyms were selected to reflect the origin of students' names.

Each interview lasted for 90 minutes. Adiredja led the interview while Zandieh videotaped the interview and at times participated in asking questions. Students started the interview by solving four tasks that might be asked in a beginning linear algebra course. We chose tasks in which basis was not mentioned directly but for which basis might be relevant or related. This was followed by more general questions as to each student's understanding of basis including the questions that are the focus for this study:

1. Can you think of an example from your everyday life that describes the idea of a basis?
2. How does your example reflect your meaning of basis? What does it capture and what does it not?

Additional questions were asked about comparing their understanding of basis to the original four linear algebra tasks. At the end of the interview the students were often given another opportunity to share an example from their everyday life, especially if they did not offer an example when first asked.

Table 1. *Students' racial/ethnic background and mathematics course history*

Student	Racial/Ethnic Background	Linear Algebra Completion	Grade	Other Mathematics Courses
Leonie	African American	Spring 2016	A	Calculus I, II, and III
Morgan	Asian/Asian American	Spring 2016	A	Calculus I, II, and III, and Differential Equations
Annissa	Hispanic/Latinx	Fall 2014	B	Calculus I and II
Eliana	Hispanic/Latinx	Spring 2014	C	Calculus I and II
Nadia	Hispanic/Latinx	Fall 2015	A	Calculus I, II, and III

Jocelyn	Hispanic/Latinx	Spring 2015	B	Calculus I, II, and III
Stacie	Hispanic/Latinx	Spring 2016	C	Calculus I, II, and III
Liliane	Hispanic/Latinx/White	Fall 2015	B/C	Calculus I, II, and III

Data Analysis

For the purpose of this paper, we focused on student responses to the two questions listed above. We additionally considered other sections of the interview in which students introduced an example from their everyday life. We transcribed the interviews and organized the transcripts by turns, marked by changes in speaker. Transcripts use modified orthography (e.g., wanna, gonna, cus) to stay close to the actual students' utterance. Hedges (e.g., like, kinda, um) were removed from the presentation of transcripts to assist in the reading of the transcripts.

We started with open coding to capture nuances of students' understanding (Strauss & Corbin, 1994). We identified everyday contexts for each student and the details associated with that context (e.g., what is a vector, the vector space, and scalar multiplication in the context?). We differentiated utterances about the roles of the basis vectors in the larger space from utterances about the characteristics of the basis vectors. These distinctions came as we focused on students' uses of nouns, verbs and adjectives in their explanations.

We started our analysis by focusing on nouns students used to describe the context and its details. Once we identified the context, we separately analyzed the details of that context. Adiredja focused on adjectives that highlighted characteristics of basis, while Zandieh focused on verbs that highlighted the relationship between the set of basis vectors and the larger vector space. This is followed by a discussion about similarities, differences, and, at times, conflicts between our codes. We negotiated and refined the codes. For example, in comparing the codes with one another, we clarified their distinctions (e.g., *minimal* focuses on quantity vs. *essential* focuses on quality), and explored other related categories (e.g., *maximal* for *minimal*).

In our presentation of the transcript, we use bolded texts to indicate phrases that capture the codes. In cases where two codes are situated next to each other in the transcript, we differentiate them using **grey** and **black bolded texts**. We use ***bolded grey italics*** for nouns that indicate the basis vectors and the vector space. We use regular *italics* to refer to codes in the text.

Results

Students' Everyday Examples

We found that the majority of the students discussed at least one everyday context to explain the concept of basis. Table 2 provides a summary of the different contexts. In what follows we elaborate on the details of some these contexts as part of illustrating the roles of the basis vectors and their characteristics.

Table 2. *Everyday contexts used to explain basis and vector spaces*

Student	Context (for basis and vector space)
Leonie	friendship
Morgan	driving in a city (on a grid), Legos, cooking, groups of pens
Annissa	set of solutions (no actual everyday example)

Eliana	least amount of myself I need to cover the space of the room, storage room, dimension, skeleton, outline of a paper
Nadia	floor, universe and earth, syntax in programming
Jocelyn	fashion, recipe, art sculpture, collage
Stacie	walking to places in a room, floor as a plane, marching band
Liliane	religious teachings

Roles of Basis Vectors

In this section we focus on the verbs students used to discuss the role that basis vectors have in relationship to the larger vector space. Before collecting the interview data we had noticed that basis vectors can be thought of as *generating* the larger space or as *describing* the larger space. As such we designed our warm-up tasks to be of both types. For example, asking students to describe the span of a given set of vectors is a *generating* task. On the other hand, finding the eigenvectors for a given matrix may involve choices as to how to *describe* the infinite space of eigenvectors. One typical choice might be to state the basis for that eigenspace. In terms of relationships between the basis vectors and the larger space, *generating* verbs refer to creating the larger space from the basis vectors, whereas *describing* verbs start with the larger space and describe it by listing basis vectors.

Generating Illustrated

In our analysis we found that seven of the eight students used generating verbs including build, make, create, add, cover and fill. Table 3 provides examples of generating verbs with quotes from students. This table serves not only to illustrate the generating examples, but also to provide more detailed examples of the contexts that students used to talk about basis. In the quotes in Table 3, bold italics grey indicates the context the student was discussing, whereas bold non-italics black indicates a verb phrase illustrating a generating relationship between the basis vectors and the space.

Table 3. *Generating verbs within students' explanations*

Student	Verbs	Quote
Leonie	fill	I think I could describe it as my ***different friend group.*** /…/ They're all completely different. One of my friends, my best friend is, she's really serious and everything. Then my roommate is really goofy. And then my other friend, she's just really wild and crazy. So it's like, they all **fill all the gaps.**
Morgan	build, create	You're given like the 3 by 2 ***Lego [pieces]*** and you have like a 2 by 2 Lego [piece] you can just like **build on to that to create** that I guess space that you have.
Morgan	get	You could use your basis of ***one block north not south, east, west***. I think of those as like basis **to get anywhere in** ***the world.***

Eliana	cover	So it's like what's ***the least amount of myself [two arms]*** I need **to cover** ***the space of the room***. I need that direction. I need that direction, and I need that direction. So that's all you need.
Nadia	make	You need to know ***the minimum syntax*** to be able **to make** any sort of ***program*** and **make it useful**.
Jocelyn	make	The span would be all the different ***recipes*** that you **can make** with ***those ingredients***.
Stacie	create, move	Well, I remember in marching band where we have to create a circle. And you need the people **to create** ***the circle***. You need ***the field***. And you need ***the music***. You need all of three of them **to help move on to** the ***different parts of the field***.
Liliane	add to, expand, come from, reach	So I'm very religious. And so the ***teachings*** that we share with each other and that we read about and all that stuff. There are a lot of things that you can **add to** and be like, here's an application and here's the things, and this **expands** to this and this and this. But there's ***the most basic teachings*** and it all comes back to that. And this is the basic thing, like you have ***the Ten Commandments***. You have ***the Scriptures*** and you have ***the prophets*** and you have your ***connection with God*** and, all of the decisions and all of things that **come from** that and you can **reach** all of the other points with this basis.

Describing Illustrated
In our analysis we found fewer examples of verbs that indicated a student was describing a vector space by using a basis. Examples from Eliana and Nadia are listed in Table 4.

Table 4. *Describing verbs within students' explanations*

Students	Verbs	Quote
Eliana	shows	So the basis is like the ***skeleton***. You know that it, it **shows you what you need**, and it **shows you where everything is**.
Nadia	describes	I'm just thinking like the ***whole universe***, and that's like ***planets and stars*** and that like **describes** the universe. But only a planet describes earth. So to get a basis for the universe you'd need planets and stars.

In addition, a student may combine both types of verbs. Just after mentioning skeleton, Eliana discussed the outline of a paper both in terms of *generating* and *describing*,

> That's the whole point of the basis so you can **see on a smaller scale** what the rest of the space is gonna look like or what type of space here. And I could go with anything depending if you're writing a ***paper***, it would be the ***outline*** and you **build** on that.

To "see on a smaller scale" is to describe or represent the larger space using a well-chosen subset of that space. On the other hand, to "build on that" is to (re-)construct the larger space (paper) from the basis (outline).

Characteristics of Basis Vectors

Our coding of the adjectives students used to describe basis led to the list of codes below. In this section, we illustrate many of these codes through our analysis of Jocelyn's explanation using the context of fashion. The three segments we selected occurred chronologically. The analysis highlights the way that Jocelyn's explanation captures these different nuances about basis, and Jocelyn's sophistication in assessing the fit of her explanation with the formal definition.

1. **Minimal** focuses on the fact that the basis is the least number of vectors necessary.
2. **Maximal** focuses on the need to include all the basis vectors and that more would lead to redundancy.
3. **Essential** focuses on the quality of the vectors being the core and necessary.
4. **Representative** focuses on naming or identifying a smaller set as the structure or representation of the larger space.
5. **Non-redundant** focuses on not wanting extraneous information in a set, or the act of reducing or removing the extraneous information.
6. **Different** focuses on comparing items (vectors) based on their differences for the sake of keeping or removing items from the basis.

Segment 1: A focus on minimality and non-redundancy

In this episode, Jocelyn introduced the context of fashion and wardrobe to explain basis. In her explanation, she described the *generating* role that basis vectors play. Her explanation focused on the characteristics of basis vectors being the *minimal* set, and the fact that none of the vectors were *non-redundant*.

> I immediately try to think of, I thought of ***fashion and a wardrobe.*** And so, say you have all these different outfits **you want to make**. You have a **minimum number of pieces**, like **a pair of shoes or a shirt, or a pair of pants** that you need that allows you to **make all of those outfits**. But **you don't want to have two of the same pairs of shoes** cause you know that's wasteful. **You don't need two of them. You just use one.**

Jocelyn emphasized that at a minimum she needed a pair of shoes, a shirt and a pair of pants to make an outfit. She also used a situation in which she had two of the same pair of shoes as an example when the non-redundant requirement was violated.

Segment 2: A focus on difference and essential-ness

Without prompting Jocelyn also discussed a scalar multiple of a vector to emphasize the nuance that separated being *different* from being *essential*.

> When you scale a vector by a constant, it might look different. It might change its length or its direction but **its identity isn't really changed**, and so it'll be the same vector. And so **if you have different pairs of heels, they'd look different but they're still heels, they're still like formal. So they're (inaudible) still the same.**

Jocelyn was emphasizing that being different was not a sufficient condition for a vector to be part of a basis. She focused on the "identity" or the essence of a vector. Items might appear to be different (e.g., different heels), but their essence was still the same and thus both could not be part of the basis.

Segment 3: Assessment of explanation

In this episode, Jocelyn was sharing the extent to which her explanation captured the meaning of basis. In the process she summarized some of the important aspects of basis for her.

> It's **minimal**. To pick **one pair** **of heels and** **one pair** **of tennis shoes.** So when I think of my idea of a basis, my mind goes to **minimal.** Um, what doesn't it capture? Well, ok, so it's weird cause I guess you can use one pair of shoes for different outfits. But if I'm trying to make...it's harder to have a casual outfit and in a formal outfit there's **not a whole lot of overlap** **you end up having each piece in each outfit in the basis.** So it's like. How do I explain this? I feel like the basis I'm making, all of the pieces aren't as, **they're not all the same**. ***Like, you have shoes, tops and pants.*** **You can't make an outfit with just shoes.** But if **you have a basis, you can pick just some of the vectors**, **combine them, and make something,** and leave all the rest out. **Cause you can't just put on shoes and pants.** So that's where it kinda...that's one of the ways that doesn't really [fit the definition].

In her summary, Jocelyn returned to the idea of *minimal*. She needed to pick one pair of heels and one pair of tennis shoes. Each selected pair of shoes became a *representative* of its own category. The limitation of the context came when Jocelyn considered overlapping items in different types of outfits. While the idea of *non-redundancy* could be used to remove redundant vectors from a basis, Jocelyn was hoping that there were some redundancy so she could pick one representative for the redundant items. She emphasized that basis vectors had to be *different* ("not all the same"), but she saw that needing all the basis vector was a limitation of the context of fashion. Each piece in the basis is considered to be *essential*. So she could not just pick some of the vectors, like in a strictly mathematical context.

Discussion and Implications

We have two aims with this paper. The first is to construct a counter-narrative about women of color in mathematics. The second is to investigate the structure of student understanding of basis. With respect to the first goal, we have documented episodes of productive sense making by women of color in mathematics. We highlighted the creativity and breadth of the everyday contexts used to describe basis by these women of color. The range of contexts that students used was particularly interesting and useful. Most of these were not contexts we were able to generate ourselves prior to beginning the study. Although it was not the main focus of the analysis, the case of Jocelyn also showed students' sophistication with their assessment of everyday contexts they generated relative to the formal definition of basis. The fact that these women constructed these accessible contexts to explain basis positions these women of color as a resource for teaching instead of a group of students that persistently needing extra support. Taken together, these students' creativity and sophistication in assessing their examples and the potential utility of these everyday contexts challenge the narrative about women of color as persistently underachieving and academically inferior to their White and male counterparts.

With respect to the second aim, we have learned that students are capable of constructing productive explanations about basis using everyday ideas. They were able to come up with a variety of contexts in which they could describe basis. In grappling with what aspects of their contexts worked well and which did not, the students revealed many nuances of basis. This is important in two ways. First, these explanations revealed different roles basis vectors play in relation to the larger vector space, and nuanced characteristics of basis. Students' explanations delineated the relationship between basis vectors and the larger space in terms of *generating* and *describing*. As we saw with Jocelyn, nuanced characteristics such as *minimal, different, essential,* and *non-redundant* were important and interacted with one another in students' explanations. Second, methodologically, we have shown the utility of students' discussions of everyday examples in revealing their understanding of a topic. We might not have discovered these nuances using strictly formal mathematical questions. Moreover, there have been very few studies done on student understanding of basis and on students' ability to create everyday examples of mathematical constructs at the undergraduate level. For these reasons, this paper adds to the literature on student mathematical cognition at the undergraduate level.

In addition, we argue that the paper adds valuable data to the corpus of research in undergraduate mathematics education in that few studies have been written about the mathematical thinking of women of color (Adiredja & Andrews-Larson, in press). Sometimes this is because women of color have not been included in data sets (perhaps because there were not many women of color in the population from which the data was drawn). Other times we simply do not know whether or not women of color were in the data sets because, a review of the papers in recent proceeding of the Conference on Research in Undergraduate Mathematics Education (RUME) would reveal, it has not been common in the community to report data on gender and particularly on ethnicity.

With regards to findings of this study, we caution against the danger of *essentializing* these women, that is, attributing these examples as inherent to students' race and gender. It is tempting to gender or racialize these examples, which can lead to essentializing the students. Students did discuss basis in the context of fashion, cooking and religion, but they also brought up other contexts like driving, skeleton, and the universe. These contexts are likely inspired by the students' experiences, and not inherent to their ethnicity or gender. Future studies can further explore the range of contexts to explain basis, and the details of their differences. One can also investigate if there are shared learning experiences among women of color that might contribute to their flexibility to come up with these examples. Moschkovich (2012) has argued that there is nothing inherently different about the cognitive processes of students of color in mathematics, but there is a difference in their "conditions of learning" (p. 96). We can begin to explore ways that differences in conditions of learning might contribute to the examples students bring up in interviews.

We would also like to recognize the tendency to validate findings from or about an underrepresented group by comparing them to the behavior of the dominant group. We believe that our findings about this group of eight women of color are valid to stand on their own. The creativity of these women, and the productivity of their examples do not rest on how they might compare to White women, men of color, or White men. While it is interesting to find out what students from those other groups might come up with, studies with such focus are not inherently necessary to validate the findings of this paper. What we are arguing here is very much related to the critique in the literature about ways that achievement gap studies always center the achievement of the dominant group (Gutiérrez, 2008).

This work may have implications for practice and curriculum design. These everyday contexts can be used as potential entry points into basis. Moreover, as we saw with students in this study, generating explanations using everyday ideas can be a very fruitful activity in the classroom to reveal students' understanding of the topic. With respect to curriculum design, consider the experientially real starting points emphasized in the curriculum design framework of Realistic Mathematics Education (Freudenthal, 1983). Our analysis challenges us to reflect on what counts as an experientially real starting point for our students. Creating these experientially real starting points requires us to know our audience. In our past work we may have focused on certain types of students more than others in imagining what is experientially real to this audience. Making sure to interview and listen to the thinking of students who are not as often interviewed in RUME studies is vital to making sure we are reaching all students with our curriculum design, and in instruction more broadly.

Exploration of the Factors that Support Learning: Web-based Activity and Testing Systems in Community College Algebra

Shandy Hauk & Bryan J. Matlen
WestEd

A variety of computerized learning platforms exist. In mathematics, most include sets of problems to complete. Feedback to users ranges from a single word like "Correct!" to offers of hints and partially- to fully-worked examples. Behind-the-scenes design of such systems also varies – from static dictionaries of problems to responsive programming that adapts assignments to users' demonstrated skills within the computerized environment. This report presents background on digital learning contexts and early results of a mixed-methods study that included a cluster randomized controlled trial design. The study was in community college algebra classes where the intervention was a particular type of web-based activity and testing system.

Key words: Computer-based Learning, College Algebra, Multi-site Cluster Randomized Controlled Trial

Many students arrive in college underprepared for college level algebra, despite its importance for future success in mathematics (Long, Iatarola, & Conger, 2009; Porter & Polikoff, 2012). Web-based Activity and Testing Systems (WATS) are one approach to supporting equity and excellence in mathematics learning in colleges. When it comes to technology and algebra learning in college: What works? For whom? Under what conditions? These ubiquitous questions plague educational researchers who are assessing the whats, whys, and hows of a technology intervention or addition to a course. Did the instructors have enough support to adequately implement the technology tool? Were the online materials appropriate to provide sufficient practice for each students' needs? Did instruction with the intervention equitably prepare students to pass the final exam?

This report offers early results from a large project investigating relationships among student achievement and varying conditions of implementation for a web-based activity and testing system used in community college elementary algebra classes. Implementing a particular WATS constitutes the "treatment" condition in this cluster randomized controlled trial study. As described below, there are several ways to distinguish WATS tools. Some systems, like the one at the heart of our study, include adaptive problem sets, instructional videos, and data-driven tools for instructors to use to monitor and scaffold student learning.

Research Questions

Funded by the U.S. Department of Education, we are conducting a large-scale mixed methods study in over 30 community colleges. The study is driven by two research questions:

Research Question 1: What is the impact of a particular WATS learning platform on students' algebraic knowledge after instructors have implemented the platform for two semesters?

Research Question 2: What challenges to use-as-intended (by developers) are faculty encountering and how are they responding to the challenges as they implement the WATS tool?

Background and Conceptual Framing

There are distinctions among dynamic and static learning environments (see Table 1). Though the focus of this report is a particular dynamic system, we offer information on both to situate what that means. WATS learning environments can vary along at least two dimensions: (1) the extent to which they adaptively respond to student behavior and (2) the extent to which they are based on a careful cognitive model.

Table 1. Conceptual framework of WATS environments based on adaptability and basis in a theory of learning.

		Type of Adaptivity in Design	
		Static	*Dynamic*
Is a particular model of learning explicit in design and implementation (structure and processes)?	*No*	Text and tasks with instructional adaptation external to the materials	Adaptive tutoring systems (e.g., ALEKS, Khan Academy, ActiveMath)
	Yes	Textbook design and use driven by fidelity to an explicit theory of learning	"Intelligent" tutoring systems (e.g., Cognitive Tutor)

Static learning environments deliver content in a fixed order and contain scaffolds or feedback that are identical for all users. Although often informed by a learning theory, this type of system is distinguished from others in that it is not designed to immediately adapt to individual learning needs of users. An example of this type of environment might be online problem sets from a textbook that give immediate feedback to students such as "correct" or "incorrect." Studies of college algebra student achievement and attitudes when instruction uses these tools in conjunction with face-to-face instruction (e.g., computer-based homework rather than paper-and-pencil homework) is mixed, generally indicating that use will do no harm but is not particularly beneficial (e.g., Bishop, 2010; Buzzetto-More & Ukoha, 2009; Hauk, Powers, & Segalla, 2015).

Dynamic learning environments keep track of some user behaviors (e.g., errors, error rates, or time-on-problem) and use this information in a programmed decision tree that selects problem sets and/or feedback based on estimated mastery of specific skills. An example of an "adaptive" dynamic environment might be a system such as ALEKS or the "mastery challenge" approach now used in the online Khan Academy Mission structure. For example, in working on a particular skill (e.g., the distributive property) in the Algebra Mission, a behind-the-scenes data analyzer captures student performance on a "mastery challenge" set of items. Once a student gets six items in a row correct, the next level set of items in a programmed target learning trajectory is offered. Depending on the number and type of items the particular user answers incorrectly (e.g., on the path to six items in a row done correctly), the analyzer program identifies target content and assembles the next "mastery challenge" set of items. Some studies have found correlations between adaptive-dynamic systems and student learning (e.g., Murphy et al. 2014). However, other than our own, we are unaware of any large-scale experimental studies assessing the efficacy of adaptive-dynamic systems in college mathematics.

Above and beyond responsive assignment generation, programming in a "cognitively-based" dynamic environment is informed by a theoretical model that asserts the cognitive processing necessary for acquiring skills (Anderson et al. 1995; Koedinger & Corbett, 2006). For instance, instead of specifying only that graphing is important and should be practiced, a cognitively-based environment also will specify the student thinking and skills needed to comprehend graphing (e.g., connecting spatial and verbal information), and provide feedback and scaffolds that support these cognitive processes (e.g., visuo-spatial feedback and graphics that are integrated with text). In cognitively-based environments, scaffolds themselves can also be adaptive. For example, more scaffolding through examples can be provided early in learning and scaffolding can fade as a student acquires expertise (Ritter et al., 2007). Like other dynamic systems, cognitively-based systems can also provide summaries of student progress, which better enable teachers to support struggling students. The efficacy of early computer versions of such an approach has been documented in some large-scale studies in high school and college settings (Koedinger & Sueker, 1996; Koedinger et al., 1997). However, no fully tested cognitively-based web-based activity and testing system currently exists for college students learning algebra.

As mentioned, several adaptive dynamic systems do exist (e.g., ALEKS, Khan Academy "Missions"). The particular WATS investigated in our study is accessed on the internet and is designed primarily for use as replacement for some in-class individual seatwork and some homework. ***Note***: We report here on data collected from the first of two years of study. The second year of the study – which repeats the design of the first – is currently underway. Hence, we purposefully under-report some details.

Methods

The study we report here uses a mixed methods approach that combines a multi-site cluster randomized trial with an exploration of instructor and student experiences. Half of instructors at each community college site were assigned to use a particular WATS in their instruction (treatment condition), the other half taught as they usually would, barring the use of the Treatment WATS tool though other WATS might be used (control condition). Faculty participated for two semesters in order to allow instructors to familiarize themselves with implementing the WATS with their local algebra curriculum. Specifically, the first term in Fall was a "practice" semester to field-test the intervention and the second semester of the same academic year was the "efficacy" study from which data were analyzed.

Sampling Strategy

Rather than recruit a sample by convenience, which is likely to result in poor generalizability, we utilized a stratified sampling approach developed by Tipton (2014). This method is a way of recruiting a sample that is compositionally similar to the target population for which the results of the study are meant to generalize. The target population for this study was defined as students at all community colleges in semester-long elementary algebra courses (also known as "developmental" or "beginning" algebra, the equivalent of a first year of algebra), in the U.S. state where the study took place. This population was selected in part because the state is large and diverse, and in part because we sought to decrease variability that may result from differing high school mathematics standards and graduation requirements across multiple states.

To recruit a sample that was compositionally similar to the target population, we first created a database that included information about all eligible community college sites (more than 100 across the state). We included information on college-level characteristics that existing research suggests will correlate with the study outcome (e.g., the average age of students at the college, the proportion of adjunct faculty, the proportion of students enrolled in remedial math courses). We conducted a cluster analysis on these potential covariates with all of the eligible colleges. The analysis resulted in a five-cluster solution that explained 29% of the variance between colleges. Examination of the characteristics that were unique to each cluster yielded the following descriptive observations:

Cluster 1. Represented 25% of colleges. These are colleges with a total student enrollment near the average (across all community colleges in the state) whose students tend to take more credits in the evening relative to colleges in other clusters. Cluster 1 colleges have more Temporary Faculty, and more Hispanic students, African American students, and students over 40 years old.

Cluster 2. Represented 15% of colleges. These colleges serve primarily students aged 25 and above who take fewer credits and more commonly are evening students.

Cluster 3. Represented 22% of colleges. These are colleges with a total student enrollment near the state average where students are more commonly Asian, younger, and enrolled full time during the day.

Cluster 4. Represented 23% of colleges. Cluster 4 represents smaller colleges that have a higher proportion of white students that tend to be younger, mostly full-time, and take fewer evening courses.

Cluster 5. Represented 15% of colleges. These are larger colleges that have more Hispanic and younger students. Students tend to take more daytime courses, with more fulltime loads and many remedial mathematics courses and high remedial math enrollment.

Our recruitment efforts aimed to include a proportionate number of colleges within each of the five clusters. Recruitment for the first cohort of participants yielded a study sample of colleges similar to the overall distribution across clusters that was the target for the sample. Due to attrition (instructors leaving the study), the representation shifted away from the target slightly for Clusters 1 and 4 by the end of the second term (see Figure 1).

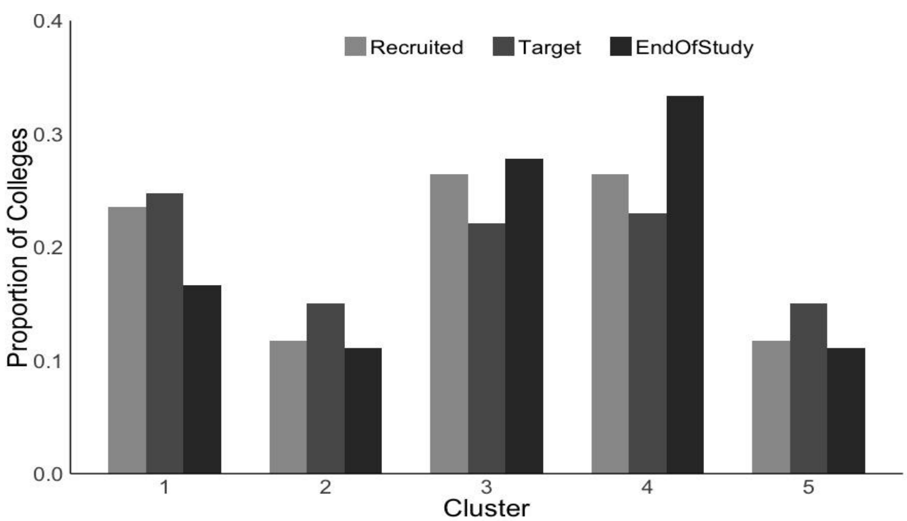

Figure 1. Recruited, target, and end of spring sample proportions across clusters.

Sample for this Report

Initial enrollment in the study included 89 instructors across 38 college sites. Attrition of instructors from initial enrollment to the end of the spring efficacy data semester was significant (68%). For this report, we analyzed the data from 510 students of 29 instructors across 18 colleges. Student and instructor numbers related to the data reported on here are shown in Table 2 and characteristics of the teachers and colleges are presented in Table 3.

Table 2. Counts of Instructors, Students, and Colleges in the Study.

Condition	*Instructors*	*Students*	*Colleges**
Control	17	328	13
Treatment	12	182	11
Total	*29*	*510*	*18*

* Note: there were multiple instructors at some colleges.

Table 3. Descriptive statistics for the student and instructor populations across the colleges in the study, by condition.

		Treatment		Control	
		M	*SD*	*M*	*SD*
		Student Characteristics			
	Enrollment	26,520	10,240	25,300	18,200
Proportions	U.S. Citizens	0.88	0.05	0.88	0.12
	Math Basic Retention*	0.80	0.03	0.82	0.06
	African American	0.04	0.03	0.06	0.03
	Asian	0.11	0.07	0.15	0.14

Measures

A great deal of textual, observational, and interview data were gathered last year and will be gathered again for the second iteration of the study. These data allow analysis of impact (Research Question 1) and careful analysis of the intended and actual use of the learning environment and the classroom contexts in which it is enacted – an examination of implementation structures and processes (Research Question 2). Indices of specific and generic fidelity derived from this work also will play a role in HLM generation and interpretation in the coming year. The instruments are summarized below. With the exception of the observation and interview tools, all measures were administered online.

Instructor Instruments

Technology and Teaching Survey. This survey measures teachers' self-reported ability to use technology for teaching.

Perspectives Survey. This survey consists of questions related to teachers' background (e.g., years of experience teaching algebra, demographic information) as well as their attitudes and perspectives about teaching.

Measures of Effective Teaching – Algebra Test. This test was developed, piloted, and validated by the Educational Testing Service as part of the *Measures of Effective Teaching* (MET) project. It assesses instructors' pedagogical content knowledge in developmental algebra.

Weekly Instructor Logs. After extensive pilot testing, weekly logs were developed that ask about course format, topics, and resources used for that week's instruction.

Observation & Interview. The observation protocol captures a variety of information, including frequency of mention of WATS use, work completed in a WATS (treatment or other), teacher in-class use of WATS tools, as well as amount of time spent in whole class, group, and individual work. The interview focus is on the successes and challenges teachers face in using a WATS as part of instruction.

Student Instruments

Mathematics Diagnostic Testing Project (MDTP) Assessment. The MDTP serves as the study's primary student outcome measure. The *Algebra Readiness* form is the pre-test administered at the start of the semester and the *Elementary Algebra* form is the end-of-semester post-test. The MDTP tests have been shown to be valid and reliable measures of students' algebraic understanding (Gerachis & Manaster, 1995).

Student Background Questionnaire. This survey asks students about academic and demographic information such as academic history in mathematics, eligibility for financial aide

Motivated Strategies for Learning Questionnaire (MSLQ). This questionnaire measures students' motivation and attitudes towards mathematics.

Student Evaluation of Teaching Survey. The evaluation survey asks students to assess their experience in the course using Likert-scale questions.

The way performance is calculated is a non-trivial issue in educational measurement. One way to estimate student achievement on the MDTP tests is to calculate the raw percentage correct (i.e., summing the number of correct scores, and dividing by the total possible score). However, such a calculation does not take into consideration other parameters of interest, such as item difficulty, that provide added information that can be used to estimate student ability. To address this issue, we used a multilevel extension of the two-parameter logistic item response theory model to compute student pre- and post-test scale scores (Birnbaum, 1968). Specifically, we computed response-pattern *expected a posteriori* estimates (EAP scores; Thissen & Orlando, 2001) for each student. Similarly, we created EAP average scores for each classroom (a teacher-level score). We used individual and classroom aggregate student EAP scores in the analytic model described below.

Results

Quantitative Analysis

The study employed Hierarchical Linear Modeling (HLM), controlling for students' pretest MDTP EAP scores, to estimate the impact of WATS use on student achievement. The hierarchical modeling approach accounts for the nested structure of the sample (Raudenbush & Bryk, 2002), specifically the nesting of students within instructors. Preliminary analysis revealed that the HLM choice was justified, as the intra-class correlation in the unconditional model was 0.36, suggesting that the observations were not independent (i.e., student scores varied based on their classroom – statistically, the teacher mattered – so other approaches, such as single-level regression, would be inappropriate). The specific HLM model we used:

$$Y_{ij} = \beta_{00} + \beta_{01}(WATS)_j + \beta_{10}(StuPre)_{ij} + \beta_{02}(InstructorPre)_j + \xi_{0J} + \epsilon_{I0} \quad \text{(Equation A)}$$

In the equation above,

- Y_{ij} is the MDTP post-test EAP score for the *i*-th student of the *j*-th instructor;
- β_{00} is the grand mean of EAP scores across all students;
- $(WATS)_j$ is a dichotomous variable indicating instructor assignment to use the particular treatment WATS or not;
- $\beta_{10}(StuPre)_{ij}$ is the student MDTP pre-test EAP score;
- $\beta_{02}(InstructorPre)_j$ is the MDTP pre-test EAP estimate for all students in the class of instructor *j*;
- ξ_{0J} and ε_{I0} represent a random effect term for instructors and a random error term, respectively.

All covariates were grand-mean centered to achieve the desired model interpretation (i.e., covariates were transformed to be centered on a mean of zero). Importantly, the impact of the treatment WATS use is captured by β_{01}.

Baseline equivalence. The What Works Clearinghouse (2014) considers baseline differences with a Hedges $g \leq .25$ to be within the range of statistical correction. However, differences of Hedges $g > .25$ are considered not amenable to statistical correction. As can be seen in Table 4, both situations occurred. The differences between Instructor mean EAP scores (i.e., classroom average) and student pre-test raw scores were moderate between the two conditions. However, the difference between student pre-test EAP scores was substantive across conditions (g = 0.30). The EAP pretest difference for students is large enough that the analytic sample might be considered non-equivalent at baseline on this variable (below, we discuss details that attempt to address this difference).

Table 4. Baseline equivalence analysis on the analytic sample.

	Effect Size Hedges g	*WATS*		*Control*	
		M	*SD*	*M*	*SD*
Student Pre (Raw Scores)	0.25	30.58	8.27	28.54	7.82
Student Pre (EAP Scores)	0.30	0.45	1.10	0.14	0.99
Instructor Pre (EAP Scores)	0.08	0.22	0.53	0.18	0.39

Intervention impact. The aim of the impact analysis was to address the question: After controlling for student and classroom-level average pre-test scores, what is the impact of the WATS intervention on students' elementary algebra knowledge, as measured by the MDTP? To address this question, we use Equation A to estimate the average impact of going from the control to the treatment condition. Ideally, what we are interested in is this: what would a control students' algebra achievement be if his/her instructor, in an alternative universe, were assigned to the treatment group? Because students cannot participate to both conditions simultaneously, our randomized trial is a proxy for this counterfactual scenario. The results of random and fixed effects in the model are presented in Tables 5 and 6, respectively.

The random effects (Table 5), tell us that the amount of variance that the instructor-level accounts for (i.e., the intraclass correlation) is about 28% (from Table 5 and a quick calculation, we see instructor variance divided by the total variance = **0.16**/(**0.40**+**0.16**)=**0.28**). This means that student level values are not independent. Put another way, students within classrooms were more similar to each other than students between classrooms. The intraclass correlation justifies our hierarchical analytic approach over single level regression. More generally (and in future work), we want to look at what instructors are doing to see how the instructor-level activity is shaping student achievement. The fixed effect model estimates are provided in Table 6. Controlling for students' pretest EAP scores, we found that using this particular WATS platform corresponded to a **0.35** increase in students' post-test EAP scores. This difference is considered a statistically significant positive effect ($p < .05$). The Hedges g value for this effect is 0.32, which is judged to be substantively important for educational research studies of this type (WWC, 2014). The 95% confidence interval around the effect estimate was 0.14 - 0.50, which is large, but spans an exclusively positive range.

Table 5. Random effects of the model.

	Variance	*Standard Deviation*
Instructor ξ_{0J}	**0.16**	0.40
Level-1 Error ε_{I0}	**0.40**	0.63

Table 6. Fixed effect results of the model.

	Estimate	*St. Error*	*p-value*
Intercept β_{00}	-0.10	0.10	0.34
WATS β_{01}	**0.35**	0.16	0.04
StudentPre β_{10}	0.73	0.03	< .001
InstructorPre β_{02}	0.30	0.19	0.13

Using raw MDTP scores (instead of EAP estimates) as outcomes and covariates in the model, we obtained similar results. In the raw score model, the impact of WATS was estimated to result, on average, in a 2.57 point increase in student raw score. This was a statistically significant positive effect ($p = 0.04$, $SE = 1.18$, *Hedges* $g = 0.32$). The control group mean was estimated at 22.04 (out of 50 points), thus, the 2.57 point difference corresponds to nearly 12 percentage points increase in post-test scores relative to the control group (2.57 / 22.04 * 100 = 11.66). Since baseline differences between treatment and control group student raw scores were within the range of statistical correction, the similarity between the two *models* (raw score and EAP score models) is important, providing more confidence in the estimates of positive impact.

The effect size across both analyses was estimated at 0.32. This result can be interpreted as the WATS group of students would have scored an estimated 0.32 standard deviations higher, on average, than the control group of students on the MDTP, had the groups been fully equivalent prior to the intervention. However, to interpret the effect size of 0.32 in a more meaningful way, we converted the effect size using properties of the normal distribution. In a normed sample, a one standard deviation increase from the middle of the distribution corresponds to a 34 percentile point increase in scores. Thus, an effect size of .32 would correspond to an approximate 11 percentile point increase in scores (i.e., .32 * 34 = 10.88). Therefore, if students in the control condition perform at the 50th percentile in a normed sample, the students in the WATS condition would perform at the 61st percentile in the normed sample (50 + 10.88 = 60.88).

While these results suggest that WATS has a positive impact on students' elementary algebra achievement, it is important to note that this study suffered from high instructor attrition. This fact, coupled with moderate to large baseline differences at pretest, warrant caution in interpreting the results. In order to determine whether the results of the present study are robust, we are repeating the study with a second cohort of instructors and their students in the 2016-17 school year. Pooling the results of these two studies will help to determine the extent to which the findings replicate with different samples and will lend more confidence in the study conclusions (Cheung & Slavin, 2015).

Qualitative Analysis

As in many curricular projects, developers of the WATS in our study paid attention to learning theory in determining the content in the web-based system, but the same was not true for determining implementation processes and structures. The pragmatic details of large-scale classroom use were under-specified. Developers articulated their assumptions about what students learned as they completed activities, but the roles of specific components, including the instructor role in the mediation of learning, were not clearly defined. Thus, there was an under-determined "it" to which developers expected implementers (instructors and students) to be faithful.

Fidelity of implementation is the degree to which an intervention or program is delivered as intended (Dusenbury, Brannigan, Falco, & Hansen, 2003). Do implementers understand the trade-offs in the daily decisions they must make "in the wild" and the short and long-term consequences on student learning as a result of compromises in fidelity? As Munter and colleagues (2014) have pointed out, there is no agreement on how to assess fidelity of implementation. However, there is a growing consensus on a component-based approach to measuring its structure and processes (Century & Cassata, 2014). Century and Cassata's summary of research offers five components to consider in fidelity of implementation: Diagnostic, Procedural, Educative, Pedagogical, and Student Engagement (Table 7, next page).

The components in Table 7 are operationalized through a rubric, a guide for collecting and reporting data in our implementation study. A rubric articulates the expectations for a category by listing the criteria, or what counts, and describes the levels of quality from low to high.

Each component has several factors that define the component. The research team has developed a rubric for fidelity of implementation that identifies measurable attributes for each component (for example, see Table 8 on the next page for some detail on the "educative" component). Data for assessing each row come from the survey, observation, and interview measures described earlier.

Table 7. Components and Focus in a Fidelity of Implementation Study.

Components	*Focus*
Diagnostic	These factors say what the "it" is that is being implemented (e.g., what makes this particular WATS distinct from other activities).
Structural-Procedural	These components tell the user (in this case, the instructor) what to do (e.g., assign intervention *x* times/week, *y* minutes/use). These are aspects of the *expected* curriculum.
Structural-Educative	These state the developers' expectations for what the user needs to know relative to the intervention (e.g., types of technological, content, and pedagogical knowledge needed by an instructor).
Interaction-Pedagogical	These capture the actions, behaviors, and interactions users are expected to engage in when using the intervention (e.g., intervention is at least *x* % of assignments, counts for at least *y* % of student grade). These are aspects of the *intended* curriculum.
Interaction-Engagement	These components delineate the actions, behaviors, and interactions that students are expected to engage in for successful implementation. These are aspects of the *achieved* curriculum.

Table 8. Example Rubric Descriptors for Levels of Fidelity, Structural-Educative Component.

Educative: These components state the developers' expectations for what the user (instructor) needs to know relative to the intervention.

	High Level of Fidelity	Moderate Fidelity	Low Level of Fidelity
Users' proficiency in math content	Instructor is proficient to highly proficient in the subject matter.	Instructor has some gaps in proficiency in the subject matter.	Instructor does not have basic knowledge and/or skills in the subject area.
Users' proficiency in content (CK), pedagogical (PK), and technological knowledge (TK)	Instructor regularly integrates content, pedagogical, and technological knowledge (TK) in classroom instruction. Communicates with students through WATS.	Instructor struggles to integrate CK, PK, and TK in instruction. Occasionally sends digital messages to students using WATS tools.	Instructor CK, PK, and/or TK sparse or applied in a haphazard manner in classroom instruction. Rarely uses WATS tools to communicate with students.
Users' knowledge of philosophy behind the intervention	Instructor understands philosophy of WATS resources (practice items, "mastery mechanics," analytics, and coaching tools),	Instructor is aware of it, but understanding of the philosophy of WATS tool has some gaps.	Instructor is not aware of or does not understand philosophy of WATS resources.
*Users' knowledge of requirements of the intervention**	Instructor understands the purpose, procedures, and/or the desired outcomes of the project (i.e., "mastery")	Instructor understanding has some gaps (e.g., may know purpose, but not all procedures, or desired outcomes).	Instructor does not understand the purpose, procedures, and/or desired outcomes. Problems are typical.

* Note: Disagreeing is okay, this is about instructor knowledge of it.

Defining and Refining Measures for the Fidelity of Implementation Rubric

The ultimate purpose of a fidelity of implementation rubric is to unpack and articulate the conditions of implementation and the relationship between those conditions and impact on student achievement. In addition to allowing identification of alignment between developer expectations and classroom enactment, an examination of implementation provides the opportunity to discover where productive adaptations may be made by instructors, adaptations that boost student achievement beyond that associated with an implementation faithful to the developers' view.

In using the rubric, we assign a number to each level of fidelity for each teacher across the year of data collection. This can be as simple as the approach shown in Table 8, a 3 for a high level of fidelity, 2 for a moderate level of fidelity, or a 1 for a low level. The general score for a teacher-level index of implementation fidelity will be the total number of points assigned in completing the rubric as a ratio of the total possible. At a more detailed level, once we have completed rubric analysis to create the row by row scores for each instructor, these scores will be used as a vector of values in statistical modeling of the impact of the intervention as part of a "specific fidelity index" (Hulleman & Cordray, 2009).

We are at the beginning of addressing Research Question 2: What challenges to use-as-intended (by developers) are faculty encountering and how are they responding to the challenges as they implement the WATS tool? To date, analysis of observations, interviews, and weekly logs has provided the opportunity to discover instructional orientations. Several orientations are emerging from analysis now and include a "denial" orientation in which instructors see the WATS as no different from themselves as a teacher, a "polarized" orientation where an instructor is either indifferent (no/low expectations for success) or enthusiastic (high/excessive expectations for success) about the power of student engagement with the WATS, a "cautious optimism" in which the instructor sees the WATS as one tool in a collection of resources to be used strategically in designing instruction, or an "adaptation" orientation in the sense that the instructor sees the WATS as a resource for which appropriate instructional use is negotiated with and through the students' goals for interaction with the software in the context of the algebra course. In addition to the fidelity scoring of alignment between developer expectations and classroom enactment, these orientations may serve to explain the relationship between implementation and impact, getting at how and for whom WATS are most effective.

Next Steps

As indicated above, we will continue this study with a second cohort of new participants in the 2016-2017 academic year. Our specific objectives in the coming six months are to complete the second cohort's efficacy semester, generate fidelity indices for each instructor in each cohort, and complete separate and collective statistical modeling explorations.

Implications for practice. Though the study is ongoing, the early results might be considered promising. If the question is: Should I use a WATS? The answer is: It depends. Taking into account the potentially biased statistical impact results to date and the exploration of variation in instructor implementation, it appears likely that an orientation of "cautious optimism" or "adaptation" may be required for a dynamic WATS tool like the one in the study to have significant impact on student learning.

Implications for research. A mixed-methods study like the one reported here is large and complex. We note here that there were significant challenges in recruiting and retaining community college mathematics faculty for the project. To build community and assist in future research efforts in two-year colleges (and as part of our dissemination about the work) we have targeted outlets read by community college faculty (e.g., MathAMATYC Educator – a journal of the American Mathematical Association of Two Year Colleges). It is important for practitioners and potential participants in studies on research in undergraduate mathematics education to be aware of research and the enormous contributions they can make to it. Secondly, a major implication for research (for us) was the work in managing all the data generated by the project. The reader is encouraged to review the piece by our colleague Aleata Hubbard that also was presented at the conference, *Data Cleaning in Mathematics Education Research: The Overlooked Methodological Step*.

"Explanatory" Talk in Mathematics Research Papers

Juan Pablo Mejía-Ramos
Rutgers University

Matthew Inglis
Loughborough University

In this paper we explore the ways in which mathematicians talk about explanation in their research papers. We analyze the use of the words explain/explanation (and various related words) in a large corpus of text containing research papers in both mathematics and physical sciences. We found that mathematicians do not frequently use this family of words and that their use is considerably more prevalent in physics papers than in mathematics papers. In particular, we found that physicists talk about explaining <u>*why*</u> *disproportionately more often than mathematicians. We discuss some possible accounts for these differences.*

Key words: corpus linguistics, mathematical language, mathematical explanation.

The notion of explanation in mathematics has received a lot of attention in both mathematics education and the philosophy of mathematics. In mathematics education, scholars have been particularly interested in proofs that explain mathematical theorems (i.e. proofs that provide an insight into why a mathematical claim is true) and their role in the mathematics classroom (e.g. Hanna, 1990). Philosophers of mathematics have discussed at length possible equivalents for mathematics of existing philosophical theories of scientific explanation (e.g. Steiner, 1978). Some of these discussions bring to bear the extent to which explanation is relevant to the actual practice of mathematicians and often cite individual mathematicians' views on mathematical explanation. In this report we explore the extent to which mathematicians talk about explanation in their research papers, and the ways in which they do so.

Literature review

In an influential paper in mathematics education, de Villiers (1990) argued that proof serves several different roles in mathematics, that proof is not only used in mathematics as a way to verify results, to provide conviction of the truth of those results (see also Bell, 1976). One of those other functions of proof was to *explain* mathematical results, to provide an insight or understanding into why these results were true, as opposed to just evidence in support of that result. Hanna (1990) made a similar distinction in the context of the teaching and learning of mathematics, discussing the idea that certain proofs fulfilled this explanatory function better than others, to the point that among the set of all proofs one could identify proofs that explain why a theorem is true, while others simply demonstrate that a theorem is true. Mathematics educators have generally suggested that in the mathematics classroom, mathematical explanation should be an important, if not the primary role of proof (de Villiers, 1990; Hanna, 1990; Hersh, 1993).

This distinction between proofs that explain and proofs that demonstrate has a longer history in the philosophy of mathematics. Steiner (1978) put forward a model of mathematical explanation, arguing that an explanatory proof could be better defined in terms of what he called *a characterizing property* of a concept in the theorem, as opposed to other alternative defining characteristics such as the abstractness or the generality of the proof. Steiner's top-down approach to modeling mathematical explanation by providing a general definition of explanatory proof (and thus creating an absolute distinction between explanatory and non-explanatory proofs) has been criticized by other philosophers of mathematics. In particular, Hafner and

Mancosu (2005) argued that ascribing explanatoriness to specific proofs should be done based on practicing mathematicians' evaluations, not philosophers' own intuitions (such as Steiner's). The extent to which practicing mathematicians not only agree with philosophers' characterization of mathematical explanation, but simply talk about explanation in their practice plays an important role in the general argument for the *existence* of explanation in mathematics (which not all philosophers believe). As such, it is not uncommon for philosophical discussions of mathematical explanation to mention how much mathematicians talk (or do not talk) about it. For example, Steiner claimed that "mathematicians routinely distinguish proofs that merely demonstrate from proofs which explain" (p.135). However, there is sharp disagreement regarding the extent to which mathematicians explicitly discuss such distinctions, or the notion of explanation in general. For instance, Resnik and Kushner (1987) claimed that mathematicians "rarely describe themselves as explaining" (p. 151), and Hafner and Mancosu (2005) responded stating that "[c]ontrary to what Resnik and Kushner claim (p. 151), mathematicians *often* describe themselves and other mathematicians as explaining" (p. 223, emphasis on the original). Hafner and Mancosu (2005) supported this claim by presenting several examples of what they called *"explanatory" talk* in mathematical practice: passages of research mathematics papers in which the authors explicitly discuss the role of explanation in their own work. However, this kind of evidence is not sufficient to settle the disagreement. Indeed, the specific cases discussed by Hafner and Mancosu have been interpreted in significantly different ways:

> "I believe that detailed case studies, such as those by Hafner and Mancosu (2005), decisively refute Resnik's and Kushner's [claim]" (Lange, 2009, p. 203, our emphasis).

> "Though philosophers have lately been pointing out some exceptions, the examples tend to be rather exotic (e.g., in Hafner and Mancosu 2005). There has been no systematic analysis of standard and well-discussed texts illustrating any pattern of mathematical explanations." (Zelcer, 2013, 179-180)

We agree that a systematic analysis of the type suggested by Zelcer (2013) is necessary to address this issue. Overton (2013) performed one such analysis in the context of scientific discourse. He analyzed all regular articles published in the journal *Science* in a one year period (a total of 781 papers and approximately 1.6 million words), searching for all "explain" words (defined to be one of the following words: explain, explains, explained, explaining, explainable, explanation, explanations, unexplained, unexplainable, explicate, explicates, explicated, explicable, inexplicable) and comparing their frequencies to those of other types of words. Overton (2013) found that approximately 45% of the 781 papers contained at least one "explain" word (with a total of 368 explain words per million words in his sample of papers) and concluded: "The numbers for "explain" are perhaps surprisingly low if scientific journals are vehicles for explanations. […] The observed frequencies of "explain" words suggests that explanation is only moderately important in science." (p. 1387)

Our goal in this paper is to report a similar analysis in the context of mathematics. One method of studying mathematical discourse at such a scale is to use the techniques of corpus linguistics, a branch of linguistics that statistically investigates large collections of naturally occurring text, known as corpora. Methods developed by corpus linguists can be used to investigate many different types of linguistic questions. Here, we report a study that employs some of these techniques to address the following questions: to what extent do mathematicians discuss explanation in their research papers, how does it compare to the extent to which they discuss other important related notions (such as *proving* theorems), and how does it compare to discussions about explanation in other types of scientific discourse?

Theoretical perspective

Discussions about mathematical explanation tend to differentiate between explanations of other mathematics (i.e. mathematics X explains mathematics Y, or X is an explanatory proof of theorem Y), and explanations of physical phenomena (i.e. mathematics X explains physical phenomenon Y). Colyvan (2011) refers to these two types of explanation as *intra-mathematical* and *extra-mathematical*, respectively. Here we focus on intra-mathematical explanations.

Hafner and Mancosu (2005) further differentiated between two uses of intra-mathematical explanations: those that are "instructions" on how to master the tools of the trade (as in explaining how to employ a certain mathematical technique), and those that "call for an account of the mathematical facts themselves, the reason why" (p. 217). While Hafner and Mancosu considered the latter to be a "deeper" use of mathematical explanation, which is also the focus of the larger philosophical discussion around explanatory proofs, others have emphasized the importance of the former type of explanation in mathematical practice. For instance, Rav (1999) insisted that one of the main reasons mathematicians read proofs is because of all the mathematical know-how embedded in them, emphasizing the mathematical methodologies and problem solving strategies/techniques contained in proofs. According to Rav, "proofs are for the mathematician what experimental procedures are for the experimental scientist: in studying them one learns of new ideas, new concepts, new strategies—devices which can be assimilated for one's own research and be further developed." (p. 20) Indeed, there is empirical evidence (from both small scale interview studies and large scale surveys) that mathematicians maintain that one of the main reasons they read proofs is to gain insights into how they can solve problems that they are working on (Weber & Mejía-Ramos, 2011, Mejía-Ramos & Weber, 2014).

An interesting question related to the specific ways in which mathematicians talk about explanation in their papers (to the extent that they do), relates to these two types of *"explanatory" talk*: to what extent do mathematicians discuss explanations of *why* a certain mathematical statement is true, compared to their talk about explanations of *how* to do something in mathematics?

Methods

One of the main ways in which mathematicians around the world communicate about mathematics is through research papers stored in the ArXiv. The ArXiv is an online repository of electronic preprints of scientific papers in the fields of mathematics, physics, astronomy, computer science, quantitative biology, quantitative finance, and statistics. These papers constitute a large corpus of scientific text that can be used to analyze mathematical discourse.

We downloaded the bulk source files (mostly TeX/LaTeX) and converted the source code to plain text, which we could then analyze using standard software packages for corpus analysis (all analyses reported in this paper were performed using CasualConc, version 2.0.3). We then sorted these articles based on their primary and secondary subject classification (Alcock et al., 2017, discussed the details about the processing of these source files). The analyses reported in this paper are based on a proper subset of this corpus, containing all mathematics and physics articles (based on their primary subject classification) uploaded in the first eight months of 2009. In the first part of the paper we focus on articles uploaded in the first four months of 2009. After analyzing these articles, we performed these same analyses on the papers uploaded in the following four months of 2009 (May through August), in search of further evidence supporting our findings.

Results

Table 1 presents the number of physics and mathematics papers (as well as the number of words[1] in each set of papers) uploaded in January-April and May-August of 2009. We notice that researchers uploaded to the ArXiv approximately 2.4 times as many physics papers as mathematics papers in these eight months. We also notice that on average physics papers contained approximately 5000 words, whereas on average mathematics papers contained roughly 6200 words.

	January-April 2009		May-August 2009	
	#papers	#words	#papers	#words
Mathematics	5,087	30,892,695	4,970	31,289,569
Physics	11,787	58,859,660	12,370	62,807,075

Table 1. Number of papers and words in the physics and mathematics corpora

Frequency of explicit *"explanatory" talk* in the January-April 2009 papers

Following Overton (2013), we defined explain-words to be one of 18 words linguistically related to the word *explain* (henceforth *explain-words*)[2]:

Explain-words: explain, explains, explained, explaining, explainable, explanation, explanations, explanatory, unexplained, unexplainable, explicate, explicates, explicated, explicating, explicable, inexplicable, explication, explications.

Table 2 shows the frequencies of explain-words in our corpus of 5087 mathematics papers and 11787 physics papers uploaded between January and April of 2009. Explain-words showed up a total of 4910 times in the mathematics papers (around 159 times per million words), an average of 0.97 times per paper, with 1898 of mathematics papers (approximately 37%) in this sample containing at least one explain-word. While this certainly provides an existence proof of explicit *"explanatory" talk* in this corpus, it is not very surprising (it would very rare if no word based on the word explain showed up in these many mathematics papers). In comparison, explain-words showed up 21345 times in the corresponding set of physics papers (around 363 times per million words), an average of 1.81 times per paper, with 6499 of these papers (roughly 55% of the physics papers) containing at least one explain-word. We see that the number of explain-words per million words in the physics papers is around 2.28 times that of the mathematics papers.

---

[1] A word here is any string of characters between spaces. Importantly, as discussed in Alcock et al. (2017), for these analyses we opted to replace all occurrences of inline mathematics with the string "inline_math" and count it as one word. For instance, the string "Let $f\colon X \rightarrow Y$ be a bijection" in a paper, coded in LaTeX by the authors as "Let $f:X\rightarrow Y$ be a bijection", would have been translated to text as "Let inline_math be a bijection" and coded as having 5 words.

[2] We added *explanatory, explication, explications,* and *explicating* to the 14 words in Overton's (2013) analysis.

	Mathematics		Physics	
	frequency	per million	frequency	per million
explain	1827	59.14	7768	131.97
explained	1690	54.71	6513	110.65
explanation	498	16.12	3564	60.55
explains	484	15.67	1601	27.20
explaining	175	5.66	914	15.53
explanations	119	3.85	675	11.47
explanatory	51	1.65	62	1.05
unexplained	22	0.71	177	3.01
explication	13	0.42	4	0.07
explicated	10	0.32	15	0.25
explicate	6	0.19	5	0.08
explicating	5	0.16	0	0.00
unexplainable	4	0.13	8	0.14
explications	4	0.13	2	0.03
explainable	1	0.03	23	0.39
explicates	1	0.03	1	0.02
explicable	0	0.00	9	0.15
inexplicable	0	0.00	4	0.07
Total	4910	158.94	21345	362.64

Table 2. Frequency and frequency per million words of explain-words appearing in the January-April mathematics and physics papers

In order to get a sense of the extent to which these frequencies were high or low in this type of mathematical discourse, we compared them against the frequencies of words related to other important mathematical activities. Table 3 presents the frequencies of words linguistically related to the notions of conjecturing, defining, modeling, proving, showing, and solving.

Conjecture-words:[3] *conjecture, conjectured, conjectures,* conjectural, conjecturally, conjecturing.

Define-words: *defined, define, definition, defines, definitions,* defining, definable, undefined, redefine, redefined, definability, redefinition, definably, redefining, welldefined, definedness, interdefinable, predefined, redefinitions, interdefinability, redefines, definitional, definitionally, undefinability, undefinable.

Model-words: *model, models,* modeled, modeling, modelled, modelling, countermodel, submodel, submodels, modelized, modelization, modelisation, modelize, modelizing, countermodels, premodel, remodeled.

[3] For each group, words are listed in order of frequency, with the most frequent words in the group listed first. The italicized words in each group make up 95% of all instances of words from that group appearing in the mathematics papers uploaded in the first four months of 2009.

Prove-words: *proof, prove, proved, proves, proofs*, proving, proven, provable, reprove, disprove, provability, provably, reproved, disproved, unprovable, unproven, reproving, disproving, reproves, prover, unproved, subproof, disproof, disproven, disproves, reproven.

Show-words: *show, shows, shown, showed*, showing.

Solve-words: *solution, solutions, solve, solving, solvable, solved, solves, resolvent,* solvability, subsolution, resolved, resolving, supersolution, resolve, solver, resolvents, unsolved, resolves, solvers, nonsolvable, supersolutions, subsolutions, unresolved, nonsolvable, unsolvable, cosolvable, equisolvable, supersolvable, unsolvability.

We note that measured against these other frequencies, mathematicians used explain-words rather infrequently. For instance, mathematicians used explain-words in their papers approximately 12 times less frequently than show-words and nearly 23 times less often than prove-words.

	frequency	per million	per paper	in #papers	in %papers
define	124129	4018.07	24.40	4838	95%
prove	111838	3620.21	21.99	4710	93%
show	59359	1921.45	11.67	4691	92%
solve	53013	1716.04	10.42	3073	60%
model	23658	765.81	4.65	2013	40%
conjecture	8362	270.68	1.64	1413	28%
explain	4910	158.94	0.97	1898	37%

Table 3. Frequencies (including frequencies per million words and per paper) of words related to *explaining, conjecturing, defining, modeling, proving, showing,* and *solving* in the January-April mathematics papers. The last two columns provide the number of papers containing at least one word in that group and the percentage of such articles

Finally, the search for explain-words may be thought of as requiring an extremely explicit discussion of explanation, one that would leave unnoticed a significant amount of the *"explanatory" talk* in these papers. Hafner and Mancosu (2005) offered a list of eight expressions that they had found to be commonly used in the mathematics and philosophy of mathematics literature to describe the search for explanations. Table 4 presents these expressions along with the specific concordance search we made to investigate their prevalence in both the mathematics and physics papers, and the frequencies with which these alternative expressions appeared. We note that the total number of occurrences of these expressions is only about 10% of the total amount of explain-words in each set of papers (with disproportionately more occurrences of these expressions in the physics papers than the mathematics ones) and thus this analysis does not affect the finding made by only investigating the use of explain-words.

Based on these results, we also conclude that Hafner and Mancosu (2005) may have grossly overestimated how common these expressions are in mathematics research papers. We are also left wondering to what extent such *common* alternative expressions exist.

Alternative expression	Concordance search	Mathematics	Physics
"the deep reasons"	deep* reason*	5	16
"an understanding of the essence"	understand* the essence	0	5
"a better understanding"	better understand*	161	767
"a satisfying reason"	satisfy* reason	0	0
"the reason why"	reason* why	312	924
"the true reason"	true reason	3	1
"an account of the fact"	an account of the fact	0	0
"the causes of"	cause* of	16	609
	Total	497	2322

Table 4. Frequencies of alternative expressions of related to *"explanatory" talk* in the January-April mathematics and physics papers

Explaining why vs. explaining how

In order to investigate mathematicians' discussion of *explanations of why* a certain mathematical statement is true (Hafner and Mancosu's "deep" explanation), in comparison to their talk about *explanations of how* to do something in mathematics (related to Rav's notion of mathematical know-how), we created a concordance of the corpus of papers and identified every instance an explain-word had been immediately followed by the words why or how (e.g. unexplained why, explanation how). We did this by searching the concordance for *expla* why and *expla* how, and checking that all results were indeed uses of explain-words. We then repeated the process with the corpus of physics papers. As, shown in Table 5, there is a clear difference between the ways that explain-words show up in the mathematics and the physics research papers.

	Mathematics		Physics	
	frequency	per million	frequency	per million
expla why	247	7.99	952	16.17
expla how	458	14.83	353	6.00
Total	705	22.82	1305	22.17

Table 5. Frequencies and frequencies per million words of explain-words immediately followed by the words *why* or *how* in the January-April mathematics and physics papers

We note that when taken together the total of *expla*-why and *expla*-how expressions were roughly as common in math papers as they were in physics papers, with approximately 22 of these expressions showing up per million words in each set of papers, and also a relatively small subset of the wider use of explain-words (roughly 14% and 6% of explain-word usage in mathematics and physics, respectively). However, the distribution of these two different types of expressions in the two sets of papers was significantly different (Fisher's exact test, $p < .001$), with mathematicians using nearly twice as many *expla*-how expressions as *expla*-why expressions, and physicists on the other hand using between two and three times as many *expla*-why expressions as *expla*-how expressions.

Frequency of explicit *“explanatory” talk* in the May-August 2009 papers

A valuable outcome of having access to such large corpora of scientific writing, and the means to analyze them, is that we can parse these corpora and use certain parts for exploratory and other parts for confirmatory purposes. As such, having conducted the previously reported analyses on the mathematics and physics papers uploaded to the ArXiv between January and April 2009, we then performed these analyses on the papers uploaded between May and August of that year. Table 6 presents the frequencies of explain-words appearing in this new set of mathematics and physics papers, while Table 7 presents the frequencies of explain-words immediately followed by the words *why* or *how* in these set of papers.

	Mathematics		Physics	
	frequency	per million	frequency	per million
explain	1881	60.12	7974	126.96
explained	1841	58.84	6596	105.02
explanation	537	17.16	3788	60.31
explains	525	16.78	1694	26.97
explaining	166	5.31	954	15.19
explanations	98	3.13	740	11.78
explanatory	36	1.15	78	1.24
unexplained	19	0.61	159	2.53
explication	1	0.03	5	0.08
explicated	6	0.19	12	0.19
explicate	6	0.19	12	0.19
explicating	0	0.00	5	0.08
unexplainable	0	0.00	1	0.02
explications	2	0.06	5	0.08
explainable	1	0.03	24	0.38
explicates	0	0.00	0	0.00
explicable	0	0.00	24	0.38
inexplicable	1	0.03	12	0.19
Total	5120	163.63	22083	351.60

Table 6. Frequency and frequency per million words of explain-words appearing in the May-August mathematics and physics papers

	Mathematics		Physics	
	frequency	per million	frequency	per million
expla why	277	8.85	970	15.44
expla how	526	16.81	464	7.39
Total	803	25.66	1434	22.83

Table 7. Frequency and frequency per million words of explain-words immediately followed by the words *why* or *how* in the May-August mathematics and physics papers

Table 6 reveals the same pattern of frequencies explain-words as those presented in Table 2. Indeed, the same five explain-words (explain, explained, explanation, explains, and explaining) made up 95% of all explain-words in each set of papers. Furthermore, the number of explain-words per million words was very similar in each set of papers (going from 158.94 to 163.63 in mathematics, and from 362.64 to 351.60 in physics), with the number of explain-words per million words in the physics papers being around 2.15 times that of the mathematics papers.

Similarly, the frequencies presented in Table 7 are consistent with those in Table 5: there was a similar number of *expla*-why and *expla*-how expressions per million words in each discipline (25.66 in mathematics, and 22.83 in physics paper), but there was a significantly different distribution of these two different types of expressions in the two sets of papers (Fisher's exact test, $p < .001$), with mathematicians using nearly twice as many *expla*-how expressions as *expla*-why expressions, and physicists on the other hand using a little over twice as many *expla*-why expressions as *expla*-how expressions.

Discussion

Our analysis of *"explanatory" talk* in a large sample of mathematics papers does not offer support for a claim often made in the philosophy of mathematics: that this type of talk is prevalent in mathematical discourse. When compared to explicit discussion of other related mathematical practices (e.g. showing results, solving problems, and proving theorems), mathematicians do not seem to discuss explanation nearly as much. Furthermore, when compared to another scientific discourse, we found that mathematical discourse contains only a fraction of *"explanatory" talk* as research papers in physics. Indeed, we believe these findings suggest that the prevalence of *"explanatory" talk* in mathematical discourse has been widely exaggerated.

Furthermore, by analyzing the frequency with which variations of the expressions *explain why* and *explain how* occur in mathematics and physics research papers, we found that, to the extent to which they engage in *"explanatory" talk*, mathematicians seem to be much more interested in discussing explanations of how to do something in mathematics, than in explanations of why things are the way they are in mathematics. In physics we found the situation to be the opposite. This is particularly interesting given mathematics educators' and philosophers' of mathematics preoccupation with the type of intra-mathematical explanations of the form X explains why Y (where X and Y are mathematical assertions), and particularly with the notion of explanatory proofs (in which proof X explains why theorem Y is true). This focus may have been inherited from the more traditional study of the notion of scientific explanation, which is not only naturally concerned with this type of explanations (the desire to explain the real world is full of why-questions), but according to our findings may also be more commonly discussed in scientific discourse in terms of answers to why-questions. However, our findings suggest that this focus may also be misguided for those interested in studying the notion of mathematical explanation as it more commonly occurs in the discourse of professional mathematicians. Indeed, as suggested by Rav (1999), it seems that when it comes to proofs and explanations, mathematicians are primarily interested in learning how to solve other problems, possibly over learning the reasons why some mathematical results hold true.

Now, one must be careful about several inferential jumps made in this kind of analysis. First, while the ArXiv may well be the largest, most widely used repository of this type of preprints and postprints in the world, we have analyzed a very specific type of mathematical discourse, leaving open the possibility that studies of mathematical discourse in others settings (conversational or other digital communications) could lead to contrasting findings. Second, we have analyzed these research papers for a limited type of *"explanatory" talk*, one required to contain explain-words or a limited number of alternative, related expressions. While this was an obvious place to start to investigate *"explanatory" talk* in mathematical discourse, it is certainly possible that the analysis of other expressions related to mathematical explanation may skew our results. These limitations of the present study indicate clear avenues for future empirical research on mathematical explanation.

How Limit can be Embodied and Arithmetized: A Critique of Lakoff and Núñez

Tim Boester
University of Illinois at Chicago

In Where Mathematics Comes From*, Lakoff and Núñez (2001) describe how the notions of infinity and limit can be constructed through metaphorical extensions of embodied experiences. This paper will critique their historical and psychological analysis, revealing an unresolved tension between a simplified, geometric "approaching" conception and the arithmetization of calculus by Weierstrass. A proposal of how to rectify this conflict through acknowledging how novices can metaphorically tie these concepts together is discussed.*

Key words: Embodied Cognition, Limit, Infinity

Lakoff and Núñez created a detailed guide of how humans learn mathematical ideas through the principles of embodied cognition in *Where Mathematics Comes From* (2001). From constructing a foundation of grounding metaphors directly connected to embodied experiences, to extending mathematical ideas beyond what can be directly experienced (such as the concept of infinity), the authors created a new theoretical paradigm for mathematics education research. The work, however, has also been criticized most notably for the inadequacies of their "mathematical idea analysis" methodology (Schiralli & Sinclair, 2003). It is long overdue that we follow the advice of these critics and attempt to solidify the metaphorical construction of the mathematical concepts that form the building blocks of their work, so that we as a field can continue to conduct embodied cognition mathematics education research on the firmest foundation possible.

Limit Conceptualization: A Brief History

In particular, an unresolved tension exists between how Lakoff and Núñez connect the two different ways a student could conceptualize limit, through either a dynamic conception or a static conception (Cornu, 1992). The dynamic conception is a motion-based idea of limit, frequently expressed using dynamic language such as "approaching". Graphically, this is demonstrated by moving a point along a graph towards another point for the limit of a function. The static conception, on the other hand, forgoes all motion in order to describe limit in terms of closeness through the coordination of intervals. This is expressed through static language such as "is close to" or "within the range of". Graphically, this is demonstrated through intervals on each axis for the limit of a function.

The underlying difficulty with Lakoff and Núñez's approach is that they conflate these two possible conceptions of limit. The following sections explore in detail the how and why they do this, and the difficulties associated with this approach, but there are a couple of general problems that should be addressed at the outset.

First, this approach is historically inaccurate. Limits were originally conceived of in terms of fluxions, or what we now think of as infinitesimals, which is a different sort of hand-waving than approaching, but it caused similar problems in terms of formality (Kleiner, 2001). Cauchy and Weierstrass later formalized the work of Newton and Leibniz (Grabiner, 1992a) by eliminating the crutch of fluxions and requiring the coordination of two small intervals for the limit of a function at a point. One interval's radius, signified by the Greek letter delta (δ), surrounds the input or x-value, while the second interval's radius, represented by the Greek letter epsilon (ε), surrounds the output or result of the function applied to the x-value. The coordination of the two intervals is accomplished through the logical quantification portion of the definition: for any epsilon, there exists a delta, such that if the input value is within the delta interval, then the output value must be within the epsilon interval. These intervals are symbolized through the distance interpretation of the absolute value, while the logical quantification uses common logical symbols for "for any," "there exists," and the "if …, then …" structure. Conflating the dynamic and static conceptions of limit misses the historical context of how the static conception was the solution to the informalities of another conception.

Second, and more important in terms of a theory of cognition, conflating these conceptions is also problematic because, if these two conceptions were one and the same, we'd see evidence of that in student thinking, and we don't. The trajectory of mathematics education research of limit began with an initial focus on establishing misconceptions in undergraduates' understanding of limit (Bezuidenhout, 2001; Davis & Vinner, 1986; Tall & Vinner, 1981), which then evolved into proposals on how students might build appropriate conceptions of limit (Cottrill et al., 1996; Lakoff & Núñez, 2001; Williams, 1991, 2001). These proposals brought about several more studies yielding successful interventions into students' limit conceptions (Boester, 2010; Oehrtman, 2009; Roh, 2008, 2010; Swinyard & Larsen, 2012). While there are unresolved questions concerning the relationship between the dynamic and static conceptions of limit, altogether, the entire body of mathematics education limit research on limit has this difference between the dynamic and static conceptions as their most basic finding. Students simply treat these conceptions as fundamentally different.

Certainly, a robust conception of limit most likely contains both a dynamic aspect and a static aspect, but that does not mean that they are the same. Conversely, this doesn't necessarily mean that embodied cognition is flawed, simply that it has been misapplied to explain how we conceptualize limits. The difficulties encountered by conflating these conceptions of limit will hopefully provide a guide to appropriately apply embodied cognition to motivate and ultimately coordinate both conceptions into a solid metaphorical framework.

Conceptualizing Limit Through the BMI

Before introducing the concept of limit, Lakoff and Núñez first discuss how we as humans can conceptualize infinity. All mathematical ideas that are not taken directly from embodied experiences must be built through metaphorical extensions. This is particularly important here, because infinity does not actually exist in the universe. Since we can't directly experience infinity, we have to use metaphors in order to conceptualize it.

Infinity is commonly thought of as an infinitely continuous process, one which goes on forever. In order to motivate this specific type of process, which cannot actually occur, Lakoff and Núñez propose a particular metaphorical leap in our thinking: finite iterative processes can be thought of as infinite iterative processes, which in turn can be thought of as infinitely continuous processes. For example, we can begin with "jump", an inherently "perfective" process, which means it has an end, a completion. Each jump has an end state. But if you describe someone as "jumping and jumping and jumping", we tend to assume this means an indefinite number of jumps. So while "jump" is a finite iterative process, "jumping and jumping and jumping" is an infinite iterative process. We can then extend this thinking further to "swimming", an imperfective process which has no designated end. Thus "swimming and swimming and swimming" is an infinitely continuous process.

Now of course, a person cannot go on swimming forever, but Lakoff and Núñez argue that we can create a metaphorical leap to think about what that would look like, as swimming is a continuous activity, and what could happen at the end of such an infinite process, which moves us from a potential infinity to actual infinity.

The Basic Metaphor of Infinity

Source Domain Completed Iterative Processes		*Target Domain* Iterative Processes That Go On and On
The beginning state	→	The beginning state
State resulting from the initial stage of the process	→	State resulting from the initial stage of the process
The process: From a given intermediate state, produce the next state.	→	The process: From a given intermediate state, produce the next state.
The intermediate result after that iteration of the process	→	The intermediate result after that iteration of the process
The final resultant state	→	**"The final resultant state" (actual infinity)**
Entailment *E:* The final resultant state is unique and follows every nonfinal state.	→	**Entailment *E:* The final resultant state is unique and follows every nonfinal state.**

Figure 1. The basic metaphor of infinity (Lakoff and Núñez, 2001, p. 159).

With the basic metaphor of infinity (BMI) in place, Lakoff and Núñez are ready to introduce limit by first discussing a one-dimensional limit: an infinite sequence along a number line that approaches a particular number (the limit). The traditional, formal definition of limit in terms of sequences is: the sequence $\{x_n\}$ has L as a limit if, for each positive number ε, there is a positive integer n_0 with the property that $|x_n - L| < \varepsilon$ for all $n \geq n_0$ (pp. 189-90). Unfortunately, this definition cannot use the BMI directly, because there is nothing being iterated. That's important because the basic metaphor of infinity relies on iteration (the jumping). Because the basic concept of limit includes infinity, the authors need to use the BMI here, but because the BMI relies on iterative processes, they need a definition of limit where something iterates.

Thus, the definition they create relies on nested sets, whose iterative quality can be directly connected to the BMI: $0 < r < |x_n - L|$, where R_n is the set of all values r bounded between zero and $|x_n - L|$. As $|x_n - L|$ gets smaller, the range of values in R_n gets smaller. Since the size of the sets R_n is decreasing, these sets can be nested: $R_{n+1} \subset R_n$. This chain of nested sets is then used in the BMI to obtain the limit (where the "last" nested set, R_∞, would be the empty set). Lakoff and Núñez take the expression $0 < r < |x_n - L|$ to be synonymous with $|x_n - L| < \varepsilon$ so that we can then extend the BMI to cover the standard formal definition.

In summary, Lakoff and Núñez are required to use the BMI to explain the concept of limit, because limit utilizes the concept of infinity. Because infinity does not exist in reality, this presents a critical challenge to a theory of mathematics that is entirely based on real-world, embodied experiences, hence the necessity of the BMI. But the BMI uses indefinite iterative processes, and the standard formal definition of sequences does not. So the authors need to formulate a new definition which does, hence nested sets. These nested sets can be plugged into the BMI as an indefinite iterative process, and thus be used to explain our conception of limit.

Simple Approaching and the Nonnecessity of Nested Sets

To demonstrate the process of approaching a limit, and how this utilizes the BMI, Lakoff and Núñez give an example sequence $\{x_n\} = n/(n+1)$. As n increases, the value x_n gets closer and closer to 1 (p. 187).

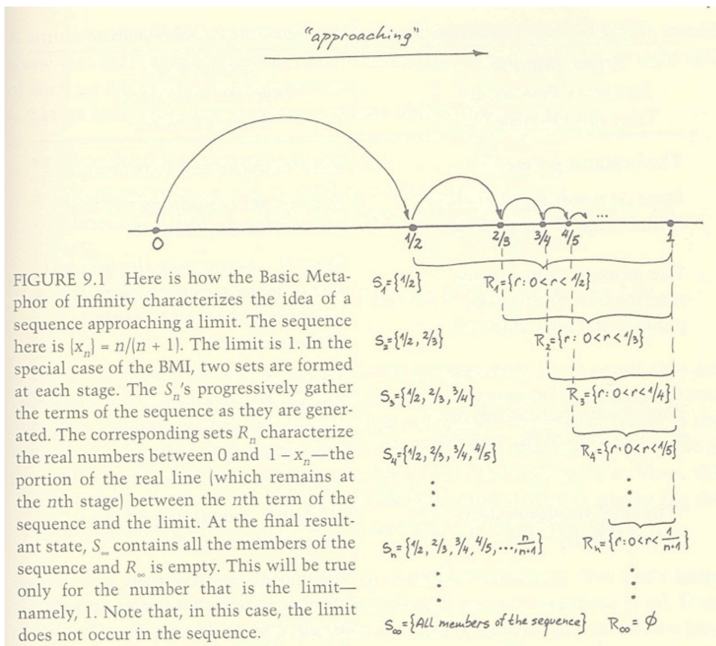

Figure 2. Example monotonic sequence (Lakoff and Núñez, 2001, p. 189).

This example is strictly monotonic, in that it creeps up on the limit in one direction, always getting closer and closer to 1, never farther away. This matches the smooth, motion-based "approaching" conception of limit. Taking smaller and smaller steps towards a wall would be a physical interpretation of the steps of this sequence.

Notice that Lakoff and Núñez are using a very formal, very complicated argument here to justify not just limit, but the concept of approaching, labeled at the top of the above diagram. Unfortunately, there is no evidence in the limit research literature to support the conclusion that students think of approaching in this complicated, set-theoretic way. One could make the argument that perhaps this is what students are doing under the surface, and we just haven't looked hard enough. Or that what Lakoff and Núñez describe is how experts think, but not students (although in that case, they don't describe what students might be thinking or the process to go from a novice to expert perspective).

The real problem here is that Lakoff and Núñez only have one definition for limit, and it must encompass both the dynamic and the static conceptions. Thus, it has to contain all of the formal pieces of the static conception, even when those pieces are overkill, like in the above example. In their attempt to mathematize the concept of "approaching", they are completely ignoring the natural, physical-ness of approaching. What they are trying to do is characterize the distance between you and the limit: the distance becomes smaller as you approach the limit. However, they use a complicated mathematical concept (nested sets) encoded in a complicated mathematical notation, when a description of "approaching" as simply going towards something would suffice.

Overextending Approaching to Cover Complex Limits

Not all sequences behave as nicely as the above example, however. Sequences (and functions) can approach limits in far more complicated ways than simply monotonically. Another example Lakoff and Núñez provide is what they call a teaser sequence.

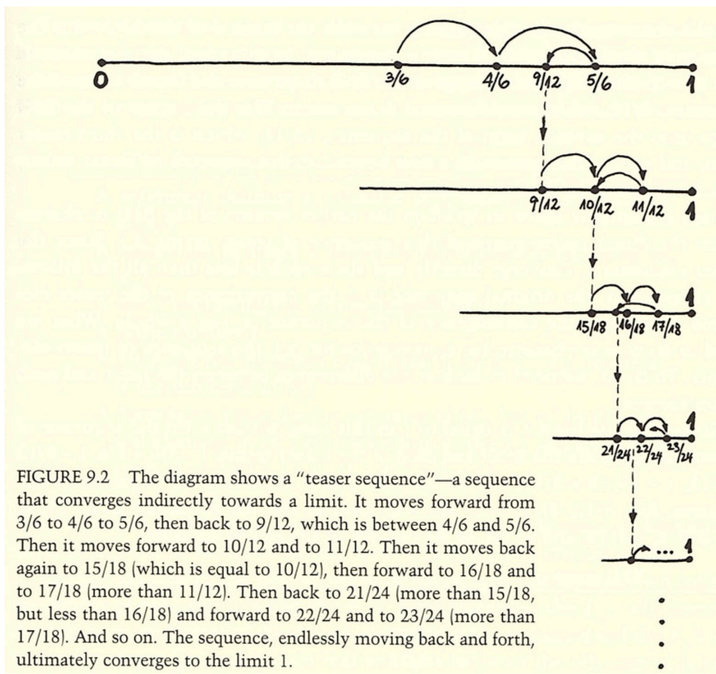

FIGURE 9.2 The diagram shows a "teaser sequence"—a sequence that converges indirectly towards a limit. It moves forward from 3/6 to 4/6 to 5/6, then back to 9/12, which is between 4/6 and 5/6. Then it moves forward to 10/12 and to 11/12. Then it moves back again to 15/18 (which is equal to 10/12), then forward to 16/18 and to 17/18 (more than 11/12). Then back to 21/24 (more than 15/18, but less than 16/18) and forward to 22/24 and to 23/24 (more than 17/18). And so on. The sequence, endlessly moving back and forth, ultimately converges to the limit 1.

Figure 3. Example teaser sequence (Lakoff and Núñez, 2001, p. 193).

This sequence converges indirectly but still has a limit. In terms of nested sets, one needs to pick particular x_n terms to ensure that $R_{n+1} \subset R_n$. In this case, every other term would work (corresponding to the dotted lines in the above diagram). This improves their coverage of possible types of limit convergence, but does stretch the metaphorical interpretation of limits as "approaching". This would correspond to a physical interpretation where, for each step taken towards a wall, a step a fraction of that size is taken going away from the wall (remembering that the steps overall are getting smaller and smaller).

The physical interpretations of both monotonic and indirect convergence also illuminate another way that students may think of limit, as a barrier that cannot be crossed (Davis and Vinner, 1986). Mathematically, this is called a bound. Both examples presented thus far are bounded at the limit because they only approach from one direction.

Lakoff and Núñez do not provide an example like an alternating sequence such as $\{x_n\} = (-1)^n / (n+1)$, whose limit is neither an upper or lower bound. (The limit of this sequence is zero, but one could consider any sequence which "alternates" above and below a non-zero limit.)

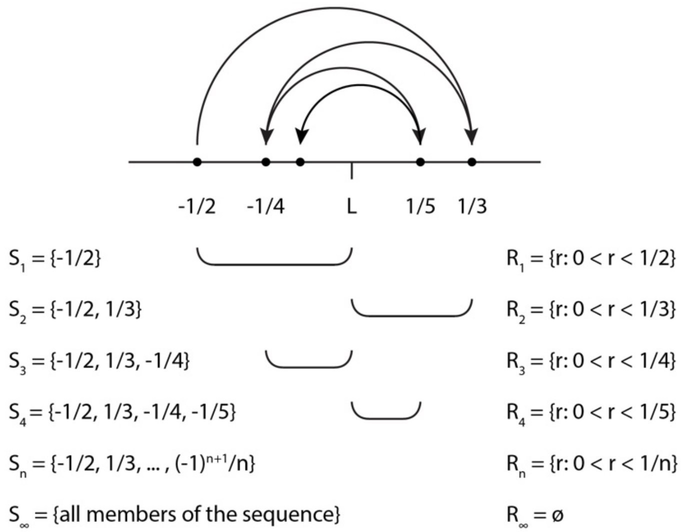

Figure 4. Example alternating sequence.

Having terms of the sequence on both sides of the limit is covered by the absolute value portion of the original formal definition of limit of a sequence: by making a range around *L*, it doesn't matter if you are above *L* or below it, as long as you are no more than ε away. Lakoff and Núñez also cover this possibility in their definition when they utilize absolute value notation for nested sets. Remember that the nested sets R_n are defined as the sets of the values *r* can take when $0 < r < |x_n - L|$. However, none of the examples presented in the book necessitate the usage of absolute value in the definition, as all instances of x_n are less than *L* (thus simply writing $0 < r < L - x_n$ would suffice). The above alternating sequence finally requires us to use the absolute value portion of the definition Lakoff and Núñez propose. But how does this example affect the meaning of "approaching"?

While it is still possible to stretch this motion-based concept to include approaching from both sides, there are some important implications in doing so. First, as one will be approaching the limit from both sides, this example is difficult to conceptualize using the types of physically-based interpretations used to ground the concept of "approaching": it would be like trying to approach a wall from both sides simultaneously. Second, one would need to abandon the idea that the limit is a barrier or bound, because you would be (repeatedly) passing through it. You could not conceptualize the wall in our example as a barrier. Third, the sequence may equal the limit while it is "approaching" the limit. In taking the limit of the sequence $x_n = \left(\sin\left(\pi n / 4\right)\right) / n$, there are many times where the sequence yields values that are zero. In fact, we don't even need to turn to something as complicated as this: a constant sequence will equal its limit everywhere. This really challenges the concept of "approaching" the limit, since, for a constant function, you don't actually move at all.

These three implications push the "approaching" metaphor away from the natural, motion-based conception of limit mentioned earlier. Of course, one might be able to create a convincing argument on how we can take a physical sense of approaching and stretch it or reinterpret it to cover the case of an alternating sequence, but then I'd just propose another sequence with more obscure "approaching" behavior. (This situation gets even more unacceptable with the definition of limit for a function at a point, as we can consider examples that misbehave in spectacular ways, such as a function that is discontinuous everywhere but still has a limit at a particular point). We'd have to keep pushing and pushing on this physical sense of approaching when confronted with worse and worse sequences, making more and more special cases and reinterpretations for those sequences, until the concept of "approaching" is a litany of exceptions and really doesn't connect with our embodied experiences much at all anymore.

Conflating Approaching With the Formal Definition

If Lakoff and Núñez want to stay with the embodied, motion-based "approaching" conception of limit, they need to stick with simple examples which are not stretched too far from normal experiences. However, in mathematizing these simple examples, they should not use the absolute value, because it is not necessary. This means that whatever mathematical definition they try to establish, based on the examples, it cannot use the absolute value, which means that it cannot duplicate the formal definition (Figure 5, argument one).

If they want to motivate the formal definition, then they must use the absolute value as it appears in the formal definition when using the BMI. In order to motivate the usage of the absolute value, they need more complex examples which approach the limit from both sides. In doing this, they then must use much more complicated explanations of "approaching" than those which naturally arise because of the implications discussed above (Figure 5, argument two).

The authors try to do both. Their bottom-up argument originates with the desire to motivate the formal definition using the BMI. They cannot do this without using the absolute value. However, working top-down they examine the "approaching" conception of limit and use examples which naturally tie into this conception. Unfortunately, there is no reconciliation between the simple examples and their usage of the absolute value (Figure 5, Lakoff and Núñez).

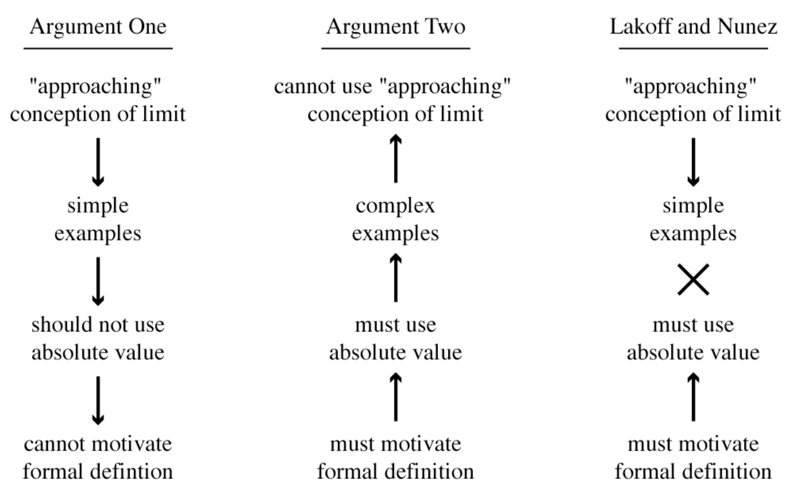

Figure 5. Linking the informal, motion-based conception of limit with the formal definition.

The way to fix this problem is to acknowledge that these two conceptions of limit are fundamentally different, they come from different things, they have different consequences, which means they should be built through separate metaphorical constructs. Traditionally, students first learn the dynamic conception, and we should base this on a natural metaphor of motion along a path. Next, students typically learn the static conception, which should be based on its own metaphor for closeness. Lakoff and Núñez's BMI-produced subset metaphor, one which is motion-free and emphasizes sets, is suitable for sequences, and a similar metaphor could potentially be used for the input-output relationship for functions. Then, students can use a final metaphorical association to combine both the static and dynamic conceptions into an overall conception of limit.

Approaching as Motion Along a Path

At the beginning of their book, Lakoff and Núñez discuss grounding metaphors, those which directly access our physical, embodied experiences. One of those utilizes motion along a path, an experience that we have all had many times, starting from an early age, to build what is illustrated below, the Source-Path-Goal schema. A schema is a coordinated combination of several concepts, which here includes a source, a path, a trajector (you moving along the path), and the goal. I propose that this is the schema that students base their conceptual metaphor for approaching a limit, for both sequences and functions.

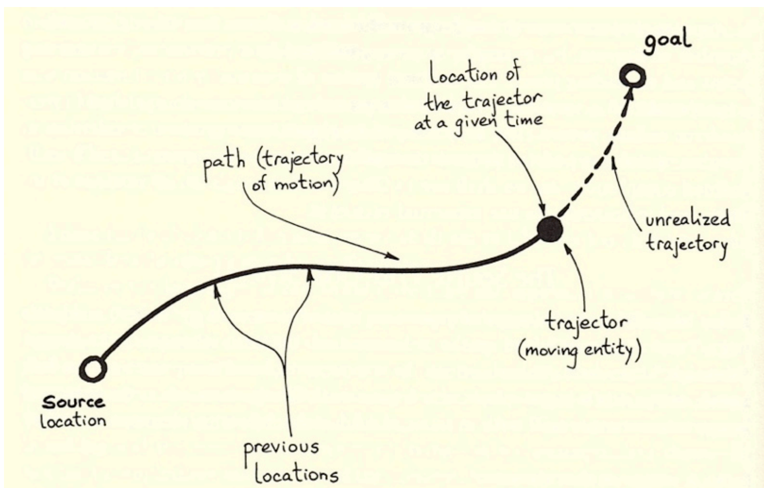

FIGURE 2.2 The Source-Path-Goal schema. We conceptualize linear motion using a conceptual schema in which there is a moving entity (called a trajector), a source of motion, a trajectory of motion (called a path), and a goal with an unrealized trajectory approaching that goal. There is a logic inherent in the structure of the schema. For example, if you are at a given location on a path, you have been at all previous locations on that path.

Figure 6. Source-Path-Goal schema (Lakoff and Núñez, 2001, p. 38).

Creating a metaphorical mapping from this schema to the limit of a function is more straightforward than a mapping to the limit of a sequence, as motion along a two-dimensional, continuous function is a more natural extension of motion along a path. If we think of a nicely behaved, prototypical function that has a limit at a point, then we can see how the parts of the Source-Path-Goal schema (left, Figure 7) can be mapped to the parts of "approaching" a limit of a function at a point (right, Figure 7). Your position on the function is the trajector, the goal is the x-value of the function being approached, the route is the path of the function's graph, and the direction is getting closer to the limit. Your starting point is a little nebulous, as that is not clearly defined, but you still have one, it is just somewhere away from the limit (wherever you started). The most important part is the last line, as the final location, the goal, is the y-value of the function the path is approaching regardless of what happens when you actually get there (since that's the whole point of a limit). This is the sort of metaphorical entailment that is possible through embodied cognition: the actual goal for the source domain may not be realized in the target domain (as the function may not equal the limit at the x-value of interest).

Approaching a Limit is the Source-Path-Goal Schema

Source Domain Source-Path-Goal Schema		Target Domain Approaching a Limit
A trajector that moves	→	Your position on the function
A source location (the starting point)	→	A coordinate on the function away from the limit
A goal – an intended destination for the trajector	→	The x-value being approached
A route from the source to the goal	→	The path (graph of) the function
The position of the trajector at any given time	→	Your (moving) position on the graph
The direction of the trajector at that time	→	Moving towards the limit
The actual final location of the trajector	→	The y-value the function tends toward, regardless of what the function does at the actual x-value being approached

Figure 7. Approaching a limit at a point on a function is the Source-Path-Goal schema.

Approaching a Limit is the Source-Path-Goal Schema

Source Domain Source-Path-Goal Schema		Target Domain Approaching a Limit
A trajector that moves	→	Your position on the number line
A source location (the starting point)	→	The first term of the sequence
A goal – an intended destination for the trajector	→	The "last" (infinite) term of the sequence
A route from the source to the goal	→	The steps from each term to the next
The position of the trajector at any given time	→	The n^{th} term of the sequence
The direction of the trajector at that time	→	Moving towards the limit
The actual final location of the trajector	→	The value the sequence tends toward

Figure 8. Approaching a limit of a sequence is the Source-Path-Goal schema.

Because a sequence is a set of discrete values, building a metaphorical mapping from this schema to the limit of a sequence is somewhat more complicated, as the “path” isn’t so obvious. Instead of the two-dimensional path present in a function, we now have a one-dimensional path with discrete steps. But the same type of metaphorical mapping from the Source-Path-Goal schema (left, Figure 8) to the target domain of a sequence (right, Figure 8) works here as well. The trajector is your position on the number line, there is a clear starting point with the first term of the sequence, the goal is the last (infinite) term of the sequence, the route is the jumps from one term to the next (even when the jumps are complicated), and the direction is still (generally) moving towards the limit. Again, the final location is the value the sequence tends towards, even if the sequence never attains that particular value.

Formal Definition as Closeness

Once students have built a dynamic conception of limit for sequences or functions, I propose that students build a separate, static conception of limit that supports the formal definition. For sequences, Lakoff and Núñez provide the details for how students metaphorically map iterative processes to the limit of infinite sequences. As long as this metaphor is not trying to support both the static and dynamic conceptions of limit simultaneously, then this mapping has none of the problematic issues detailed above. If it is only used to provide a sense of closeness divorced from the conception of approaching a limit, then the notation and rigor of nested sets is entirely appropriate.

THE BMI FOR INFINITE SEQUENCES (PROTOTYPICAL VERSION)

Target Domain ITERATIVE PROCESSES THAT GO ON AND ON		*Special Case* INFINITE SEQUENCES WITH A LIMIT L
The beginning state (0)	⇒	The Sequence and Limit frame
State (1) resulting from the initial stage of the process	⇒	S_1 = the set containing the first term of the sequence
The process: From a prior intermediate state (n–1), produce the next state (n).	⇒	From S_{n-1} containing the first n–1 terms of the sequence, form S_n containing the first n terms of the sequence.
The intermediate result after that iteration of the process	⇒	The set S_n. The set R_n containing all positive real numbers r such that $0 < r < \|x_n - L\|$. $R_n \subset R_{n-1}$.
“The final resultant state” (actual infinity “∞”)	⇒	**The set S_∞ containing all the terms of the sequence**
		There is no positive real number r such that $0 < r < \|x_i - L\|$ for all x_i in S_∞. Hence, $R_\infty = \varnothing$. L is the limit of the sequence.
Entailment *E*: The final resultant state (“∞”) is unique and follows every nonfinal state.	⇒	**Entailment *E*: L is the unique limit of the sequence.**

Figure 9. The BMI for infinite sequences (Lakoff and Núñez, 2001, p. 190).

Lakoff and Núñez do not provide a similar metaphorical mapping from the BMI to the limit of a function at a point. They suggest that the input and output of a function can be thought of as two infinite, coordinated sequences, and therefore the output of the function is close to the limit of the output sequence when the input is close to the limit of the input sequence (p. 198). However, this coordination of the two sequences is nontrivial. In an earlier paper, Lakoff and Núñez (1997) attempt to characterize this coordination:

> Many students of mathematics are falsely led to believe that it is the epsilon-delta portion of these definitions that constitutes the rigor of this arithmetization of calculus. The epsilon-delta portion actually plays a far more limited role. What the epsilon-delta portion accomplishes is a precise characterization of the notion of "correspondingly" that occurs in the dynamic definition of limit where the values of $f(x)$ get "correspondingly" closer to L as x gets closer to a. That is the only vagueness that is made precise by the epsilon-delta definition. (Lakoff & Núñez, 1997, p. 71).

While it is true that mathematicians must formalize the concept of "correspondingly", that, in and of itself, does not formalize "closeness". And by creating two infinite, coordinated sequences, it is the "closeness" of the input and output to their respective limits that Lakoff and Núñez have formalized, not the "correspondingly".

For this reason, I propose a different metaphorical mapping for the formal definition of limit at a point on a function, taken from an earlier study (Boester, 2010). The bolt problem was introduced to students to give them a real-world context for the logical quantification involved in the formal definition (the "correspondingly"). It basically asks the students to state the relationship between the error tolerances on the input (raw materials) and the output (length of the bolts produced by the machine).

The bolt problem is the formal definition of limit

Source Domain Bolt Problem		Target Domain Formal Definition of Limit
For any bolt length tolerance	→	$\forall \varepsilon > 0$
There exists a raw materials tolerance	→	$\exists \delta > 0$
Such that	→	Such that
If ..., then ...	→	... → ...
the amount of raw materials put into the machine is within the raw materials tolerance	→	$0 < \lvert x - a \rvert < \delta$
the length of the bolt the machine produces will be within the bolt length tolerance	→	$\lvert f(x) - L \rvert < \varepsilon$

Figure 10. The bolt problem is the definition of limit at a point on a function (Boester, 2010).

Once students could explain the solution to the problem (left, Figure 10), the notation of the formal definition and the canonical delta-epsilon picture were given, and the pieces of all three were mapped to each other.

Resolution: Connecting Approaching With the Formal Definition

Finally, once students have both the dynamic and static conceptions, how could they ultimately combine both conceptions? It could potentially occur in a few different ways, but data collected from the earlier study (Boester, 2010) suggests that students put the static conception into motion (rather than freezing their dynamic conception to make it static). These students still preferred the dynamic conception over the static (as shown through their language choices). When describing the static conception, they no longer restrict themselves to static language, and instead use a mix of static and dynamic language. (The same students use solely dynamic language when asked to explain how a limit "approaches" a number.) Eventually, some people will flip this relationship, so that the static conception will be the dominant conception and the dynamic conception is a special case.

For example, in an interview, I asked Lisa to explain the formal definition of limit at a point. She drew the following diagram while giving the explanation below:

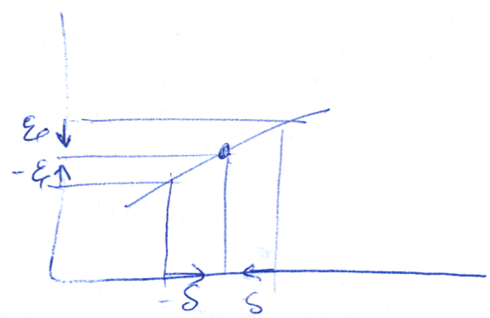

Figure 11. Lisa's limit graph (Boester, 2010).

30. L: I don't, not really, 'cause I can't really remember. But um, like, so you're like *going towards* a point on a graph…
31. T: Mmm-hmm.
32. L: … like this is [unintelligible]. And then, you have like here, here, so this is your um, this is your, uhh, **delta**, and this is your other **delta**…
33. T: Mmm-hmm.
34. L: … and as you're like *getting closer* this way …
35. T: Ok.
36. L: … then you're *getting closer* that way, I think.
37. T: Ok.

Even though she's describing delta (and the "other delta", as she had forgotten the word "epsilon" – she's referring to the ranges), she's using dynamic language to do it. The only static language pieces (bold) are those referring to the ranges. The dynamic language pieces (italics) describe those normally static ranges being put into motion. She's coordinating the delta and epsilon intervals, and is expressing that as the epsilon interval gets smaller (arrowheads), then the corresponding delta interval has to get smaller too, depending upon the function. She's leveraging the dynamic aspects of approaching in order to help her understand and connect the formal, normally-static definition of limit of a function at a point.

This suggests that students initially connect these distinct metaphors by assuming the "approaching" conception is the correct one, and that the static conception of the formal definition is a special case, as shown by putting the synchronized ranges created in the definition into motion. This would imply that students are using the pieces of the "approaching" conception as the source domain and the static conception as the target domain, thus mapping the dynamic aspect of motion along a line to the static (now dynamic) aspect of the range. As students' conception of limit evolves through this connection, recognizing that the formal definition conception is the correct one and that the "approaching" conception is the special case, they take on a conceptual structure analogous to an expert view. This would imply that the students are using the static conception as the source domain and the dynamic conception as the target domain, thus mapping the static ranges to the dynamic (now static) aspect of approaching.

Conclusion

The dynamic, "approaching" conception of limit and the static, formal definition cannot be reconciled the way Lakoff and Núñez propose. Instead of the argument presented, the authors could have simply kept the motion-based conception and the formal definition initially separate, instead of conflating the two. First, they could have presented the motion-based, "approaching" conception of limit, the examples which match this, and a conceptual metaphor which does not use the absolute value. Then later, they could have shown how the motion-based, "approaching" conception of limit breaks down when faced with more complicated types of limit convergence, how this ultimately lead Cauchy (Grabiner, 1992a, 1992b) to move to a new conceptual metaphor of proximity or range, which was later refined by Weierstrass (Lakoff and Núñez, 2001, p. 308) and how this leads to the absolute value being used in the formal definition.

By mixing a motion-based definition with an static-based definition, Lakoff and Núñez cloud the real issue: how do people move from the intuitive, grounded, dynamic conception of limit to the formal, static definition? This is the central pedagogical question that we need to be asking, but through their casual use of absolute value, they gloss over it. The authors attempt to begin with the "approaching" conception of limit, which students use, and try to directly connect it to an understanding of the formal definition. However, while the formal definition is an important concept for students to understand, it is based on a completely different metaphorical foundation than the motion-based conception of limit. This implies that, when it is time for the transition from the "approaching" conception to the formal definition to take place, a new metaphor needs to be introduced.

The formal definition was created to solve and explain cases of limit convergence that the "approaching" conception cannot explain, thus no amount of twisting the informal conception of limit will suffice. This has happened with other prominent scientific concepts as well. For example, Einstein's theory of general relativity was created to explain not only the normal cases explained by Newtonian mechanics, but also cases where those ideas break down (particularly situations concerning the very large and the very small). Thus, a new metaphor was created which encompasses the old one, but does not build off of it. Newtonian mechanics cannot be sufficiently extended in order to link to the general theory of relativity; however, the general theory of relativity can still be used in situations where Newtonian mechanics works. The same principle should be attempted here: because the "approaching" conception simply cannot be extended to cover all cases of limit convergence, a new metaphor which explains the formal definition needs to be introduced to students, making clear that, while the formal definition works in all cases, the "approaching" metaphor still works in simple cases. The informal dynamic conception should not be abandoned, as there is value in supporting such dynamism, even if the expert view needs to contain the formal definition (Marghetis & Núñez, 2013).

Alice Slowly Develops Self-Efficacy with Writing Proof Frameworks, but Her Initial Progress and Sense of Self-Efficacy Evaporates When She Encounters Unfamiliar Concepts: However, It Eventually Returns

Ahmed Benkhalti — New Mexico State University
Annie Selden — New Mexico State University
John Selden — New Mexico State University

We document Alice's progression with proof-writing over two semesters. We analyzed videotapes of her one-on-one sessions working through the course notes for our inquiry-based transition-to-proof course. Our theoretical perspective informed our work and includes the view that proof construction is a sequence of mental and physical, actions. It also includes the use of proof frameworks as a means of getting started. Alice's early reluctance to use proof frameworks, after an initial introduction to them, is documented, as well as her subsequent acceptance of and proficiency with them by the end of the real analysis section of the course notes, along with a sense of self-efficacy. However, during the second semester, upon first encountering semigroups, with which she had no prior experience, her proof writing deteriorated, as she coped with understanding the new concepts. But later, she began using proof frameworks again and regained a sense of self-efficacy.

Key words: Transition-to-proof, Proof Construction, Proof Frameworks, Self-efficacy, Coping with Abstraction, Working Memory

This case study focuses on how one non-traditional mature individual, Alice, in one-on-one sessions, progressed from an initial reluctance to use the technique of proof frameworks (Selden & Selden, 1995; Selden, Benkhalti, & Selden, 2014) to a gradual acceptance of, and eventual proficiency with, both writing proof frameworks and completing many entire proofs with familiar content. We also consider how this approach to proof construction helped this individual gain a sense of self-efficacy (Bandura, 1994, 1995) with regard to proving, but later evaporated upon encountering unfamiliar abstract concepts. However, after some time she was able to return to using the technique of proof frameworks and regained a sense of self-efficacy. This study also further illuminates the well-known, documented tendency of students to write proofs from the top-down, who consequently are often unable to develop complete proofs.

Theoretical Perspective

In our analysis and in our teaching, we consider proof construction to be a sequence of mental and physical actions, some of which do not appear in the final written proof text. Such a sequence of actions is related to, and extends, what has been called a "possible construction path" of a proof, illustrated in Selden and Selden (2009). For example, suppose that in a partly completed proof, there is an "or" in the hypothesis of a statement yet to be proved: "*If A or B, then C.*" Here, the situation is having to prove this statement. The interpretation is realizing the need to prove C by cases. The resulting action is constructing two independent sub-proofs; one in which one supposes A and proves C, the other in which one supposes B and proves C.

When several similar situations are followed by similar actions, an *automated link* may be learned between such situations and actions. Subsequently, a situation can be followed by an action, without the need for any conscious processing between the two (Selden, McKee, & Selden, 2010). When a situation occurs together with an action well beyond the simple forming of a link through associative leaning, it may be "overlearned" and the action will then occur automatically in the presence of the situation (Bargh, 2014). In our course, we have observed that, with sufficient practice, many proving actions can become the result of the enactment of linked, and sometimes automated, situation-action pairs. We have called these automated situation-action pairs *behavioral schemas* (Selden, McKee, & Selden, 2010; Selden & Selden, 2008). Linking proving actions to triggering situations and automating those actions can considerably reduce the burden on working memory, a very limited resource, and this tends to reduce errors (Baddeley, 2000).

Related Research and Concepts

While studies of students' proving have been made before, they have *not* often focused on students' use of proof frameworks. For example, Selden and Selden (1987) examined errors and misconceptions in undergraduate abstract algebra students' proof attempts. They found instances of assuming the conclusion, proving the converse, improper use of symbols, misuse of theorems, and trouble with quantifiers. Similarly, Hazzan and Leron (1996) in their study of students' misuse of Lagrange's Theorem found that students often used the converse of a theorem as if it were true or invoked the theorem where it did not apply. Selden, McKee, and Selden (2010) reported instances of students' tendencies to write proofs from the top down and their reluctance to unpack and use the conclusion to structure their proofs. (See the case of Willy, who focused too soon on the hypothesis in Selden, McKee, & Selden, 2010, pp. 209-211).

The Formal-Rhetorical and Problem-Centered Parts of Proofs

Previously, we (Selden & Selden, 2013) introduced the idea of the *formal-rhetorical* part of a proof as the part of a proof that comes from unpacking and using the logical structure of the statement of the theorem, associated definitions, and previously proved theorems. In general, this part *does not* depend on a deep understanding of, or intuition about, the concepts involved or on genuine problem solving in the sense of Schoenfeld (1985, p .74). However, the *problem-centered* part of a proof *does* depend on genuine mathematical problem solving, intuition, and a deeper understanding of the concepts involved. A major portion of the formal-rhetorical part of a proof can consist of a proof framework.

Proof Frameworks

An early version of the idea of proof frameworks was introduced by us (Selden & Selden, 1995):

> By a *proof framework* we mean a representation of the "top-level" logical structure of a proof, which does not depend on detailed knowledge of the relevant mathematical concepts, but which is rich enough to allow the reconstruction of the statement to be proved or one equivalent to it. A written representation of a proof framework might be a sequence of statements, interspersed with blank spaces, with the potential for being expanded into a proof by additional argument. (p. 129).

We went on (Selden & Selden, 1995) to connect the ability to unpack the logical structure of mathematical statements with the ability to construct proof frameworks and with proof validation. We also pointed out that mental skills were involved. The learning and mastering of such mental skills can involve much mental energy and considerable working memory. (p. 132). While we did not state this explicitly at the time, in the sample validation in the Appendix, we did note that sometimes checking a sufficiently complex part of a proof might overload working memory and potentially lead to error. (p. 146).

The First and Second Levels of a Proof Framework

Later, we further developed the idea of proof frameworks, including that there are often both first-level and second-level proof frameworks. A *proof framework* is determined by just the logical structure of the theorem statement and associated definitions. The most common form of a theorem is: "If P, then Q", where P is the hypothesis and Q is the conclusion. In order to construct a proof framework for it, one takes the hypothesis of the theorem, "P", and writes, "Suppose P" to begin the proof. One then skips to the bottom of the page and writes "Therefore Q", leaving enough space for the rest of the proof to emerge in between. This produces the *first level* of a proof framework. At this point, a prover should focus on the conclusion and "unpack" its meaning. It may happen that the unpacked meaning of Q has the same logical form as the original theorem, that is, a statement with a hypothesis and a conclusion. In that case, one can repeat the above process, providing a *second-level* proof framework in the space between the first and last lines of the emerging proof. (For some examples, see Selden, Benkhalti, & Selden, 2014).

Finally, we do not claim that mathematicians should write proofs using this technique, but only that doing so will be helpful for novice students and that their mathematics professors will accept the results. As long as the logical flow and clarity of a proof submission is correct, it does not matter (and is impossible to recover) in which order the sentences were written. We now return to the problem of overloaded working memory that can occur when a proof construction, or a proof validation, is sufficiently complex.

Working Memory

It has been said that the "two major components of our cognitive architecture that are critical to [thinking and] learning are long-term memory and working memory" (Kalyuga, 2014). *Working memory* makes cognition possible but has a limited capacity that varies across individuals. It is associated with the conscious processing of information within one's focus of attention. However, working memory can only deal with several units, or chunks, of information at a time, especially when working with novel information (Cowan, 2001; Miller,1956). In contrast, *long-term memory* can be thought of as a learner-organized knowledge base that has essentially unlimited capacity and can be used to help alleviate the limited capacity of working memory (Ericsson & Kintsch, 1995). However, when working memory capacity is overloaded, errors and oversights are likely to occur.

Coping with Mathematical Abstraction and Formality

While the mathematics education research literature does not seem to have considered working memory overload during learning per se, there are a few studies of coping with abstractions. These could be reinterpreted as related to working memory overload causing confusion. For example, Hazzan (1999) investigated how Israeli freshman computer science students, taking their first course in abstract algebra in a "theorem-proof format", coped by "reducing the level of abstraction". Specifically, she found that they tended "to work on a lower level of abstraction than the one in which the concepts are introduced in class" (p. 75). For example, when doing homework on abstract groups, a student might actually be thinking of a familiar group like the integers under addition.

Further, Leron and Hazzan (1997) pointed out that students in mathematical problem-solving situations "often experience confusion and loss of meaning." (p. 265), and that students attempt to make sense of a problem situation "in order to better *cope* with it." (p. 267). While this coping perspective occurs at all levels, they stated that "the phenomena of confusion and loss of meaning are even more pronounced in college mathematics courses." (p. 282). They also suggested that more work on the coping perspective in mathematics education is needed. Indeed, somewhat similarly, Pinto and Tall (1999) considered two different university students' coping mechanisms when confronted with formal definitions and proofs in real analysis. These were the ideas of *giving meaning* to definitions using concept images versus *extracting meaning* from the formal definition via deduction. However, not many university level mathematics education studies have specifically considered students' coping perspectives.

Methodology: Conduct of the Study

We met regularly for individual 75-minute sessions with a mature working professional, Alice, who wanted to learn how to construct proofs. Alice followed the same course notes previously written for our inquiry-based transition-to-proof course[1] used with beginning mathematics graduate students who wanted extra practice in writing proofs. The sessions were almost entirely devoted to having Alice attempt to construct proofs in front of us, often thinking aloud, and to giving her feedback and advice on her work. The notes had been designed to provide graduate students with as many different kinds of proving experiences as possible and included practice writing the kinds of proofs often found in typical proof-based courses, such as some abstract algebra and some real analysis. The notes included theorems on some sets, functions, real analysis, and algebra, in that order.

Alice had a good undergraduate background in mathematics from some time ago and also had prior teaching experience. She only worked on proofs during the actual times we met. While she usually came to see us twice a week to work on constructing proofs. Sometimes, when her paid work got a bit overwhelming, she would take a week off. Thus, unlike the graduate students who took the course as a one-semester 3-credit class, Alice worked with us on our course notes for two semesters at her own pace and did not want credit.

We met in a small seminar room with blackboards on three sides, and Alice constructed original proofs at the blackboard, eventually using the middle blackboard almost exclusively for her evolving proofs. After several meetings, she began to use the left board for definitions and the right board for scratch work. She did not seem shy or overly concerned with working at the board in front of us, and from the start, we developed a very collegial working relationship. She seemed to enjoy our interactions as she worked through the course notes. Thus, we gained

[1] A description of the course and course notes can be found in Selden, McKee, and Selden (2010, p. 207).

greater than normal insight into her mode of working. We videotaped every session and took field notes on what Alice wrote on the three boards, along with her interactions with us. For this study, we reviewed the first and second semester videos and field notes several times, looking for progression in Alice's approach to constructing proofs.

Alice's Progression Through the First Semester

Our First Meeting with Alice

We introduced Alice to the idea of proof frameworks and explained in detail how and why we use them. We also introduced her to the idea of unpacking the conclusion and mentioned that proofs are not written from the top down by mathematicians. With guidance, she was able to prove "If $A \subseteq B$, then $A \cap C \subseteq B \cap C$." In addition, she worked three exercises on writing proof frameworks--one on elementary number theory and two on set equality. Near the end of this meeting, Alice produced a proof framework for the next theorem in the notes. We felt that she not only understood our rationale for using proof frameworks, but also how to construct them.

Our Second Meeting with Alice—Her Reluctance to Use Proof Frameworks Surfaces

At the beginning of the second meeting, Alice went to the middle board and produced the same proof framework that she written five days earlier at our first meeting (Figure 1).

Theorem: Let A, B, and C be sets. If $A \subseteq B$, then $C - B \subseteq C - A$. Proof: Let A, B, and C be sets. Suppose $A \subseteq B$. Suppose $x \in C - B$. So $x \in C$ and x is not an element of B.	Thus $x \in C$ and x is not in A. Therefore x is in $C - A$. Therefore, $C - B \subseteq C - A$.

Figure 1. A proof framework that Alice produced on the middle blackboard.

Then Alice stopped and after a long silence of 65 seconds, much to our surprise, said, "I have a question for you. I find it very difficult to see the framework. Let me show you how I do it, because somehow I get confused with the framework." We asked her what it was about the framework that was confusing, but she seemingly could not put it into words. So we encouraged her to write a proof the way she preferred. Thus, on the left board, Alice began to write the proof in her own way in top down fashion (Figure 2).

Theorem: Let A, B, and C be sets. If $A \subseteq B$, then $C - B \subseteq C - A$. Proof. Let A, B, C be sets. Suppose A is a subset of B. We need to prove that $C - B$ is a subset of $C - A$. Suppose $x \in C - B$. We need to prove that $x \in C - A$.

Figure 2. Alice's attempt at constructing a proof in her own way.

Then she then paused for 15 seconds, and said, "We need to have one more," and wrote into her proof attempt, **"and $x \in A$"** immediately below **"$x \in C - B$"**, indicating with a caret that **"and $x \in A$"** was also part of her supposition (Figure 3). Then, after a 35-second pause, she added to her proof attempt, “**Since $x \in A$ and A is a subset B. Then $x \in B$.**” Shortly thereafter, Alice quietly said, “Oh, a contradiction”. This was followed by, “Yeah, ‘cause x doesn’t belong to B. Yeah, problem here.” Then, after a ten second pause, Alice said, “The problem is right here, isn’t it?” pointing and underlining “$\boldsymbol{B}$” and the statement “**and $x \in A$**.” We asked, “And what do you think that problem is?” Alice replied, “I assumed that [pointing to **“and $x \in A$”**], but I do not know. I only know this [pointing to **“A is a subset of B”**]. We replied, “So that’s a good point you’ve made.”

Theorem: Let A, B, and C be sets. If $A \subseteq B$, then $C - B \subseteq C - A$. Proof. Let A, B, C be sets. Suppose A is a subset of $\underline{\boldsymbol{B}}$. We need to prove that $C - B$ is a subset of $C - A$. Suppose $\boldsymbol{x \in C - B}$. We need to prove that $x \in C - A$. **<u>and $x \in A$</u>.**

Figure 3. Alice’s adjustments to her proof attempt, done in her own way.

After that, for a few minutes, we talked about the structure of proofs, and why we use proof frameworks. Then we asked Alice to elaborate on why **“and $x \in A$”** is a problem. She said, “I didn’t write it right. I should have said here [pointing to the blank space to the left of **“and $x \in A$”**] I’m going to make an assumption like **‘Suppose x belongs to the A’**, and then since x belongs to the A and I know that A is a subset of B, **then the x will belong to the B**.” She continued, “I also know that x belongs in the $C - B$, because I said it earlier. Then x belongs to the C but **x does not belong to the B**.” To which one of us replied, “And then you said something. I thought I heard you say the word **‘contradiction’**.” Alice explained, “Yeah, I got a contradiction because then I’m saying here [pointing to the board] the x belongs to the B, and the x doesn’t belong to the B.” We agreed, and she offered, “That assumption [pointing to **“and $x \in A$”**] was bad.” We then reiterated why proof frameworks are structured the way they are, and suggested that we could take Alice’s original framework (Figure 2) and what Alice had written on the left board (Figure 3), and change the order to write a proof. We proceeded to help Alice do this. For the rest of the semester, Alice seemed more inclined to attempt to use proof frameworks.

Alice’s Way of Working

By midway through the first semester, Alice had developed her own pattern of working. She would:

1. First write the statement of the theorem to be proved on the middle board.
2. Then look up in the course notes the definitions of terms that occurred in the theorem statement and write them exactly as stated on the left board.
3. Next underline the relevant portions of definitions to assist with writing the proof framework. However, we did not teach her to use this strategy. (See Figure 4).
4. Use the right board for scratch work as needed.

Alice continued this pattern of working into the second semester.

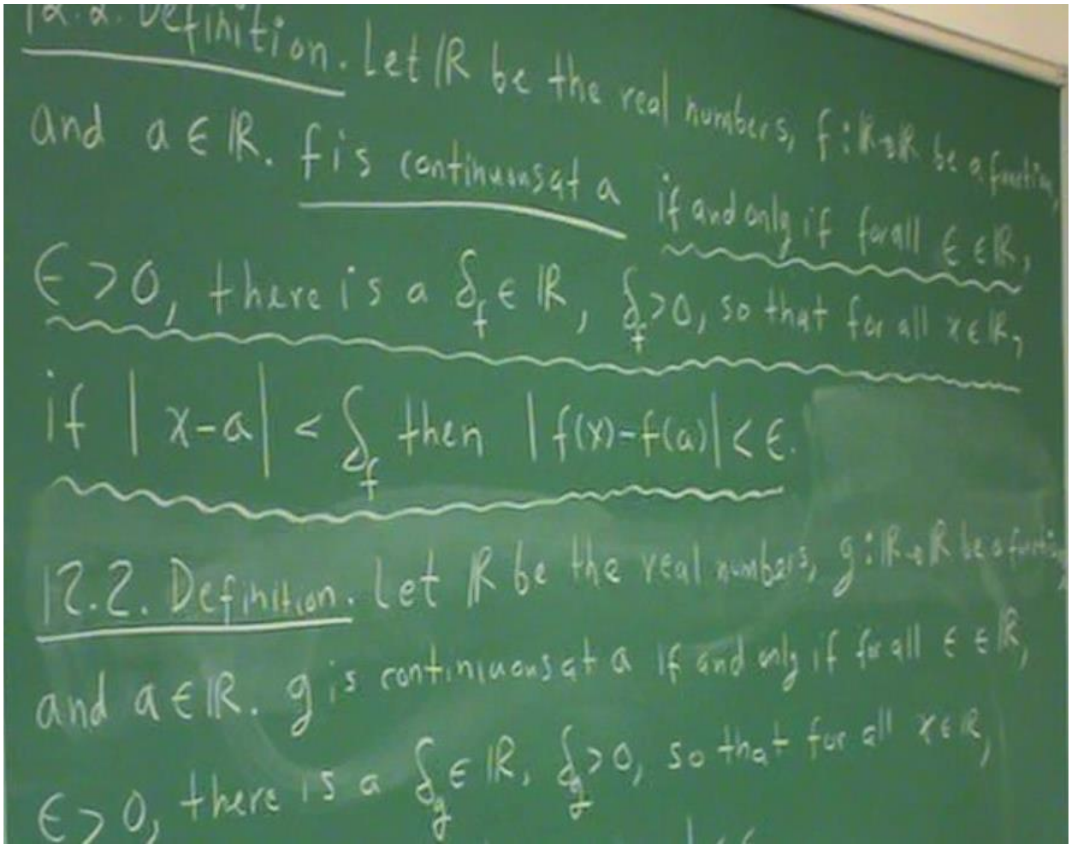

Figure 4. Alice's underlining of relevant parts of a definition.

Subsequent Meetings with Alice

As the first semester meetings went on, we observed that Alice became very methodical in her approach to proving, and also somewhat more accustomed to writing proof frameworks. We hypothesize this was because of her technical work experience and perhaps because of her natural tendencies. By the 12th meeting, Alice had developed the following pattern of working: She would write the statement of the theorem to be proved on the middle board, then look up in the course notes the definitions of terms that occurred in the theorem statement, write them exactly as stated on the left board, and use the right board for scratch work. Indeed, during the 12th meeting, when she got to the theorem, "*Let X, Y, and Z be sets. Let f: X→Y and g: Y→Z be 1-1 functions. Then g○f is 1-1*," she wrote the first- and second-level frameworks ostensibly on her own, and with some guidance from us, completed the proof and read it over for herself aloud.

By the 19th meeting at the end of the first semester, Alice was more fluent with writing proof frameworks than on the 12th meeting, and she had adopted the technique of writing definitions on the left board and changing the variable names to agree with those used in the theorem statement – all without prompting from us. This is remarkable as our experience has been that many students do not change variable names in definitions even when we suggest doing so, and this can often lead to difficulties. At this 19th meeting, Alice proved that the sum of two continuous functions is continuous (Figure 5). This proof has a rather complicated proof framework that necessitates leaving three blanks spaces -- one for using the hypothesis appropriately, one for specifying a δ, and one for showing that the chosen δ "works" (by showing the relevant distance is less than ε.)

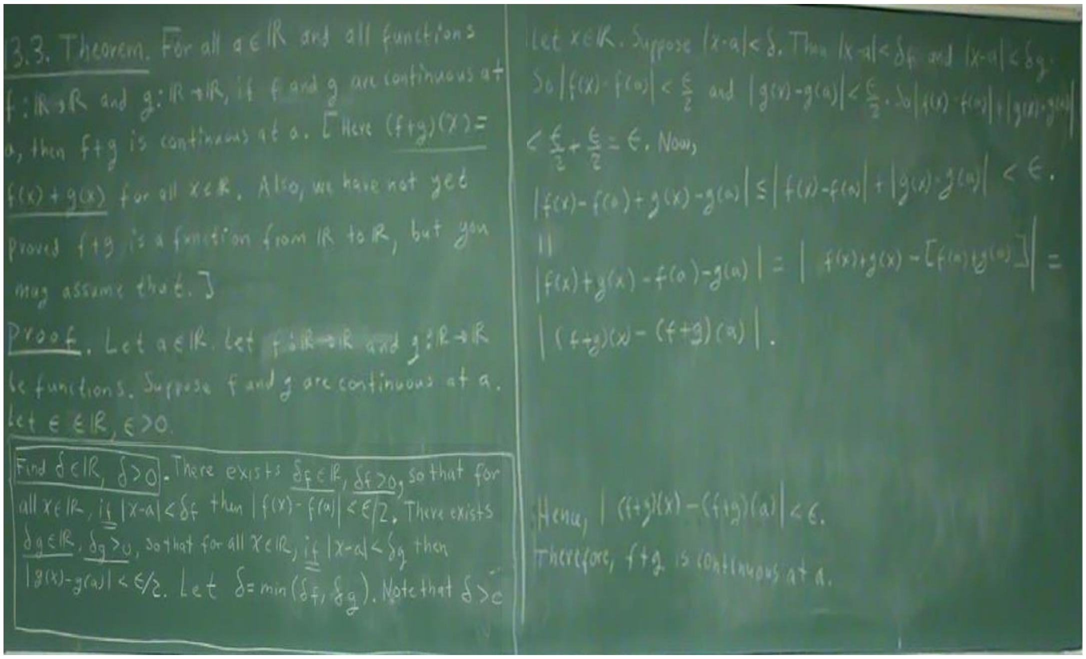

Figure 5. Alice's proof of that the sum of two continuous function is continuous.

Alice continued meeting with us and working on the course notes at her own pace during the second semester.

Alice's Progression through the Second Semester

Alice Continues Proving Real Analysis Theorems

Upon resuming in the second semester, Alice continued proving real analysis theorems, attempting to prove that the product of two continuous functions, f and g, is continuous in our first three meetings (i.e., our 20^{th}-22^{nd} meetings). She set up the proof framework correctly and explored the situation in scratch work. During this proving process, Alice made some astute observations, for example, having gotten to $|fg(x) - fg(a)| = |f(x)g(x) - f(a)g(a)| \le |f(x)|\,|g(x) - g(a)| + |g(a)|\,|f(x) - f(a)|$, and having dealt with term involving $|g(a)|$, she noted that the former term was the "hard part" because $|f(x)|$, unlike $|g(a)|$, is not a constant. Somewhat later, Alice exhibited some self-monitoring, noting that she needed to move her sentence about the bound on $|f(x)|$, prior to setting δ equal to the "minimum of [the] three" deltas she had found. (See Figure 6). She also noted, in the 22^{nd} meeting, that it seemed "weird" to write the restrictions on $|f(x) - f(a)|$ and $|g(x) - g(a)|$ without immediately explaining why she had chosen the bounds $\frac{\varepsilon}{2|g(a)|}$ and $\frac{\varepsilon}{2M_f}$, respectively, when applying the definition of continuity at a point to f and g.

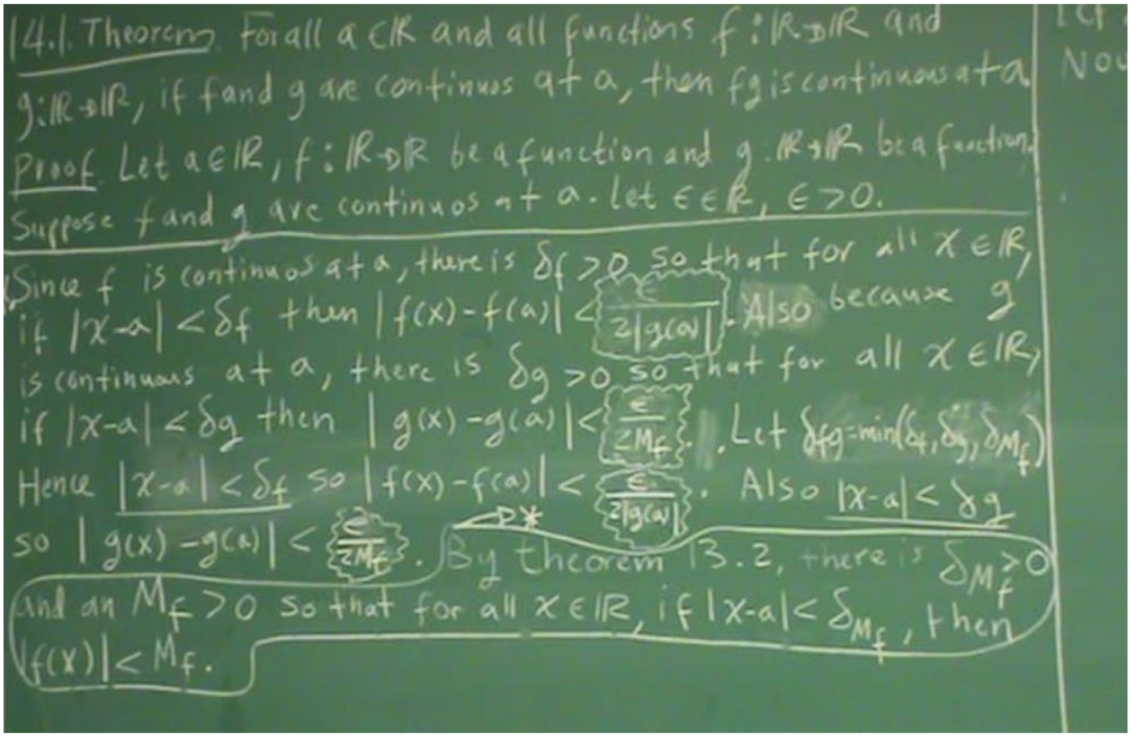

Figure 6. The first half of Alice's proof that the product of continuous functions is continuous, showing the "minimum of the three deltas".

Figure 7 shows the remainder of Alice's proof that the product of continuous functions is continuous, that is, that the her chosen δ "works".

Alice's Encounter with Semigroups Begins

By our 25th meeting, Alice had completed the real analysis section of the notes, and was ready to begin the abstract algebra (semigroups) section that starts with the definitions of binary operation and semigroup, followed by requests for examples. She provided only the most obvious of examples, such as the integers under addition or multiplication, and when asked for something "stranger", she said she could use the real numbers. When asked for another "strange" example "with no numbers at all", she suggested union as the binary operation, and with help, wrote up the example of the power set of a set of three elements. Next, when it came to providing examples of semigroups, she suggested the natural numbers with subtraction, but had to be prodded to check associativity; for this she considered (3 - 7) - 2 versus 3 - (7 - 2) and correctly inferred this was not a semigroup. To provide examples of left and right ideals, Alice needed to come up with a noncommutative semigroup, but she drew a blank. We suggested the semigroup of 2×2 real matrices under multiplication, and for an ideal, the subset of matrices of the form $\begin{bmatrix} x & y \\ 0 & 0 \end{bmatrix}$. After some calculation, Alice correctly concluded the subset is a right ideal, but not a left ideal.

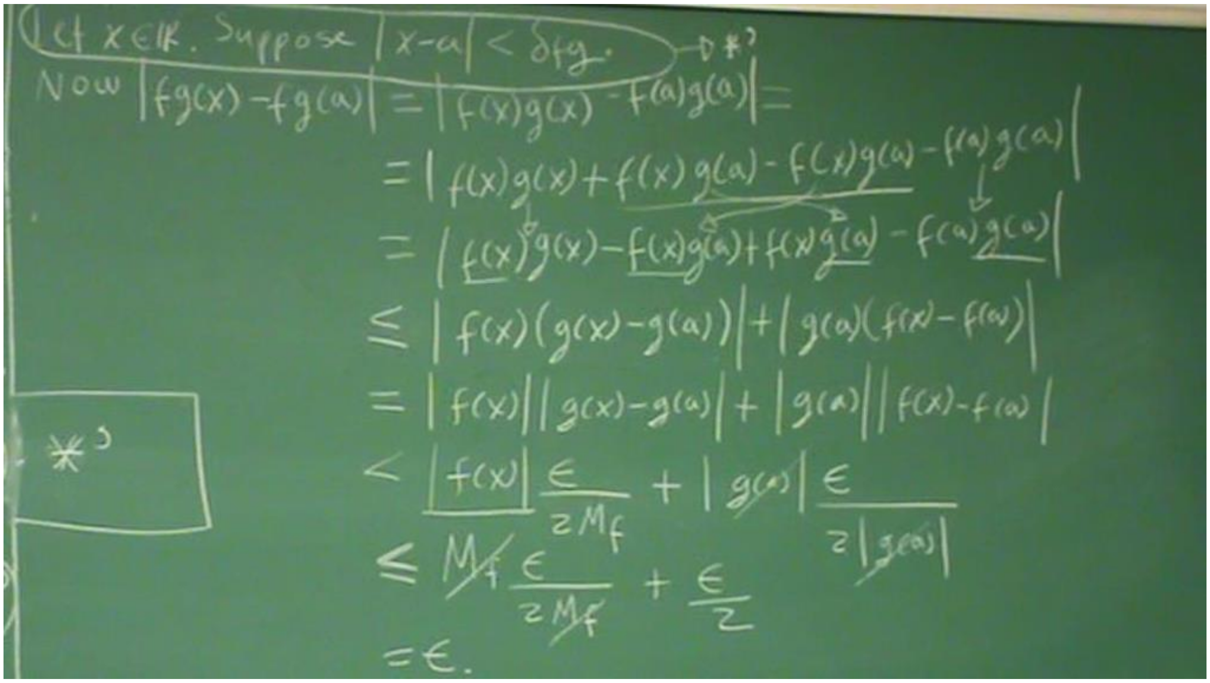

Figure 7. The remainder of Alice's proof that the product of continuous functions is continuous, showing that her chosen δ "works".

Alice Hits a "Brick Wall" with the First Semigroup Theorem

Alice continued considering examples for the first 35 minutes into the next (26th) meeting, after which she came to the first semigroup theorem to prove: "*Let S be a semigroup. Let L be a left ideal of S and R be a right ideal of S. Then* $L \cap R \neq \emptyset$." She first wrote the definitions of semigroup, left ideal, right ideal, and ideal on the left-hand board, as she had done many times before. Then she wrote the first-level framework on the middle board, after which she went to the right-hand board and began doing some scratch work, which included drawing a Venn diagram of two overlapping circles, L and R, with an arrow pointing to the intersection. She wrote in her scratch work "$L \cap R = \emptyset$" and "there exists an element $a \in L \cap R$". With this, it seemed that Alice was trying to clarify the theorem statement for herself. However, she had not yet attended to the second-level framework. We pointed this out.

During the rest of her proving attempt, we seemed to need to remind Alice of relevant actions, such as considering what she knew about ideals (i.e., that they are nonempty), and hence, concluding that each of L and R contains an element, which she labeled l and r respectively. Then, using those, she tried to "explore" to find an element in $L \cap R$, in order to conclude it was not empty. With our guidance, Alice finished the proof, but her sense of self-efficacy seemed shaken.

Indeed, at the next (27th) meeting, Alice wanted to reprove the theorem about the intersection of left and right ideals before continuing. (See Figure 8).We now feel that she had been somewhat overwhelmed, or confused, by the new content, perhaps causing working memory overload. She had tried to cope as best she could by concentrating on the new concepts, while “forgetting” her prior proof writing skills. Alice’s hesitant behavior continued for eight more meetings.

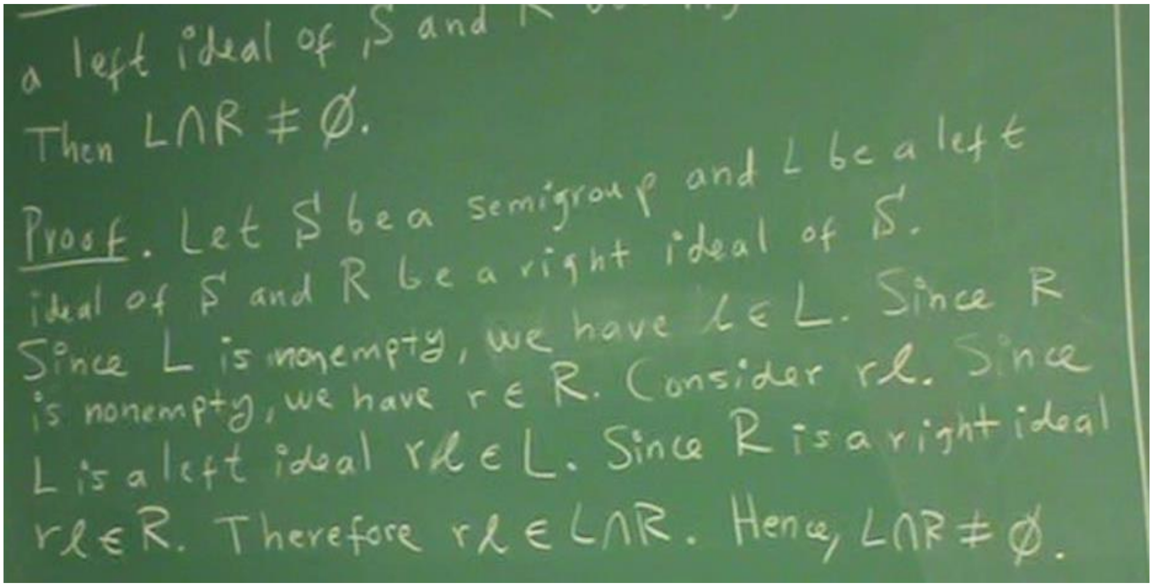

Figure 8. Alice’s proof that the intersection of a left ideal and a right ideal is nonempty.

Alice Regains Her “Footing”

Then, during the 35th meeting, Alice considered the theorem, “*If S and T are semigroups and f: S→T is an onto homomorphism and I is an ideal of S, then f*(*I*) *is an ideal of T*”. She wrote the definition of homomorphism on the left board, wrote “What I know” on the right board, constructed the first-level proof framework, unpacked the conclusion, wrote the second-level proof framework, and decided to do a two-part proof – one part for left ideals and a second part for right ideals. (See Figure 9). With this, Alice seemed to have regained “her footing”. At the next meeting, she finished the proof, with some help from us. She continued proving semigroup theorems for the rest of the semester, exhibiting increasing proficiency and self-efficacy.

Discussion

Working with Proof Frameworks

Alice came to us with a reasonable undergraduate mathematics background, some of which she had forgotten. At the first meeting, we explained the use of proof frameworks and our rationale for using them, and she practiced producing several of them. However, at the second meeting she told us that she found this way of working confusing. When she attempted her own alternative method of proving, she got into difficulty, and as a result, was more willing to try using proof frameworks again. Over the course of our subsequent meetings during the first semester, Alice became fluent with writing both first- and second- level proof frameworks and adopted her own methodical way of working. As the first semester went on, she was able to complete proofs with less guidance from us. Indeed, she often mainly required some help with the problem-centered parts of proofs.

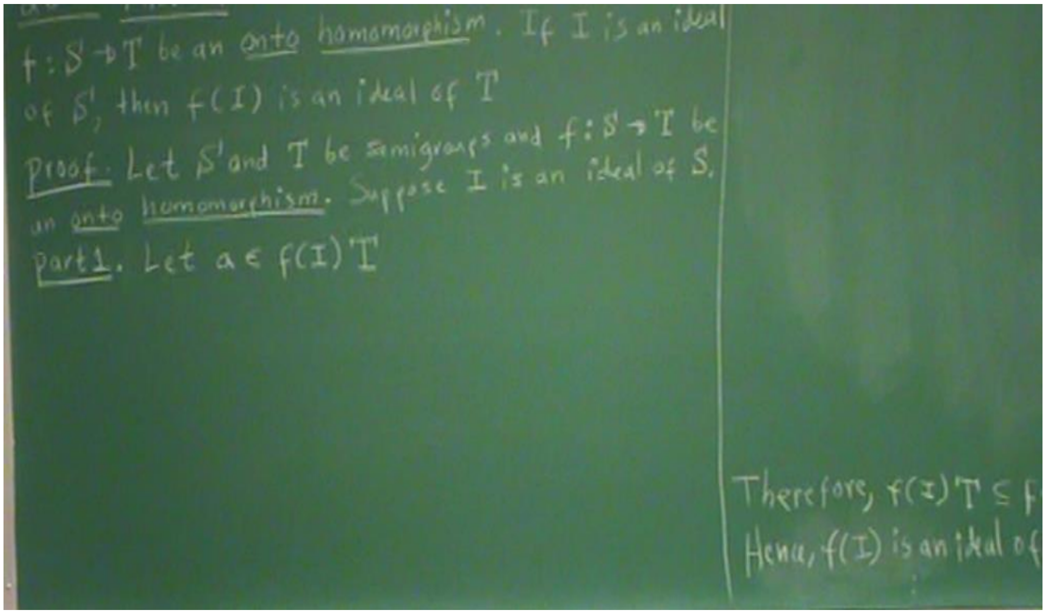

Figure 9. Alice's proof framework for the theorem about homomorphic images of ideals.

During the second semester, Alice continued meeting with us and working on the course notes. She began the second semester with the construction of additional real analysis proofs and seemed to be making very considerable progress, both with writing proof frameworks and with the harder problem-centered parts of proofs. By the end of the real analysis section of the course notes, we felt that she had developed greatly in her proving ability and had developed a sense of self-efficacy (Bandura, 1994, 1995) about proving.

Difficulties Surface When Encountering Unfamiliar Content

However, the subsequent introduction of unfamiliar, abstract content in the form of several definitions and a theorem about semigroups at the 25th meeting seemed to cause her confusion. She constructed only the most obvious examples somewhat hesitantly. Also, when asked to prove the first theorem about semigroups, she did not begin by producing a proof framework, as she had previously consistently done with the real analysis proofs, but rather began writing what she knew or could find in the notes, on the right-hand blackboard. Her proof construction, while not top-down, seemed to consist of first trying to gather as many semigroup ideas as she could, followed by trying to arrange them into a final proof. We feel that concentrating on understanding the unfamiliar abstract content was Alice's initial way of coping, that her working memory may have been overloaded, and that she wasn't able to deal with the additional onus of constructing a proof framework. It was not until the 35th meeting, almost at the end of the second semester, that Alice seemed to have regained her sense of self-efficacy, and she again constructed proofs using the technique of proof frameworks that she had learned and perfected previously with real analysis proofs.

Implications

It seems that coping with newly introduced abstract concepts is not easy, even for someone as experienced as Alice. It also seems that one cannot expect, having learned the skill of constructing proof frameworks in more familiar settings, that this skill will be easily invoked while new abstract content is being learned, perhaps due to working memory overload.

Fragility of Recently Acquired Proving Skills Can Be Overcome

Amongst other things, this case study illustrates the fragility of recently acquired proving skills, in the context of the acquisition of new abstract mathematical concepts. It also suggests that, with persistence, the difficulty due to such fragility can be overcome. Our own experiences as mathematicians suggests that one can (implicitly) learn not to be greatly disturbed by the introduction of several new abstract ideas at once. However, some school curricula avoid certain introductions of concepts, such as the Bourbaki definition of function, because they are considered too abstract (Tabach & Nachlieli, 2015). Further, as Hazzan (1999) found, students sometimes cope by "reducing the level of abstraction." Yet Alice's case suggests that, with time, effort and persistence, students can learn to cope with abstraction.

Eventual Successful Use of Proof Frameworks, along with Persistence and Self-efficacy

The initial tendency of many university students to write proofs in a top-down fashion tends to fade after sufficient exposure to writing proof frameworks. One might ask where this tendency comes from. According to Nachlieli and Herbst (2009), it is the norm among U.S. high school geometry teachers to require students, when doing two-column proofs, to follow every statement immediately by a reason. This implies top-down proof construction. However, as noted previously (Selden & Selden, 2013), automating the actions required to write the formal-rhetorical part of a proof (i.e., writing first- and second-level proof frameworks) can allow students to "get started" writing a proof and exposes the "real problem" to be solved in order to complete the proof. For this, persistence and self-efficacy are needed.

Questioning Assumptions about the Measurability of Subdomains of Mathematical Knowledge for Teaching

Heather Howell	Yvonne Lai	Heejoo Suh
Educational Testing Service	University of Nebraska, Lincoln	Michigan State University

One common approach to assessing mathematical knowledge for teaching (MKT) is designing items to measure individual subdomains of MKT as specified by a theoretical framework, with factor analyses confirming (or disconfirming) hypothesized subdomains. We interpret this approach as adhering to a "compartmentalized" view of MKT, as opposed to a "connected" view of MKT. We argue in this paper that a compartmentalized view of MKT is embedded in the ways that frameworks are represented, discussed, and used in the field, but that this view of MKT may unintentionally undermine understanding of MKT, and in turn, how to measure and cultivate it in teachers. Using an analysis of nine items previously shown to assess MKT, we illustrate that the tendency for practice-based items to capture multiple subdomains is a common issue across frameworks, and perhaps one that is a necessary result of their design.

Key words: mathematical knowledge for teaching, content knowledge for teaching

We define mathematical knowledge for teaching (MKT) in broad terms as the content knowledge used in recognizing, understanding, and responding to mathematical situations, considerations, and challenges that arise in the course of teaching mathematics. In the 1980s, Lee Shulman advanced a framework to describe a professional knowledge base for teaching (e.g., Shulman 1986), and since that time there have been persistent efforts to describe that knowledge base in greater detail, with particular interest among mathematics educators in the dimensions relating to mathematical knowledge. Scholarly attention to the construct of MKT emerged from work in the 1990s led by Ball and Bass at the University of Michigan in which a close qualitative analysis of video records of teaching allowed researchers to build a descriptive account of the *mathematical* work of teaching, documenting ways in which the work of teaching demands that teachers invoke mathematical knowledge in ways that are quite different than the ways their students do so (Ball & Bass, 2003). In the 2000s, Ball and colleagues described a resulting framework for MKT that subsumes Shulman's content related categories of *subject matter knowledge* and *pedagogical content knowledge* (PCK) and in which particular attention is called to the components of MKT that are both purely mathematical and "unique to teaching" (Ball, Thames, & Phelps, 2008, p. 400).

Another product of this line of research has been the development of assessments to measure MKT and its sub-components, the most well-known of which, the Learning Mathematics for Teaching (LMT) assessments, was developed by the Michigan team beginning in 2000 (LMT Project, n.d.), and has been recognized in the field as an example of the state of the art in terms of assessing MKT (National Research Council, 2013). As interest in both the construct and its measurement has increased, a number of competing theoretical frameworks have been introduced, often based loosely on Ball et al. (2008) but differing in focus or intended use (Heid, Wilson, & Blume, 2015; McCrory, Floden, Ferrini-Mundy, Reckase, & Senk, 2012), or focused on differing areas of content by extending the framework to secondary or post-secondary levels (Baumert & Kunter, 2013; Krauss, Baumert, & Blum, 2008) or narrowing to particular bands of content (Herbst & Kosko, 2014).

In this paper, we call attention to two ways one might think about these frameworks – *compartmentalized* or *connected*– and discuss the implications for assessment of and teacher learning of MKT. One view, the *compartmentalized* view, is that frameworks map out distinct knowledge domains, with clear boundaries, each of which can be conceptualized, organized, taught, and measured individually, with separate tests for each domain, and each of which might rely on separate coursework to help novice teachers learn the content of the domain. A second view, the *connected* view, is that these frameworks describe important features of MKT in ways that help us understand it better, but that these features may not correspond to clearly non-overlapping portions of the knowledge, and that the overlap may necessarily play out during the work of teaching as teachers draw on connected knowledge. We argue in this paper that the first view is embedded in many of the ways that various MKT frameworks are represented, discussed, and used in the field, but that in adopting this compartmentalized view of MKT we may unintentionally undermine our understanding of MKT, and in turn our understanding of how to measure it and cultivate it in teachers.

The study we present here is not a critique of MKT frameworks, but rather an attempt to step back from the ways in which those frameworks have come to be used and consider this key distinction, between compartmentalized knowledge domains and connected knowledge domains. We designed the study to examine instances of knowledge application, using brief MKT assessment items to which respondents must apply their MKT in solving a problem of practice, and we explore the extent to which these instances of knowledge application involve applying compartmentalized or connected knowledge domains of MKT, looking across a set of five frameworks. We offer the analysis as an illustration of the degree to which MKT knowledge domains may be naturally connected in situations that approximate actual teaching. We suggest that the compartmentalized view may be incompatible with how assessments are designed, especially when the design is based on a connected view of MKT. We suggest that the connected view has implications for teacher education, including how to support to practice-based approaches that engage pre-service teachers in the work of teaching rather than attempting to provide coursework tailored to distinct domains of knowledge.

Theories of MKT and MKT Measurement

In this section, we discuss MKT frameworks in the literature. We define practice-based item design, a widely shared approach to measuring MKT, and provide an example MKT assessment item. We discuss the emergent empirical research base supporting claims that practice-based assessment items do indeed measure MKT as intended, and revisit our distinction between compartmentalized and connected views of MKT.

Theoretical Frameworks for MKT

In recent years, a number of frameworks for MKT have emerged, building on Shulman's (1986) theorized knowledge classifications of subject matter knowledge and pedagogical content knowledge (PCK). The predominant framework, particularly in the US, is that of Ball et al. (2008). Other frameworks generally overlap with, draw on, or complement the Ball et al. framework, and for the most part they likewise maintain Shulman's high-level distinctions but differ in whether and how they define any distinctions below that level. For example, the Cognitively Activating Instruction (COACTIV) framework (Baumert & Kunter, 2013) draws directly on the Ball et al. theory, but COACTIV only distinguishes between content knowledge and PCK in their accompanying assessments, essentially ignoring some of the subdomains that Ball et al. consider most crucial from a theoretical standpoint.

Several frameworks focus directly on subsets of content or particular grade levels. Examples include Knowledge of Algebra for Teaching (KAT: McCrory et al., 2012), focused on Algebra; COACTIV and Teacher Education and Development Study in Mathematics (TEDS-M: Tatto et al., 2008), focused on upper and lower secondary level content respectively; and MKT-Geometry (Herbst & Kosko, 2014), focused on secondary level geometry. KAT also differs from a number of other frameworks in its underlying organizational structure, which diverges from Ball et al. (2008) by categorizing knowledge according to where in a typical university trajectory a prospective teacher is likely to have learned that knowledge. And a number of frameworks are organized to support quite different aims than assessment development, including the Mathematical Understanding for Secondary Teaching (MUST) framework, which is designed to support professional development and teacher education (Heid et al., 2015), and the Knowledge Quartet, which focuses on identifying situations in which mathematical knowledge is used in teaching (Turner & Rowland, 2008).

Practice-based Items: A Different Kind of Theory

One could argue that part of the reason early theories of MKT were compelling was their grounding in analysis of the work of teaching, a kind of job analysis technique examining the work teachers need to do, generating descriptions of what they called the *mathematical work of teaching* (Thames, 2009), and working back from there to determine the knowledge teachers need to have in order to do that work. Early work by Ball and Bass (2003) described this as "practice-based theory" in that it was developed through the study of teaching practice. The term "practice-based" has also been used to describe assessment items developed out of this theory, and while it is often left unspecified what characteristics make an item practice-based, those who do describe it focus on close approximation of the cognitive work of teaching as the defining characteristic. Phelps, Howell, Mikeska, Kirui, and Mislevy (in press) describe the early LMT items as practice-based in that they "are designed to situate the test taker in a context of practice" (p. 9). Bridging multiple content areas, Gitomer, Phelps, Weren, Howell, and Croft (2014), Selling, Garcia, and Ball (2016), and Mikeska, Phelps, and Croft (in press) describe item development efforts across content areas, all of which are guided by frameworks organized around the work of teaching are used to develop practice-based assessment items. Hill (2016) also cites the use of such frameworks as critical.

Implicit in the cited assessment development efforts is an approach we call a *practice-based item design theory*, in which the design of such items is intended to engage the test taker in some approximation of the cognitive work of teaching, asking the test taker, for example, to analyze a student work sample or choose an appropriate problem for a particular instructional goal. By doing so, items are intended to prompt test takers to apply their mathematical knowledge as they would in such a teaching situation. By requiring test takers to apply their knowledge to a teaching situation, the item is intended to more accurately capture MKT, which be described as a form of applied knowledge (Bass, 2005; Stylianides & Stylianides, 2014). Perhaps because of the widespread influence of the LMT assessment as a model, most MKT assessment items currently available in the field show evidence of a practice-based item design theory approach (Hill, 2016), although there are differences in the ways that various efforts provide context to situate the test taker (Phelps et al., in press).

What is more subtle about practice-based item design may be the underlying way in which it defines MKT according to the contexts in which it is used. MKT, as these items assess it, is defined by the work of teaching that invokes it. The items are *practice*-based in that the organizing unit is work done in teaching *practice*, and what is assessed is what we will call the associated package of knowledge required to engage in that work. It has been argued elsewhere that this organization around the work of teaching is a natural organization, in that it makes sense to teachers and allows them to apply their knowledge in ways that they would in their teaching (Phelps et al., in press), and it "brings the development of measures closer to the actual practices we hope teachers will successfully master" (Hill, 2016, p. 5). Because items are organized around the work of teaching, they are designed to require application of knowledge, including recognition of what to pay attention to and the ability to bring relevant information to bear as well as simply knowing that information. And this plays out in response patterns. Howell, Phelps, Croft, Kirui, and Gitomer (2013) highlighted an interview response pattern in which respondents discussing an MKT item clearly hold propositional knowledge about a common student error pattern but are unable to recognize an instance of that error pattern in student work. A test designed simply to measure knowledge of student error patterns might miss critical information that the practice-based item, by requiring applied knowledge, reveals. One can easily appreciate the argument that this applied knowledge is critical to the work teachers do.

We discuss the practice-based item design theory in some detail for three reasons. First, it will help the reader to understand the items that we analyze in this paper, which are written to a practice-based item design theory. Second, authors of each of the frameworks examined in this study describe their theoretical development as practice-based. Third, we point out that this is a fundamentally different type of theory than the knowledge theories described in the prior sections, one that does not necessarily compete with or contradict knowledge frameworks. One goal in this paper is to illustrate that practice-based item design theory and frameworks of knowledge domains within MKT are not incompatible unless one assumes a direct mapping between assessment items and knowledge domains, as the compartmentalized view invites.

During a lesson near the end of a unit on quadratic functions, Mr. Swift asked his students how many ordered pairs are needed to determine a quadratic function. Some students in the class responded as follows.

Andrew: Well, I could draw lots of different parabolas that are functions through two points by changing where the maximum or minimum is located, but once I have a third point only one of those parabolas would work.

Bria: But what if all three points are on the same side of the vertex? You can determine the function with three points, but at least one point needs to be on each side of the vertex.

Cynthia: That isn't right. All you need are the two roots of the function. Like if the two roots are a and b, you can just do $(x-a)(x-b)$ and you know what the function is.

Daniel: But you wouldn't be able to tell where the maximum or minimum is if you only have the roots. You gotta have three points, and they gotta be the two roots and the vertex.

Which of the students demonstrated the *best* understanding of the ordered pairs needed to determine a quadratic function?

(a) Andrew (b) Bria (c) Cynthia (d) Daniel

Figure 1. Swift item: An example of a practice-based item.

Figure 1 presents an example of practice-based item that we analyzed in the present study, the Swift item. This item requires the test taker to decide which of four students has demonstrated, in his or her comments, the best understanding of the ordered pairs needed to determine a quadratic function. To do so requires a subtle mix of understandings. At stake, mathematically, is the fact that the students are attending to both the number and the nature of the points that determine the function. The test taker must first figure out, on the basis of students' statements, the claim each student is making. He or she must then evaluate the accuracy of each statement, taking into account that each statement may simultaneously demonstrate both strengths and weaknesses. The test taker has been asked to evaluate the relative strengths of the students' understandings, not just determine mathematical correctness.

The Swift item exemplifies practice-based item design. It asks the test taker to engage in a constrained version of the work of teaching. Analyzing student statements in terms of their mathematical strengths and weaknesses is something that teachers must do routinely, which requires not only a deep mathematical knowledge, but also an ability to apply that knowledge to a situation in which multiple ideas may be on the table, and those ideas may be expressed inchoately. In this case, the best understanding is that shown by the first student, Andrew, who indicates that three ordered pairs are needed and that they need not be any particular pairs, and who gives a reasonable if incomplete justification in terms of a visualization of the possible graphs.

Evidence that Practice-based Measures Capture MKT and Its Subdomains

There is an emerging research base supporting the conclusion that practice-based measures such as those cited above capture the overall construct of MKT as intended. Studies have examined records of the reasoning elicited by assessment items seeking qualitative evidence of MKT being used as theorized (Howell et al., 2013), or observing differences in how members of known groups such as teachers, mathematicians, mathematics doctoral students, or mathematics majors reason about the items or perform on practice-based measures (Buschang et al., 2012; Hill, Dean, & Goffney, 2007; Krauss et al., 2008). A number of studies link performance on MKT measures to student achievement (Baumert et al., 2010; Hill et al., 2005; Rockoff et al., 2011). These studies are often cited as evidence that MKT is important to teaching, and they also provide additional evidence that the measures capture MKT as theorized, because part of that theorization is that it is knowledge that underlies effective instruction and, in turn, student learning.

Across efforts to assess MKT, a common practice has been to apply factor analysis to determine whether items hypothesized to measure distinct subdomains of the MKT construct do so. Factor analysis, generally speaking, is a method in which data gathered from assessment items are used to describe the measured construct(s) in terms of a manageable number of hypothetical variables, or factors (Lester, Inman, & Bishop, 2014). Factor analysis can be confirmatory or exploratory, and researchers often use both together. In confirmatory factor analysis, researchers pre-specify factors so that they can "test some theory about the number and nature of the factor constructs needed to account for the intercorrelations among the variables being studied" (Comrey & Lee, 2013, p. 4). In exploratory factor analysis, researchers use intercorrelations to "explore the underlying dimensions of a given data set" (Lester et al., 2014, p. 61) and generate conceptual explanations, after the fact, for the factors that emerge. Applications of factor analysis can be useful for theory testing (Hill, 2016), as they permit generalization to theory from the item pool, but only to the extent that items can be successfully produced to capture the theorized knowledge.

Results of studies applying factor analysis to assessments of MKT have been mixed. For example, Hill, Schilling, and Ball (2004) found that some items designed to measure attributes of PCK loaded instead as content, some as intended as PCK, and some as both. Similarly mixed findings have been reported in other studies spanning mathematics and other content areas (e.g., Floden & McCrory, 2007; Herbst & Kosko, 2014; Phelps & Schilling, 2004). Our perspective is that this set of analyses, across multiple practice-based measures, suggests that practice-based items are likely to measure multiple subdomains of the construct.

The Critical Distinction between Compartmentalized and Connected MKT

We return here to the critical distinction between compartmentalized and connected views of MKT. We argue that the compartmentalized view is supported in many ways by the manners in which framework authors and other scholars have presented and used the frameworks. Frameworks are often represented in graphics as area models in which non-overlapping sets are joined together to make up the whole of MKT. Ball et al. (2008), as an example, call careful attention in textual descriptions to what they call the "boundary problem" (p. 403), that knowledge domains are often closely coordinated in the work of teaching and so it is difficult to discern the precise division between domains. However, the powerful heuristic of the graphical representation by Ball et al., with its unambiguous divisions, tends to be the reader's main takeaway, rather than fuzzy overlap among domains; the representation strongly suggests mutually exclusive categories with clear divisions. And it is not incorrect to emphasize distinctions; in fact, the distinctions between knowledge types such as common and specialized content knowledge are what make them conceptually powerful ideas. The fact that specialized content knowledge exists as a construct that is distinct from both PCK and common content knowledge is an important and influential idea. Nonetheless, the distinctiveness of specialized content knowledge does not imply that it can be applied, learned, or measured entirely separately from common and pedagogical content knowledge.

Factor analysis approaches clearly adopt a compartmentalized framework view, taking as given a test design logic that maps the items based on a framework directly onto subdomains of that framework. Researchers of these studies often design items for the explicit purpose of assessing subdomains, sometimes on separate tests. These researchers then use factor analysis in attempts to answer underlying questions to the effect, are subdomains empirically distinguishable? However, test design logic may simply be incompatible with practice-based item design theory because one relies on a compartmentalized view and the other on a connected view of MKT. The mixed evidence resulting from factor analysis across multiple assessment efforts may reflect this incompatibility.

Our analysis takes a different approach to the question by asking, in responding to a set of nine practice-based items, how knowledge domains across multiple frameworks are elicited, and whether, under any of these frameworks, they are invoked in isolation from one another. Our logic is as follows: by selecting strong items known to exemplify practice-based item design and to measure MKT, we create a common comparison point across the frameworks. For each item under each framework, we examine which subdomains of that framework the item measures, noting in particular how many subdomains are measured. Our goal is to illustrate that the tendency for practice-based items to capture multiple subdomains is a common issue across frameworks, and perhaps one that is a necessary result of practice-based item design. In the following section we describe the items and frameworks we selected for the analysis and describe our coding procedures. We then present our results table and discuss the implications with respect to the frameworks and with respect to assessment item design.

Methods

We examined a set of nine assessment items designed to measure mathematical knowledge for teaching (Howell, Lai, Miller, & Phelps, 2016). These items were selected for several reasons. The items are typical representations of practice-based item design. A prior study provided evidence that this set of items captured MKT as they were designed to and demonstrated no significant design flaws (Howell et al., 2016). Additionally, as part of this prior work, researchers generated knowledge maps for each item specifying the knowledge measured, and these knowledge maps were validated by comparison to responses captured in think-aloud interviews. In the present study, the items themselves became the data, which we then coded by subdomains of each of the five specified frameworks. For the purposes of this study, the responses to each item were used to validate that the knowledge maps were accurate. The analysis presented in this study is not of responses to the items, but rather of the knowledge maps of the items. An example of the analysis is given below for the Swift item. Before the example analysis, we discuss our selection process for MKT frameworks to use and the coding process.

Framework Selection

In this study, we considered five theoretical frameworks for MKT: Ball et al.'s (2008) MKT framework; KAT (McCrory et al., 2012); COACTIV (Krauss et al., 2008); TEDS-M (Tatto et al., 2008); and MUST (Heid et al., 2015). We restricted our analysis to frameworks that are fully developed in available, seminal documents, which directly claim to describe the MKT construct, and for which the framework describes the entire construct. We did not restrict framework selection to those explicitly designed for secondary level MKT, but did exclude those that could not reasonably be taken to describe the MKT measured in our item set. For example, we excluded the MKT-Geometry framework because our item set did not include geometry items.

Operational Definitions

We examined seminal documents for each of the five frameworks to extract operational definitions of key subdomains. We added clarifications throughout the coding process where authors' original language was insufficient to inform coding decisions, and did so for all frameworks. A list of source documents for each framework and subdomains coded is provided in Table 2. We illustrate this process for one framework (Ball et al., 2008).

The article, "Content knowledge for teaching: What makes it special?" (Ball et al., 2008), lays out clear definitions for six subdomains of MKT and discusses the authors' sense of the relative clarity of each. Ball et al. first subdivide all of MKT into CK (content knowledge) and PCK (pedagogical content knowledge), following Shulman's (1986) distinctions. They then further decompose each of these. CK is decomposed into *common content knowledge*, *specialized content knowledge*, and *horizon content knowledge*. Common and specialized knowledge are distinguished from one another by context of use, and the authors stress that this is a key distinction, suggestive of a body of professional mathematical knowledge needed by teachers alone. Each is a form of "pure" mathematical knowledge and explicitly excludes knowledge of students or teaching, but *common* is knowledge that is needed in settings other than teaching, whereas *specialized* is knowledge that is only needed for the teaching of mathematics. *Horizon* content knowledge is defined somewhat more ambiguously, as "an awareness of how mathematical topics are related over the span of mathematics included in the curriculum" (Ball et al., 2008, p. 403), but the authors also specify that it is a less robustly theorized knowledge type than the other two and, in fact, that it might be a different way of describing a component of PCK or a type of specialized content knowledge.

Given the strength of the claim made by Ball et al. that the distinction between common and specialized CK is important and their hesitance about the construct of horizon content knowledge, we decided to code for common and specialized but not horizon content knowledge. We planned, in the course of coding, to flag any cases which suggested the missing code might be problematic, but no such cases were noted. An ambiguity we noted in the distinction between "common" and "specialized" is the under-specification of what it means for knowledge to be needed in "settings other than teaching," (Ball et al., 2008, p. 399). We operationalized this distinction as *professional work other than teaching that requires similar levels of educational preparation; for secondary level topics, this is work that requires a math degree or equivalent*.

We note here that early in this process we were faced with the need to make a choice about coding subdomains of PCK. Several frameworks included a subdomain called PCK, making explicit reference to Shulman's (1986) definition of the term and delineating similar subdivisions within PCK, but two of these frameworks (COACTIV and TEDS-M) elected not to differentiate subdomains of PCK in their assessment design. And while the Ball et al. (2008) framework does define subdomains of PCK, most assessment efforts based on this framework have focused on differentiating between common and specialized knowledge, with less focus overall on measuring PCK and its subcomponents. Given these considerations, we elected not to code subdomains of PCK.

Table 2. MKT frameworks examined.

Coding

As described above, each item had a previously produced knowledge map, which included a summary of the key knowledge, skills, and reasoning required to respond to the item. Once an initial code list was developed from seminal documents of each framework, these codes were in turn applied to each of the identified pieces of knowledge, skill, or reasoning for each item..A codebook was created and used in order to maintain adequate rigor (MacQueen, McLellan, Kay, & Milstein, 1998; Saldaña, 2012), and, following Creswell's (2009) suggestion to document as many steps as possible, the coding sheet included a note section for the coders to keep a record of their reasoning for assigning certain codes to an item, any questions they had, the decisions made, and additional observations worthy of attention. For each item and each framework, researchers coded pieces from its knowledge map for the subdomain(s) of the framework that the piece represented. Coding was done independently, with two coders per item, and a third coder brought in to arbitrate discrepancies as needed. At least one author coded each item; two colleagues familiar with research on MKT served as additional coders as needed. Initial inter-rater reliabilities were generally adequate, ranging from .69 to .97, but our goal in this coding was less to establish reliability in coding and more to produce a consensus around accurate final coding. Because we drew on codes extracted from the selected frameworks, we were limited in how far we could develop our code list without compromising fidelity to each framework's author's intentions. Given this, the inter-rater reliability in this study may reflect more than anything else the degree to which each framework's provided definitions were amenable to use as codes. What is more salient to our study is the intercoder agreement, a term introduced by Creswell (2009) to represent the final agreement among researchers after reconciling discrepancies in initial coding. Gibbs (2007) suggested that researchers can minimize bias by first individually coding the same set of data using the same codes, and then discussing the results of the coding with a goal of reaching a common agreement about the meaning and application of each code. Following this method, we attained 100% agreement on final codes.

From coding to results: The Swift example. We illustrate our coding process using the Swift item example presented in Figure 1. The previously generated knowledge map for this item called out the following four distinct components of knowledge, skills, and reasoning that a test taker might draw on in responding to the item:

1. Knowledge that any three ordered pairs is sufficient to determine the equation of a quadratic.
2. Knowledge that the complete formula for a quadratic expression is $c(x-a)(x-b)$.
3. Ability to construct the general mathematical claim implicit in a student's responses in the context of discussion.
4. Ability to evaluate the generalizability and validity of a mathematical claim.

Under the Ball et al. (2008) framework, the first and second points were coded as common content knowledge, and the third and fourth coded as both specialized content knowledge and PCK, reflecting a certain ambiguity in the framework that we were not able to resolve because, as described in Hill et al. (2008), specialized content knowledge and PCK may be used toward similar ends. For example, constructing the general mathematical claim implicit in a student's response might be accomplished from a purely analytical standpoint, attending only to the mathematics represented in the stated claim independently of the idea that it was presented as student work. But it also might be informed by knowledge of common ways that students approach such problems or represent their thinking in words. Under this framework, then, the item was coded as measuring three of the subdomains of the framework: *common content knowledge*, *specialized content knowledge*, and *PCK*.

Under the COACTIV framework, the first point was similarly unambiguously coded as content knowledge, but the coders indicated that the second point did not fall into the framework at all, due to the COACTIV's conceptualization of content knowledge as a "deep understanding of the secondary school mathematics curriculum" (Krauss, Baumert, & Blum, 2008, p. 876). COACTIV's content knowledge category, unlike that of the prior framework, explicitly excludes "the school-level mathematical knowledge that good students have" (p. 876), effectively excluding from the MKT construct portions of what Ball et al. (2008) term common content knowledge. The same definitional distinction shifted the coding of the third point, which was less ambiguous under this framework and was coded simply as PCK. And the fourth point was again double coded as content and PCK but for a different reason, as deep mathematical knowledge as defined by COACTIV would include the ability to evaluate mathematical claims in general. Under this framework the item was coded again as measuring two of the subdomains: *content knowledge* and *PCK*. Similar patterns of coding occurred across the remaining frameworks.

Results and Discussion

Number of Subdomains Assessed by Framework and Item

Table 1 shows the number of subdomains of each framework assessed by each of the nine items. There was some variation by item. For example, the Hillyard item measured a single knowledge subdomain (PCK) under four of the five frameworks, and measured multiple subdomains under only one, the MUST framework (Heid et al., 2015), where it was coded as measuring both *mathematical activity* and *mathematical context*. By way of contrast, the Swift item measured multiple subdomains under all five frameworks, indicating that it measures a blend of knowledge regardless of which framework is selected, and in fact measured three subdomains in all but the COACTIV framework (which contained only two content-specific subdomains) and the TEDS-M framework (which contained only two subdomains).

One explanation for our results is that this set of items was designed to capture MKT by following a practice-based item design theory. From the practice-based perspective, what makes an assessment task effective in measuring MKT is how closely it represents the work of teaching and, hence, the item is considered successful based on how well it represents "the actual practices we hope teachers will successfully master, rather than the more-slippery notion of the 'kinds of knowledge' teachers should possess" (Hill, 2016, p. 5). And because these tasks of teaching are designed to approximate the work of teaching, it stands to reason that, like teaching, a strong assessment item might call on multiple types of knowledge and ask the test taker to coordinate them in application to the work of teaching. Because the set of items we examined were designed to be practice-based, we cannot claim that our findings are likely to generalize to assessment items that follow a different design. However, as Hill (2016) points out, many current assessments (and all of those explicitly based on the frameworks we examined) follow some degree of this practice-based design in which an item focuses on engaging the test taker in key tasks of teaching mathematics. This suggests that the findings may generalize, at least in part, to many current MKT assessment efforts.

Additional Results

We note here one minor result that may be of interest. When multiple frameworks used the same terminology, we found a number of items that were coded inconsistently with respect to that terminology. For instance, three frameworks contain "PCK" as a subdomain. However, coding for PCK in one framework did not guarantee that the item was coded as PCK in all other frameworks, due to how PCK was defined. Moreover, as reflected in the Swift coding examples, there were also some significant differences between frameworks in how mathematical content knowledge was defined. While in the case of mathematical content knowledge, the framework authors did not use identical terminology, the similarity of terminology around content knowledge, which one might reasonably expect to be fairly unambiguous, arguably creates the potential for misunderstanding. These observations mirror those made by Kaarstein (2014), who found similarly divergent categorizations analyzing a different set of items across a subset of the frameworks we considered, and substantiated concerns more broadly that the field may be suffering from an unproductive lack of coherence with respect to our work around MKT (Hill, Sleep, Lewis, & Ball, 2007). While different frameworks may serve different purposes, certainly it is potentially problematic when common terms are used differently in ways that undermine clear communication, and our results provide additional evidence that this may be the case.

Table 1. Number of Subdomains Measured by Item by Framework

	Ball et al.	KAT	COACTIV	TEDS-M	MUST
# subdomains coded	3	3	3	2	3
Item name					
1. Allen	3	2	1	2	2
2. Hillyard	1	1	1	1	2
3. Morgan	3	3	2	2	3
4. Watkins	2	2	1	2	2
5. Carlies	3	2	2	2	3
6. Swift	3	3	2	2	3
7. Rose	3	2	1	2	3
8. Swain	3	2	2	2	2
9. Williams	2	2	1	1	3

Limitations

We caution here against potential overgeneralizations of our results, which we would characterize as more illustrative than generalizable. Our set of items is clearly quite small, and while we intentionally selected items to represent strong examples of practice-based item design theory for which we had evidence of success in capturing MKT, our observations may not generalize to all practice-based items and almost certainly do not generalize to differently designed assessment items. That a practice-based approach is prevalent in the field provides some evidence that it is a fruitful design method, but other approaches may emerge that are equally able to measure MKT and better able to capture its subdomains, or more careful domain analysis and framework development might produce a set of knowledge distinctions that can be measured in clear isolation from one another.

We also note that the evaluation or comparison of frameworks on the basis of our numerical results is inappropriate given the purpose and method of the coding. Frameworks did not have equal numbers of categories to begin with, and our coding decisions may have exaggerated these differences or obscured them. Some frameworks afforded clearer coding decisions than others, but none were designed to support this type of coding, and many of the authors of the frameworks acknowledge some ambiguity in the boundary cases between knowledge types. Not all the frameworks were explicitly designed to support assessment design, and it is also worth noting that none were utilized to design the set of items we analyzed, and it is possible therefore that our items may distinguish subdomains less well than items designed for that purpose under a particular framework might do.

We also call attention to the two items that seemed to measure distinct subdomains best: the Hillyard item, which was coded as measuring one subdomain under most frameworks, and the Williams item, which was coded as measuring one subdomain under three frameworks. These cases illustrate that is clearly possible, even within the set of items we analyzed, for an item to measure a single subdomain under a framework, and it is not our claim that practice-based items measure multiple subdomains, with no exception. We simply claim that measuring isolated subdomains is unlikely to be the typical pattern.

Conclusions

We conducted an analysis of the study items in which we coded each item for the knowledge subdomains measured using five different frameworks that have been proposed in the field. Our results illustrate that this set of items does not measure subdomains of any of these frameworks distinctly, suggesting that the types of MKT elicited by the items are interconnected. We discuss three implications of these results. One implication is that these frameworks, each designed with different and particular intent and potentially useful with respect to that purpose, may not be useful for distinguishing measureable subdomains of MKT. To some degree this is a divide between approaches to theory and approaches to assessment. If one takes a compartmentalized view of an MKT framework, assuming that subdomains must be distinctly measureable in isolation from the larger construct in order to establish the value of the theory, this result could be viewed as problematic. We hold, however, that identification of distinctly measurable subdomains is not the only or even the most desirable purpose of theory; a theorized subdomain need not be distinctly measureable in isolation from the larger construct to be useful in informing the field's thinking, designing policy, or as a heuristic for organizing teacher supports. For example, Ball et al.'s (2008) framework, and in particular the subdomain *specialized content knowledge*, has pushed the field substantially by drawing attention to difficult mathematics that elementary teachers need to know and are not likely to learn in conventional preparation; this attention has changed policy for the mathematical education of elementary teachers (e.g., Conference Board of the Mathematical Sciences, 2001). The KAT framework helps us think about where prospective teachers are likely to learn particular types of knowledge, and by tying their categorization closely to existing course structures for secondary teacher preparation they directly inform what might be the content of such courses. In other words, different frameworks can be powerful in calling attention to different aspects of MKT and of its importance, and while there are many reasons to measure important constructs, it is not obvious that measurability is a necessary indication of a theory's importance or validity. However, much assessment development work in this area has focused on doing precisely this: producing items to measure specific subdomains of MKT in an effort to validate the theory. We hold that this approach is not necessarily optimal if the goal is either to produce valid and reliable assessments of MKT or to generate useful theory, unless the explicit intended use of that theory is to support assessment development.

A second implication is that items written to a practice-based framework are unlikely to measure isolated subdomains of MKT well. Items organized around the idea of capturing a moment in the work of teaching, where the work of teaching of necessity demands that teachers draw on and coordinate complex pieces of various types of knowledge simultaneously, are likely to be successful only insofar as they measure complex and coordinated knowledge. In other words, under this design theory the key to an item's "success" in measuring the MKT domain is its authentic approximation of teaching practice, which may undermine its ability to capture distinct knowledge domains. We nevertheless propose that, given the field's current knowledge, the benefit of a practice-based item design in successfully measuring the MKT construct far outweighs any drawbacks associated with such items not being able to distinguish among theoretical subdomains particularly in cases where there is no clear rationale for the necessity to distinguish subdomains.

Finally, we call attention to the implications for teacher education. Frameworks for MKT effectively called the field's attention to aspects of teachers' content knowledge that are needed but which traditional teacher preparation provides inadequate opportunity to learn, prompting attempts to organize coursework to support that learning (e.g., CBMS, 2001; CBMS, 2012). We would argue, however, that it is crucial to attend to the way MKT occurs in the work of teaching, and not just to particular subdomains of MKT, however important they might be. While the content knowledge that can be called specialized content knowledge, for example, may be important for novice teachers to learn, there is no evidence that courses can be organized to teach specialized content knowledge directly in isolation from other components of MKT, or that the mathematics that makes up specialized content knowledge makes up a mathematically coherent topic area. Programmatic organizations that attempt to do this may be, in essence, missing the point of a practice-based approach. The work of teaching may form a natural organizing structure for teacher learning, just as it does in practice-based items, because the work of teaching is, in fact, the work we want to help teachers learn to do. We would argue that it makes sense to organize teacher preparation around that work in ways that support learning of the whole of MKT, and that we use theory not to decompose what is to be learned into distinct pieces but rather to help us appreciate the depth and complexity of the knowledge needed to do that work.

Those Who Teach the Teachers: Knowledge Growth in Teaching for Mathematics Teacher Educators

Shandy Hauk
WestEd & University of Northern Colorado

Billy Jackson
University of Tennessee Chattanooga

Jenq-Jong Tsay
University of Texas Rio Grande Valley

This theory-based report gives evidence and builds a conceptual framework for a construct called "mathematical knowledge for teaching future teachers" (MKT-FT). Mathematics teacher educators construct MKT-FT as they teach courses for pre-service teachers. Connections to mathematical knowledge for teaching (MKT) are discussed, with an emphasis on the complex relationships among aspects of pedagogical content knowledge in MKT-FT and MKT.

Key words: Mathematical knowledge for teaching, Discourse, Teacher educators

In the 30 years since Shulman's (1986) seminal speech on the importance of pedagogical content knowledge, a variety of theories about such knowledge have emerged (Depaepe, Verschaffel, & Kelchtermans, 2013). Among the most well known in the U.S. is at the heart of a primary-grades-focused model of *mathematical knowledge for teaching* (MKT) introduced by Hill, Ball, and Schilling (2008). The subject matter knowledge (SMK) and pedagogical content knowledge (PCK) components of Ball and colleagues' model of MKT are illustrated in Figure 1.

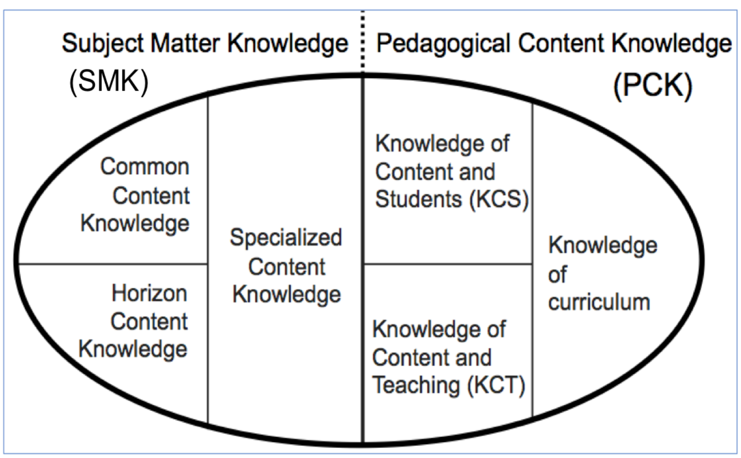

Figure 1. Model of mathematical model for teaching (Hill et al., 2008)

In the context of more advanced mathematics, others have explored how the idea of MKT may be productively refined for use in research and development in secondary and post-secondary settings (Hauk, Toney, Jackson, Nair, & Tsay, 2014; Speer, King, & Howell, 2015). Speer and colleagues considered college instructional questions such as: What are the types of specialized, horizon, and common mathematical knowledge for teaching calculus? While Hauk and colleagues have tackled: How does one unpack the aspects of PCK – knowledge of content and curriculum, content and teaching, content and students – when the teaching is in a college, the students are adults, the collections of mathematics experiences brought to the classroom are larger, and the sociocultural relationships among students, teacher, and institutions are quite different from those assumed in the K-8 foundations of the initial framing of MKT? Hauk and colleagues (2014) developed an expanded model for college teacher PCK. They used the PCK components in Figure 1 as the vertices of the base of a tetrahedron and added a fourth vertex which they called *knowledge of discourse* (knowledge about the nature of communication, including context and valued forms of inquiry, socio-mathematical norms, and language in, for, and through mathematics in post-secondary educational settings) – see Figure 2.

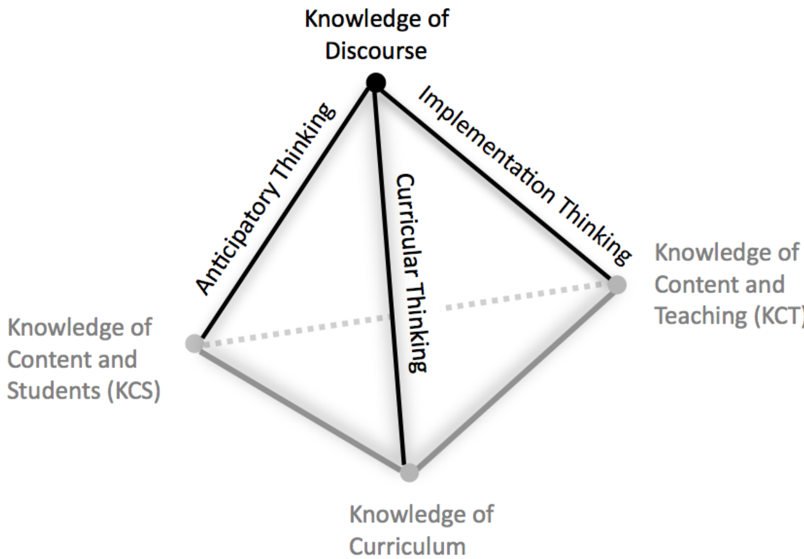

Figure 2. Tetrahedron model of PCK (Hauk et al., 2014).

Context and Researcher Stance

Here we consider an MKT-related question in undergraduate mathematics education: What is the nature of "mathematical knowledge for teaching" for college instructors who teach mathematics for pre-service elementary teachers? Such instructors are teaching adults in post-secondary settings where the mathematical content is in the context of elementary school mathematics (rather than advanced) *and yet* the content is itself linked to MKT for grades K-8.

Indeed, Gallagher, Floden and Gwekwerere (2012) note that we know little about what skills are required to be an effective teacher of future K-8 mathematics teachers nor do we know much about how those skills develop. Here, by *mathematics teacher educator* we mean anyone who provides guidance, mentoring, or professional learning opportunities to prospective or in-service teachers. The current paper focuses on the subpopulation of mathematics teacher educators who teach mathematics-content-rich courses where the learners are pre-service K-8 teachers.

For us, an important aspect of the context of this work are the experiences we bring to it. Below, we outline background that has informed our thinking.

Shandy Hauk. My experience in the last 25 years includes being a classroom teacher in K-6, middle, and high school. The latter as both an English and a mathematics teacher. Others perceive me as a white woman though my early experience growing up in and around Los Angeles was as a "transcultural kid" (ours was one of two pink families in a neighborhood of more than 30 brown families; all were poor). I was raised and have worked in socio-economically and culturally diverse communities. Along the way, I completed a PhD in mathematics (chaos theory and global climate modeling) and a post-doc for research in undergraduate mathematics education. The work I have done with mathematics teacher educators has included research about the professional practices of district-level coaches and teachers on special assignment. Most closely related to the work reported here is a recently completed project where we spent five years looking at the practices and professional development of in-service high school teachers and the mathematics faculty who teach them. In that project, Billy and I, with several others, began our journey of model-development for how to describe the aspects of knowledge (and thinking) about teaching we saw (e.g., Hauk et al., 2014). Billy, JenqJong and I are just starting a new project that develops and researches professional learning about MKT among college mathematics faculty who teach future K-8 teachers.

Billy Jackson. I grew up in the southeastern U.S. as a member of a typically privileged group (white and male). Like Shandy, my PhD is in mathematics and I did a post-doc in mathematics education. As part of my post-doc years, I spent a year as a high school mathematics teacher. An eye-opening experience. My passion in understanding how to unpack MKT and communicate that to other people has grown to include how to represent and communicate MKT to mathematics teacher educators and to people who do research with teacher educators. I have typically had success in mathematics and know the culture of mathematics and now am working in undergraduate classrooms where my professional values are not shared by my students. Being a male mathematician when 90% of the student audience is female (pre-service elementary school teachers) is a challenge. One bias I face is that as a white male mathematician I am not perceived as a "nurturer" by my students. In the classroom, on the first day of class a student told me "I get the sense you are a no nonsense kind of guy and get straight down to business." I have found I am more accepted as a nurturer in a one-on-one environment like office hours, when we have more time and space for negotiating the cultural differences. In a lot of ways, I am the antithesis of what my students perceive about my School of Education colleagues. One of the biggest rewards in working with K-8 future teachers is the great feeling to see learners have aha! moments and ask me "Why weren't we taught this way? It makes so much more sense!"

JenqJong Tsay. I was raised, educated, and initially taught elementary school in Taiwan and completed a PhD in mathematics education in the US. I have spent the last 15 years working in and developing skill in a new culture. It means I can draw on my learning experience about what teaching and classrooms are like in the U.S. and in Taiwan. This comparison has been part of the perspective I have brought to this work. Billy noted that being male when 90% of the preservice teacher student audience is female was a challenge. For me, the more pertinent challenge comes in the perceptions and assumptions students have of me because of my appearance and accent. Most of the time I teach middle and high school pre-service teachers. This year I am teaching the K-8 Number and Operations content course for the first time. My perception is that most of my preservice elementary teacher students do not like, okay to be honest, hate mathematics. This is a challenge for me. My instruction is inquiry-based, so I do not use direct instruction or create procedural guidelines. For most of the students in the K-8 fundamentals of math course, the inquiry-based approach is met with impatience and frustration. My students are not used to the idea of spending time to contextualize mathematics and make sense with mathematics for 20 minutes on one idea. The first few weeks, we spent a lot of time building socio-mathematical norms with some reinforcement every class period of this negotiation. In Taiwan, undergraduates in general, and preservice teachers in particular, are more persistent and concentrated in their study, in part because of their parents' expectation and financial support. Nevertheless, what I have learned from my teaching and research in the U.S. seems to be that conceptual understanding is emphasized more in the preparation of teachers in the U.S. than Taiwan.

We are still building our personal experiences in research with mathematics teacher educators. We rely heavily on the work of others, including the policy and research literature on people who teach in-service teachers (see for example AMTE, 2017 and Bitto, 2015). We also pull from the limited research and practice literature on the nature of professional knowledge among instructors responsible for the collegiate mathematics education of pre-service teachers. It is a strength of our theory and model development work that we have these three distinct sets of practical experiences. At the same time, we may still have blind spots about the theory and we look to the reader and other people in the field to contribute to the triangulation needed in rigorous research.

Importance to RUME Community

A natural question arises: Why should the Research in Undergraduate Mathematics Education (RUME) community have an interest in examining the knowledge required of mathematics teacher educators to perform their jobs effectively? First and foremost, much of the mathematical preparation for teaching among future K-8 teachers happens in colleges, most at the undergraduate level (Masingila, Olanoff, and Kwaka, 2012). In fact, Masingila and colleagues found that 88% of the teaching of "mathematics for elementary teachers" courses happens in mathematics departments. Across institution types (2-year, 4-year, and master's and doctoral degree granting) most faculty teaching these courses have advanced degrees in mathematics (e.g., more mathematics PhDs teach the courses than those with doctorates in mathematics education).

We know that early learning experiences are formative and that children who learn to see themselves as mathematical agents do better in secondary school and beyond (Aud, et al., 2013, Shim, Ryan, & Anderson, 2008; Woodward et al., 2008). We know teaching that supports children in building skills with mathematical process, practices, and content is socio-culturally rich and responsive to community experiences and needs (Aud & KewalRamani, 2010; Gay, 2010; Khisty & Chval, 2002; Téllez, Moschkovich, & Civil, 2011). We know that future teachers have greater resources to draw on and are more likely to offer children what they themselves have experienced as learners (including the undergraduate learning experiences that are most proximal to their launch as teachers; e.g. Ball and Bass, 2000; Conference Board of the Mathematical Sciences, 2012; Hodgson 2001). There is a need for mathematics faculty who are prepared to teach mathematics content courses for pre-service elementary teachers (PSETs) in ways that resonate with the kinds of classrooms those future teachers are expected to sustain.

In the U.S., the current population of instructors for such courses includes adjuncts, graduate students, and full time tenure- and non-tenure-track track mathematics faculty (Masingila, et al., 2012). Large segments of this instructor population have difficulty teaching courses for PSETs (Flahive & Kasman, 2013; Greenberg & Walsh, 2008). Though instructors in mathematics departments usually have a deep mathematical background, they often face challenges teaching content that is relevant and has utility for PSETs, unaware of the "cognitive and epistemological subtleties of elementary mathematics instruction" (Bass, 2005, p. 419).

Given this state of affairs, Masingila, Olanoff, and Kwaka (2012) advocate for the design and implementation of professional development for mathematics teacher educators. Indeed, Masingila and colleagues note that many faculty who participated in their study asked the researchers where they could find professional learning resources!

The RUME community includes experts on such matters. Any design and implementation of effective professional development for mathematics teacher educators must involve attention to identifying the types of knowledge that faculty use and need. In this case, the research and subsequent implications for practice involve the teaching of college students who are on a professional path to teaching K-8 students.

Mathematical Knowledge for Teaching Future Teachers (MKT-FT)

For these reasons, we propose that college instructors possess a specialized constellation of knowledge to be studied: *mathematical knowledge for teaching future teachers* (MKT-FT). We posit that like MKT, MKT-FT is largely individually constructed by mathematics teacher educators while being heavily socially mediated. Seaman and Szydlik (2007) discussed the necessity but insufficiency of the early model of MKT for college mathematics instruction, particularly in the context of teaching future teachers. Several authors have noted the existence of what we see as components of MKT-FT. Zopf (2010) and Olanoff (2011) argued that effective teaching of future teachers requires mathematical knowledge of the work of teaching K-8 mathematics and awareness of the complexities of K-8 MKT itself.

According to Rider and Lynch-Davis (2006) and Smith (2003), the mathematical knowledge needed for teaching future teachers attends to the fact that one is teaching adult learners who have some familiarity with the mathematics (as opposed to teaching children who may be learning content for the first time). And, we note, there is a perceived autonomy of the learner in the post-secondary setting that is largely absent in K-8 and high school contexts. Smith (2005) has claimed that faculty who work effectively with future teachers have some (perhaps implicit) knowledge of educational theory and K-12 practice, as well as knowledge resources for connecting ideas and concepts in ways that prepare pre-service teachers to review, select, and engage with the wide array of curricular decisions that must be made by a schoolteacher (e.g., decisions regarding which resources, worksheets, texts, and activities to use or avoid, decisions about how to orchestrate classroom mathematical discussions). Olanoff (2011) points out that Deborah Ball herself considers MKT to be the analog of "common content knowledge" for faculty "mathematical knowledge for teaching" teachers.

Research and development on the preparation of teacher educators has long assumed a nesting of types of knowledge. One representation of that can be seen in Carroll and Mumme's work (2007). Figure 3 represents the nesting of mathematical content as subject matter knowledge (orange disk), linked to (future) teacher and elementary student within the larger context of the classroom (yellow disk).

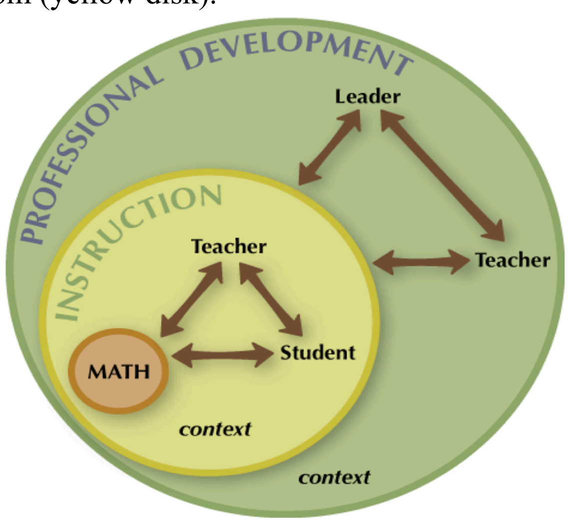

Figure 3. Nesting of teaching and learning connections (Carroll & Mumme, 2007).

Similarly, in Figure 3, mathematical knowledge for teaching (the stuff in the yellow disk) is linked to (future) teacher and mathematics teacher educator ("leader") within the larger context of teacher professional learning (green disk).

Clearly, this is a multi-dimensional situation. For each disk in Figure 3 there is an associated set of specifications for what counts as the context and for what constitutes the content about which one has "pedagogical content knowledge." Perks and Prestage (2008) made the case that an additional aspect they called "professional traditions" connects to the categories in Figure 3. Like Carroll and Mumme, they asserted that knowledge for teaching and for teaching teachers operates on several levels with a partially-nested self-similar design. Their model for *teacher-educator knowledge* is shown in Figure 4. On the left in Figure 4 is the model they associated with Instruction. Unlike Figure 3, Perks and Prestage focused on kinds of knowledge brought to a classroom (rather than the interactions among people and content foregrounded by Carroll and Mumme). So, though both models involve a self-similar nesting, the nature of what is nested and of what is represented by arrows/edges differs.

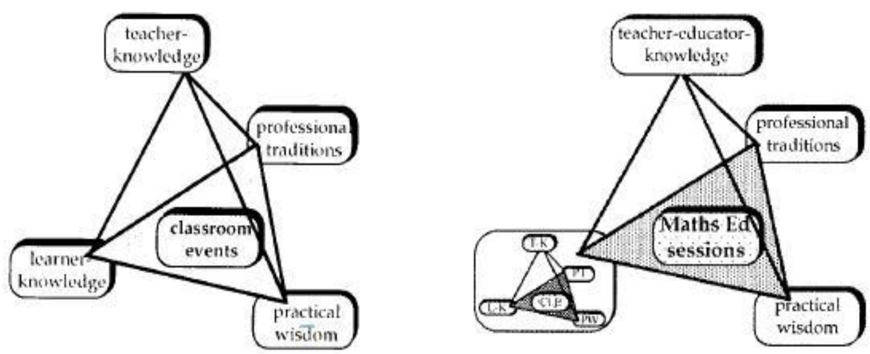

Figure 4. Tetrahedron models for teacher-educator knowledge (Perks & Prestage, 2008).

Model of *Pedagogical Content Knowledge* for MKT-FT

In our own work since 2006, we have used a tetrahedron to represent the relationships among types of knowledge (4 vertices) and types of thinking (6 edges) associated with the development of mathematical knowledge for teaching. As discussed above for Figure 2, the model for MKT-FT in Figure 5 (next page) foregrounds attention to pedagogical content knowledge. At each vertex in Figure 5 are the mathematical content in the college class *and* "content" that is the mathematical knowledge for teaching K-8 students (illustrated for just the KCS vertex as magnified and highlighted, lower left, in Figure 5). We claim a similar cascade of knowledge structures, related to Content & Teaching, Curriculum, and Discourses in K-8 are embedded in the vertex knowledge of college mathematics instructor MKT-FT (illustrated by similar "mini" tetrahedra at each of the other vertices in Figure 5, next page).

While the nesting of knowledge structures within others is represented as geometrically self-similar, a fractal structure, the knowledge and thinking represented in the "big" and "small" tetrahedra are not identical. Each vertex of the "big" tetrahedron representing MKT-FT has a ten-to-one mapping (i.e., the 4 vertices and 6 edges of the "small" tetrahedron). For instance, suppose the MKT-FT vertex for *knowledge of content and students* (KCS) is defined, as by Ball and colleagues, as "content knowledge intertwined with knowledge of how students [who are future teachers] think about, know, or learn this particular content" (Hill et al., p. 375).

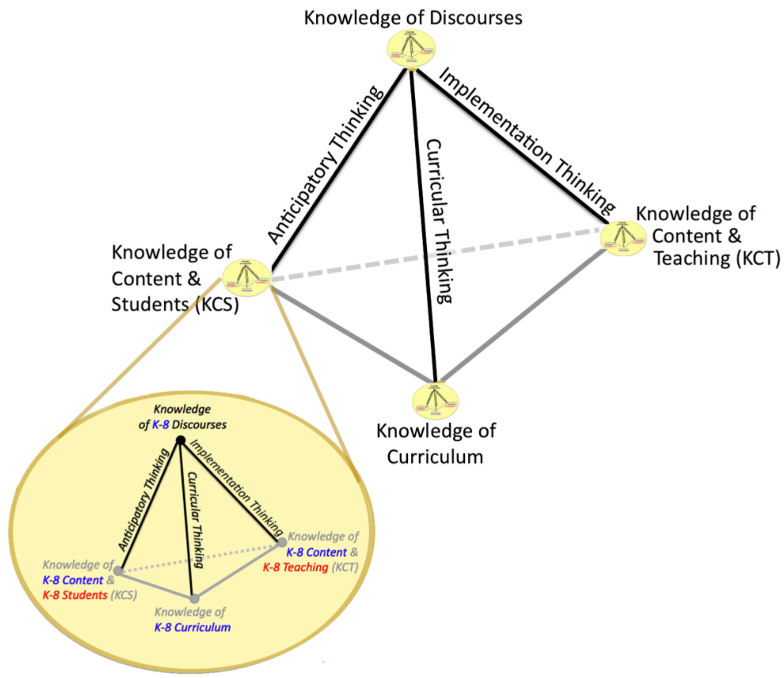

Figure 5. Model of MKT-FT pedagogical content knowledge – each vertex itself contains knowledge structures related to K-8 MKT.

In Figure 5, the KCS vertex represents teacher educator knowledge of (a) how to create instruction that will engage college students with acquiring the profound understanding of mathematics they will need in their future work as teachers as well as (from the small tetrahedron) (b) instruction that engages college students in learning to encapsulate, do, and unpack mathematical ideas in anticipation of their future work with children in K-8 mathematics lessons (i.e., K-8 MKT). In the MKT-FT model, knowledge of content and teaching includes a knowledge of teaching mathematics in a college course for future teachers as well as attention to K-8 MKT in making instructional choices in that college course.

MKT-FT and Task Design

Example 1. As a math teacher educator I incorporate my knowledge about my students and about their future work as teachers into the design of tasks we do in the college classroom. Using my knowledge of content and future teachers, I know that they know how to use the distributive property of multiplication across addition, but may not understand what it means (their mathematical knowledge) or how to unpack and describe that meaning to teach others (K-8 MKT). So, one task I have created starts like this:

> The situation: You are teaching a 5th grade class about division, talking about the properties of division. Daisy, one of your students, raises her hand and says “shouldn’t division distribute across addition just like we say multiplication does since division is the opposite of multiplication?”
> The goal of this activity is to investigate Daisy’s claim.

In the task, future teachers make groups of objects and circle groups of objects. Among other things, they compare 30 divided by 10 to 30 divided by 5 plus 30 divided by 5.

Example 2. In an activity for college faculty new to teaching future teachers, to illustrate how a task for pre-service teachers might be designed, we have used video of Sybilla Beckmann's college classroom (Beckmann, 2013) and a fourth grade classroom (from the Teaching Channel). In the college video, the instructor asked preservice teachers to come up with scenarios in which multiplication is not a correct operation for the multiplicative phrase "four times as many as." At first glance, this multiplicative phrase indicates a number sentence of the form $b = 4a$ (i.e., product (b) = 4 (multiplier) times a (multiplicand). Stated this way, a and b have a multiplicative relationship, but if b is given and a is the unknown to be found, an appropriate operation would be division. When problem solvers take a direct translation approach to convert a verbal sentence into a number sentence, an inappropriately stable piece of knowledge – about the operation – can be adopted. In the fourth grade classroom video, the majority, if not all, of the children demonstrate such difficulties with the problem "Maria saved $24. She saved 3 times as much as Wayne. How much did Wayne save?" This, in spite of the teacher's effort to show them otherwise. When a mathematics teacher educator is aware of the in-the-wild demands of elementary school teaching and the fractal structure of PCK, a task for their preservice teachers can be designed to build future teachers' knowledge to tackle this obstacle. A simple task could be similar to Beckmann's questioning of undergraduates to find different scenarios. A more complex task would emphasize the syntax and semantics of linguistics and introduce attention to analytic translation and compare it to direct translation.

These examples illustrate an important aspect of what mathematics teacher educators do with their MKT-FT. Teacher education has long noted that task design is a significant component in the development of knowledge for teaching teachers. For example, Stylianides and Stylianides (2006) asserted that it is crucial for activities to be *teaching-related mathematics tasks,* so future teachers learn important school mathematics while at the same time making connections between how learning the content relates to its teaching. For Seaman and Szydlik (2007), well-designed tasks deepen the "mathematical sophistication" of future teachers, which they define as occurring as a result of enculturation into the mathematics community (e.g., this might be signified by teachers exhibiting as their own the ways of knowing and values of mathematicians). A broader example comes from the *Journal of Mathematics Teacher Education* issue devoted to the important topic of task design (Zaslavsky, Watson, & Mason, 2007). Papers in this special issue discussed different aspects of good task design in courses for teachers. For instance, according to Chapman (2007), effective tasks facilitate new understandings of familiar concepts and prompt reflection, while Bloom (2007) argued that quality tasks enhance mathematical habits of mind among college learners who are future teachers.

Yackel, Underwood, and Elias (2007) demonstrated the profound effect that attention to task design and reflection on task implementation can have on MKT and MKT-FT development of those who teach future teachers. One of their mathematics teacher educators commented,

> I found it interesting that adult students also go through some of the same progressions that children do. In particular, I often noticed that many students initially needed to use [iconic representations] to perform calculations, such as explicitly drawing boxes, rolls, and pieces…Having never taught young children, I had never seen this first hand. *Base 8 gave me the opportunity to experience this part of children's learning* [emphasis added]. I think this is valuable to college instructors because most, like myself, will never have an opportunity to work with elementary school children closely. (p. 364)

Hence, we see that experiences with task design can support teacher educator growth of Knowledge of Content and Teaching in MKT-FT by creating and leveraging a knowledge of content and K-8 students. This example also illustrates the nonlinearity needed for an MKT-FT model. The instructor in Yackel and colleagues' work mentioned building Knowledge of Content and Students (both for child and adult learners) by thinking about Knowledge of Content and Teaching.

As another example of the multi-dimensional nature of MKT-FT, consider what constitutes the "subject matter knowledge" in the mathematical knowledge needed for teaching future teachers. For MKT-FT, the "subject matter" is a combination of mathematics and mathematics education As Ball noted, MKT (everything in Figure 1) becomes common content knowledge for mathematics teacher educators. Simultaneously, "specialized content knowledge" for mathematics teacher educators includes an awareness of educational policy and literature as a means of supporting future teachers' awareness about why certain mathematical or pedagogical practices are favored (e.g., in the Common Core Standards). Horizon knowledge for teacher educators includes recognition of pending consequences of district, state, and national mathematics standards. So, in MKT-FT, specialized content knowledge is rich in educational as well as mathematical knowledge.

And what about the knowledge of discourse discussed earlier? Well, for mathematics teacher educators, MKT-FT knowledge of discourse subsumes the same knowledge of discourse that teachers have, and draws on knowledge of communicating about MKT and the teaching of mathematics in different instructional situations.

As Hauk, et al. (2014) point out, the literature on PCK includes both stable and dynamic features. The edges in the tetrahedron represent the *ways of thinking* about teaching mathematics used in planning for, implementing, and reflecting on practice. These ways of thinking are enacted as teachers adapt to varying sociomathematical and cultural contexts that arise over time. In like manner, effective mathematics teacher educators also possess ways of thinking about teaching mathematics and about teaching MKT that change as the social, mathematical, and cultural climates change in their courses for future teachers. The edges in our fractal tetrahedron also represent these dynamic ways of thinking for faculty who teach future teachers.

Concluding Remarks

It is worth noting that much of what we have presented here as knowledge required to teach future elementary mathematics teachers is documented in the recent *Standards for Preparing Teachers of Mathematics* issued by the Association of Mathematics Teacher Educators (AMTE) in February of 2017. For instance, the AMTE document stresses (as we have done here) the importance of task design and implementation:

> In such [active learning] sessions, learners [future teachers in this case] are typically provided challenging tasks that promote mathematical problem solving and are provided opportunities to discuss their thinking in small group and full group discourse, thus promoting important mathematical practices. (p. 31)

This quote also underlines the importance of discourse knowledge that is required of teacher educators. Facilitating active learning in a collegiate classroom requires the teacher educator to navigate across the many social, cultural, and socio-mathematical norms present in the room.

Discourse knowledge is further amplified in paying attention to building reasoning and justification skills among future teachers, which the *Standards* address by noting that "without explicit classroom attention to mathematical argumentation, effective programs risk diminishing the opportunities candidates have to engage in the mathematical practice of constructing viable arguments" (p. 32). The fractal nature of MKT-FT is also reflected in the *Standards:* "In effective programs, mathematics teacher educators explicitly identify and address mathematical practices" (p. 31). Ultimately, faculty teaching future teachers must possess sufficient knowledge of mathematical content and of the mathematical nuances of K-8 MKT to offer instruction the uses and is aware of valued mathematical practices (e.g., those in the Common Core State Standards).

Raising reasoning through revision: A case study of an inquiry-based college geometry course

Janessa Beach
Texas A&M-Commerce

Rebecca-Anne Dibbs
Texas A&M-Commerce

Geometry is the subject where U.S. students are weakest on international assessments, but college geometry is an area of proof that is understudied. Since geometry is secondary students' only exposure to proof, it is vital our secondary teachers can prove effectively in this content area. The purpose of this case study, drawn from a larger project, was to understand how, if at all, pre-service teachers' proof schemes became more axiomatic throughout a one-semester inquiry-based college geometry course. Participants in this study, Alexis and Lindsey, were pre-service teachers enrolled in an inquiry based college geometry course. Although Alexis and Lindsey had differing experience with proof at the start of the course, the change to revise their proofs and discuss problems with their peers helped both students advance to more axiomatic geometric thinking.

Key words: College geometry, inquiry based learning, proof

Introduction and Motivation

Compared to other nations, the students of the United States of America are floundering in geometry. The Trends in International Mathematics and Science Study (TIMSS) evinced that twenty-one educational systems, including China, Japan, Israel, and England, have higher geometry scores than the U.S. (Mullis, Martin, Foy, & Arora, 2012). This deficiency is partly because pre- and in-service teachers possess an inadequate understanding of the structure of geometry. Despite this difficulty for students and educators, college geometry remains severely under-researched (Speer & Kung, 2016).

A possible solution to this problem is to reassess our preparation of pre-service teachers for geometry content and proof. Research suggests that instead of teaching proof in instructor-centered environments, proof courses should consist primarily of "student-student and student-teachers interactions regarding students' proof attempts" (Selden & Selden, 2008, p.19). One way this can be achieved is through implementation of inquiry-based learning (IBL) pedagogies. In an IBL environment, instruction is content- and student-centered, it is driven by students' exploration, and it is concentrated on acquisition of the material (Padraig & McLoughlin, 2009).

The research question of this study was: to what extent do students' proof schemes became more axiomatic throughout a one semester inquiry-based college geometry course? Through this study, we can determine whether or not this type of instructional environment is a potential solution to pre-service teachers' shallow understanding of proof and geometry. Mathematicians and teacher educators can then make more informed decisions on how to structure college geometry courses. We argue that the revisions present in an inquiry based classroom were vital to help students develop from a perceptual to a more axiomatic proof scheme.

Literature Review

Geometry arises from a set of undefined terms and axioms through which all other theorems and definitions are constructed. Hence, a thorough understanding of geometry involves a deep understanding of axiomatic proof; yet, pre-service teachers are not necessarily equipped with the geometry content knowledge required for teaching after merely majoring in mathematics (Jones, 1997). Furthermore, teachers possess a narrow understanding of proof. Studies indicate that pre- and in-service teachers believe proof only helps explain ideas used in mathematical concepts, and they do not recognize the ability of proof to systemize results (Mingus & Grassl, 1999; Knuth, 2002b). Pre- and in-service teachers are prone to accept pictures and other types of empirical arguments as proof (Knuth, 2002a). Also, research depicts teachers disregarding or accepting an argument as proof based on its format (Dickson, 2008).

Constructing proofs at the post-secondary level, compared to proofs at the secondary level, requires student to possess a larger knowledge base to apply in the proving process. The final products are expected to have a more complex structure as well as expected to be precise and concise (Selden, 2012). However, Jones discerned that undergraduates do not recognize "…mathematics as a field of 'intricately related structures'…" (Jones, 2000, p. 59). Hence, students fail to establish the connections between ideas required to formulate a proof. Undergraduates are also presumed to enter into a proof course with some strategic knowledge, knowledge of which proof techniques and helpful theorems, to apply in the proving process; yet, research depicts that undergraduates do not have these understandings (Weber, 2001). Therefore, undergraduate students are not entering into proof courses with the background required to confront proofs at the post-secondary level.

A multitude of proof research has devoted itself to unearthing the reasons students do not enter a post-secondary proof course with the required background knowledge. Alarmingly, students do not have an adequate understanding of what arguments qualify as mathematical proof (Weber, 2001). Harel and Sowder (1998) attribute this to the fact that teachers often present proof as an obvious proposition instead of engaging students in the process of discerning which arguments are convincing. Furthermore, students lack the important comprehension of the mathematical language and concepts necessary to construct proof. For example, students may not recognize the difference in certain terms when used in everyday vernacular and when used in a mathematical argument (Selden, 2012). Another difficulty associated with mathematical language for students is the poor comprehension of quantifiers – students misunderstand the implications and the importance of universal and existential quantifiers (Selden, 2012). Research also depicts that students possess shallow understandings of definitions and theorems (Weber, 2001; Selden, & Selden, 2008). Hence, students may misapply or misinterpret ambiguous terms, quantifiers, or the pieces of knowledge essential in constructing or validating a proof.

If educators assume students will develop proficient proof skills without any feedback, research manifests students will fail and most likely cultivate ineffective strategies (Weber, 2001). These ineffective strategies are typically proof schemes dependent upon external and empirical convictions. A proof scheme "consists of what constitutes ascertaining and persuading" for a particular person (Harel, & Sowder, 2007, p. 7). Rather than rely simply on external or empirical convictions to formulate geometry proofs, students need to be able base arguments on axioms and logical deductions. Table 1 depicts the proof schemes observed in this study as well as their definitions. Proof schemes dependent upon external and empirical justifications are the authoritarian, ritual, and perceptual proofs schemes. Proof schemes that utilize axiomatic and deductive justifications are the deductive, intuitive axiomatic, and structural axiomatic proof schemes.

Methods

The theoretical perspective used in this project was the reduced Toulmin model of argumentation. In mathematics education literature, there are two formats in which the model appears. We will distinguish them as the reduced Toulmin model (Figure 1) and the extended Toulmin model. The reduced model consists of three types of statements that represent different pieces of the argument, and the extended model consists of six statements. The three statements in the reduced Toulmin model are as follows: The data (D) is the foundation on which the argument is based. The conclusion (C) is the statement the arguer intends to convince. The warrant (W) justifies the relationship between the data and the conclusion. When students are asked to prove a claim, the conclusion is correct because it is given to the students. However, the data is typically a mixture of right and wrong. This amalgamation occurs because of the warrant the student applies – their reasoning from a piece of information to the conclusion. Although a warrant is specific to an argument, a warrant-type is a category of warrants with similar properties.

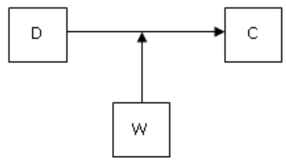

Figure 1. Reduced Toulmin model. Adopted from (Inglis, Meija-Ramos, & Simpson, 2007).

This study took place at a midsized, rural, research university in the South, and the students who participated were those enrolled in a college geometry course based upon Miller (2010) geometry course notes. The data collected was part of a larger study; this study is a case study of two students – Alexis and Lindsey. Both Alexis and Lindsey are Caucasian females whose majors were math education. Alexis was classified as a senior and had one prior proof courses and Lindsey was classified as a freshman with no prior proof experience. Students in the course were provided with course notes that presented open-ended problems related to a specific learning goal. For each new assignment, students were assigned a specific problem from the provided course notes and a group. If a group appeared to be making little progress or moving in an unproductive direction, the teacher would use guided questioning to redirect students' thoughts. If multiple groups stopped progressing, the teacher would initiate a whole class discussion.

To determine students' proof comprehension, researchers examined the assignments students turned in. Students were allowed to revise and resubmit all assignments, and these were analyzed as well. Researchers also used observations to gain further understanding of students' proof comprehension. As students discussed their ideas, a researcher sat behind them listening and taking notes on their interactions.

The submissions were analyzed by assignment, and all the drafts from an individual participant were analyzed at the same time. After this initial reading of blinded assignments, researchers would journal their impressions of the coding and the trajectory exhibited in the multiple submissions. These journals were used to operationalize the proof schemes in Harel & Sowder (1998) and Harel (2007), and to construct the standards of evidence (Table 1). Although it is not standard to give numerical values to the proof schemes, we did so in this case because of the nature of the assignments in the course. Students were always given a situation where they had to collect data and use that data to draw a picture and make a geometric conjecture before writing a proof of their findings. For a complete solution, students needed to give the data, the geometric conjecture based on their data, and a proof. As a result, we privileged axiomatic proof schemes for the proof portion of the assignment, since a student using an axiomatic proof scheme also had to use perceptual proof schemes to form their conjecture.

Table 1. Standards of Evidence (Harel, 2007; Harel & Sowder, 1998; Harel & Sowder, 2007).

Code	Definition	Standards of Evidence
Authoritarian (1)	Acceptance of an argument as proof is based mainly on if the argument is presented by an authority source.	○ Argument produced after intentional scaffolding or direct instruction from the teacher. ○ Student did not participate in the group's reasoning, and/or writing process. ○ The correct pieces of reasoning were discussed in class, and the argument does not arise from the students' data.
Ritual (2)	Acceptance of an argument as proof is based mainly on the appearance or format of the argument.	○ Student misapplies multiple axioms and theorems. ○ Argument mirrors the format of a known correct argument, but the argument does not arise from the axiomatic system. ○ Student restates the axiom or theorem as it is originally written despite the fact that the terminology does not relate to the context of the proof.
Perceptual (3)	Acceptance of an argument as proof is based on perceptions – rudimentary mental images formed without forming or considering the results of transformations.	○ Student refers to or provides only a diagram as justification for reasoning. ○ The argument is driven by students' perceptual observation of the figure he or she drew and not by the implications of axioms and theorems.
Deductive (4)	Acceptance of an argument as proof is based on validating conjectures by logical deductions.	○ The argument follows the correct deductive process, but the student does not establish the definitions, theorems, or axioms the process utilizes. ○ The argument follows the correct deductive process, but there is one instance in which the student relies on another lower warrant. ○ The argument follows the correct deductive process, but at least one clarification statement is necessary for validity. ○ The argument follows the correct deductive process, but an axiom or theorem is misinterpreted and misapplied.
Intuitive Axiomatic (5)	Acceptance of an argument as proof is based on justifying conjectures using intuitively grasped undefined terms and axioms.	○ The argument is built from undefined terms and axioms, definitions, and theorems of an axiomatic system that is intuitively grasped such as Euclidean geometry.
Structural Axiomatic (6)	Acceptance of an argument as proof is based on justifying conjectures from different realizations using an understood common structure determined by a permanent set of axioms.	○ The argument is logical and made up of systematic application of axioms and theorems. ○ If any portion of the argument could be clarified, the clarification is not necessary for the argument's validity.

Findings

After analyzing the data, we mapped Alexis' and Lindsey's warrants throughout the course. Figure 2 presents a chronological summary of their proof scheme warrants. On all assignments, except Midterm Problem 3biii, students worked on the solutions with a group during class.

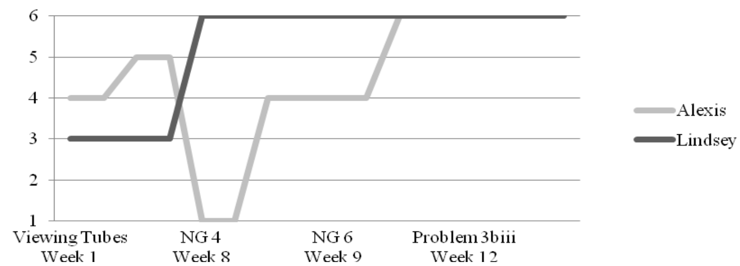

Figure 2. Proof schemes used throughout the semester

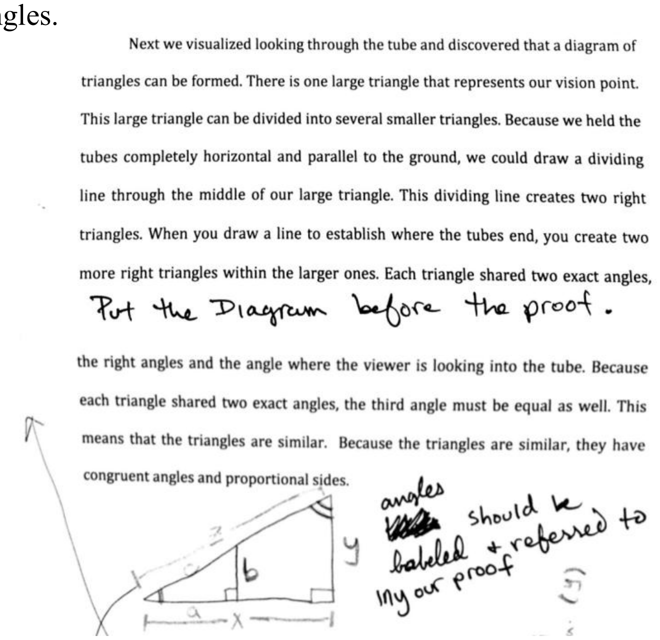
Viewing Tubes. The Viewing Tubes was the first assignment of the course and the required the only Euclidean proof. In this assignment, students were asked to determine the formula for the area of the wall that can be seen through a tube. To accomplish this, students needed to establish that the two triangles resulting from the situation are similar, and they struggled with the justification that both triangles are right triangles.

Although Alexis turned in three drafts for the Viewing Tubes assignment, her second draft addressed formatting and not argumentation issues. The proof scheme warrant in the first draft is deductive, and the proof scheme warrant in the third draft is intuitive axiomatic. Since Alexis' draft two had only formatting changes, in the following section, we will discuss Alexis' first and third drafts.

The first draft from Alexis claims each triangle has a right angle, and her data is the explanation of the actions she took in constructing the situation. Alexis' warrant is the deductive proof scheme because she follows the correct deductive process, but she lacks the important clarification that her actions produce perpendicular lines which establishes right angles.



Next we visualized looking through the tube and discovered that a diagram of triangles can be formed. There is one large triangle that represents our vision point. This large triangle can be divided into several smaller triangles. Because we held the tubes completely horizontal and parallel to the ground, we could draw a dividing line through the middle of our large triangle. This dividing line creates two right triangles. When you draw a line to establish where the tubes end, you create two more right triangles within the larger ones. Each triangle shared two exact angles,

Put the Diagram before the proof.

the right angles and the angle where the viewer is looking into the tube. Because each triangle shared two exact angles, the third angle must be equal as well. This means that the triangles are similar. Because the triangles are similar, they have congruent angles and proportional sides.

Figure 3. Alexis Viewing Tubes Draft 1

Alexis' third draft employs the same data and claim from draft one. However, her warrant is the intuitive axiomatic proof scheme because in draft three Alexis clarifies that the lines formed through her actions are indeed perpendicular lines. With this correction, she produced a valid argument based of Euclidean definitions and theorems, and it was achieved prior to the scaffoled class discussion.

Because we held the tubes completely horizontal and parallel to the ground, we could draw a dividing line through the middle of our large triangle (AE). This dividing line creates two right triangles. When you draw a line to establish where the tubes end, it is perpendicular to the tubes' midline and you create two more right triangles within the larger ones

Figure 4. Alexis Viewing Tubes Draft 3

In the Viewing Tubes assignment, Alexis was able to map the correct deductive process for justifying the claim and her warrant was the deductive proof scheme. Receiving feedback allowed her to reassess and amend her argument to include an important clarification, and ultimately, Alexis was able to reason at the intuitive axiomatic level.

While Lindsey drafted three different versions of the Viewing Tubes assignment and alterations were made between each of the drafts, the argument portion of the paper remained unchanged. The proof scheme warrant used in this argument is perceptual. Lindsey claims that each triangle is a right triangle, and her data is her diagram. In her justification, Lindesy provides the diagram in Figure 4 and states, "On the triangle, angle BAC and angle DAE were the same angle. Angles ACB and AED were both right triangles. This made the last angles ABC and ADE the same…" To convince herself that the triangles are right triangles, she relies only on her observations. Each of her revisions presented this same argument even after a scaffoled class discussion. Hence, Lindsey never grasped that her argument lacked the necessary reasoning to determine the truth of her claim.

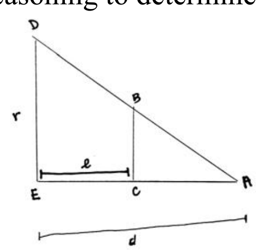


Figure 5. Lindsey Viewing Tubes Draft 1

Neutral Geometry Worksheet 4 (NG 4). NG 4 was assigned after students completed their revisions of the Viewing Tubes assignment. Using the NG axiom system (Figure 6) students were asked to prove each point belongs to at least two different lines. This proof requires the consideration of multiple scenarios in different spaces that arise from application of the axioms, and students struggled to foresee the axiom system in a non-Euclidean context.

"Point" and line are undefined. Lines will consist of points.
Axiom 1. If L is a line, then there exists at least two points belonging to L.
Axiom 2. If L is a line, then there exists at least one point not on L.
Axiom 3. There exists at least one line.
Axiom 4. If A & B are distinct points, then there is at least one line containing both A & B.
Theorem 1. There exists at least three different points.
Theorem 2. If P is a point, there is a line containing P.
Theorem 3. If P is a point, then there exists two different lines containing P.
Axiom 4'. If A & B are different points, then there exists one and only one line which contains both A & B.

Figure 6. Neutral Geometry Axiom System and Theorems Proven in the Course

Alexis' warrants for the Viewing Tubes assignment was deductive on draft one and intuitive axiomatic on draft three. For the NG 4 assignment, Alexis turned in four drafts, and her proof scheme warrant starting this assignment is authoritarian. Her second draft consists primarily of formatting changes, but her third draft utilizes the deductive. Alexis' fourth draft contained only formatting changes, so in the following section, we will discuss her first and third drafts.

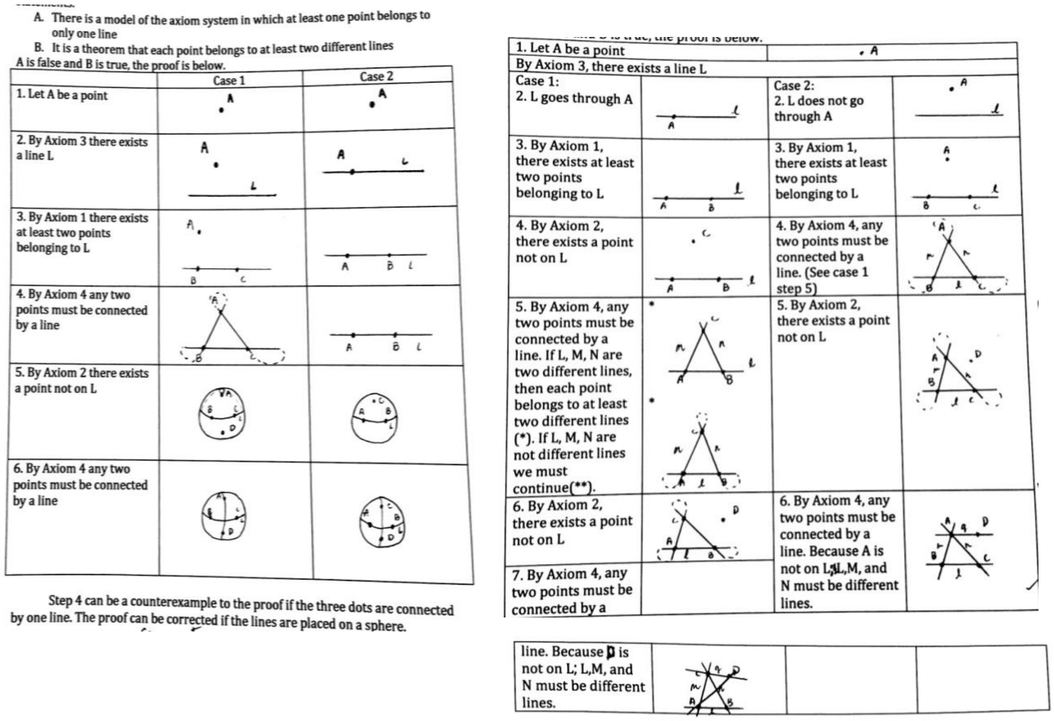

Figure 7. Alexis NG 4 Draft 1 (left) and Draft 2 (right).

The first draft provided by Alexis claims that each point belongs to at least two distinct lines, and her data is her written portion of the argument. When students worked on this assignment during class, Alexis was absent, so she received notes from her group members. Her first draft portrays some correct pieces of reasoning such as her consideration of two cases and the sphere; however, these correct ideas are not applied appropriately. For example, Alexis states that step 4 could be a counterexample to a proof, so it is apparent she does not understand the implications of what she is trying to argue. Hence, her warrant is the authoritarian proof scheme because although there are correct portions, they are not formed from her data.

On her third draft, Alexis' claim remains the same, and she clarifies and completes her data. Unlike her previous drafts, the warrant for this argument is the deductive proof scheme. She follows a generally correct deductive process and considers situations that could arise on different surfaces. However, Alexis forgets the truths established by her applications of the axioms such as in step 5 of case 1. In this step, she connects a point using line L, but that point was established to not be on line L. This misuse of the axiomatic system detains her from reaching the structural axiomatic proof scheme, but her consideration of the generality of the axioms places her warrant at deductive.

Lindsey's proof scheme warrant for all of her Viewing Tubes drafts was the perceptual proof scheme. On the NG 4 assignment, Lindsey was partnered with Martin and she turned in two drafts of this assignment. The proof scheme warrant used in both drafts is structural axiomatic. Lindsey's second draft consisted only of formatting alterations, so in the following section, we will discuss the first draft submitted by Lindsey.

For her first draft, Lindsey's data is the written argument she provides for both cases. Her claim is that each point belongs to at least two distinct lines,

Assumption: Let there be a point, A.	
By Axiom 3, there exists at least one line, L.	
CASE 1: If the point A lies on Line L, then at least point is not on L, point B, by Axiom 2.	CASE 2: If point A does not line on Line L, then by Axiom 1, at least two points, points B and C belong to Line L.
Since points A and B are two different points, then by Axiom 4, another line, Line M contains points A and B.	By Axiom 4, since A and B are two different points, there exists a line containing both A and B, line M.
Because B does not lie on L, line L and line M are two different lines. Therefore, point A belongs to two different lines, Line L and Line M.	By Axiom 2, there exists another point not on Line M, point D.
CASE 2: If point A does not line on Line L, then by Axiom 1, at least two points, points B and C belong to Line L.	Since Point A and Point D are two different points, then by Axiom 4, there exists a line containing points A and D.
By Axiom 4, since A and B are two different points, there exists a line containing both A and B, line M.	By Axiom 2, there exists another point not on Line M, point D.	Because points A and D are two different points, and point D does not belong to line M or Line L, then Line M, N, and L are different lines. Therefore, point A belongs to 2 different lines. Line N and Line M.

Figure 8. Lindsey NG 4 Draft 1

and her warrant is the structural axiomatic proof scheme. Although Lindsey needs to clarify why she continued her argument after establishing line M, the validity of her argument is not hindered by the lack of this statement. Lindsey also considers the generality of the axioms, and she applies the axioms to form a deductive argument.

While her arguments on Viewing Tubes employed only the perceptual proof scheme as a warrant, Lindsey moves past this type of reasoning in this assignment. Between these assignments, students explored other arguments and the Neutral Geometry Axiomatic System. Lindsey was able to garner a better understanding of the arguments that constitute as proof. She then applied this knowledge on the NG 4 worksheet, and her warrant on this assignment was the structural axiomatic proof schemes.

Neutral Geometry Worksheet Problem 6 (NG 6). The NG 6 assignment took place after students had completed at least their first NG 4 drafts. This assignment asked students to prove there exists a line not containing a given point on the NG Axiom System; however, for this problem, axiom 4 is replaced with axiom 4' which establishes the uniqueness of a line containing two points.

Alexis' warrants for the NG 4 assignment started as the authoritarian proof scheme, and through revisions, her warrants became the deductive proof scheme. For the NG 6 assignment, Alexis was partnered with Jeremy, and she turned in two drafts. The proof scheme for the first draft is deductive, and the proof scheme warrant for the second draft is structural axiomatic.

Alexis claims on her first draft that for a given point, there exists a line not containing that point, and her data is the written argumentation she provides. Her warrant is the deductive proof scheme because she applies axioms and theorems to develop a correct deductive process; however, there is a portion of her argument that lacks clarity. Although she states that the line constructed by axiom 4' "cannot curve to connect non-collinear points," she needs to clarify why such a line would violate axiom 4'.

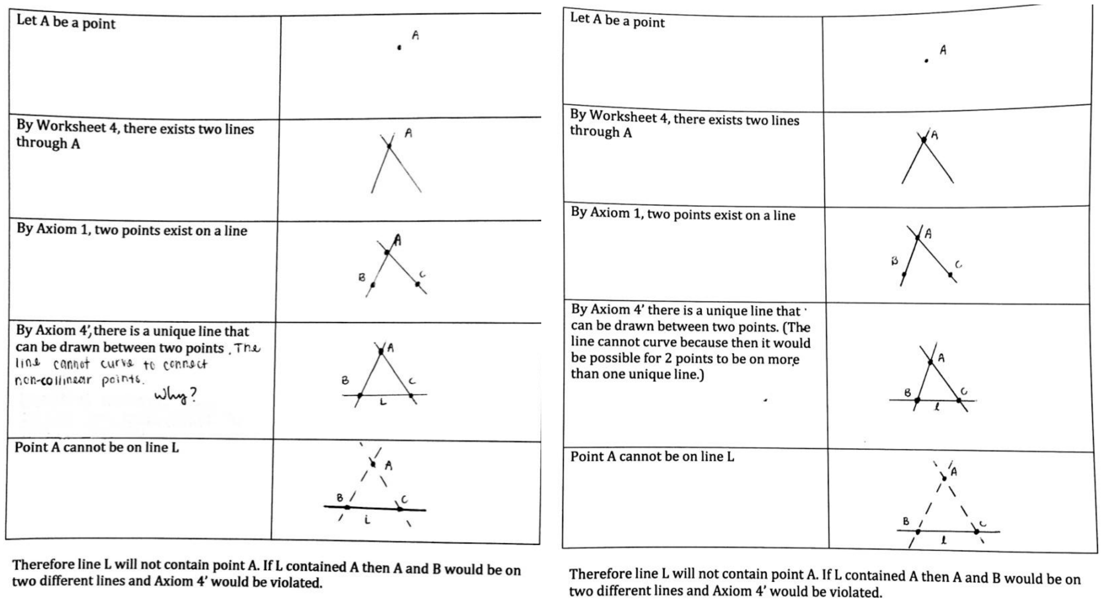

Figure 9. Alexis NG 6 Draft 1 (left) and Draft 2 (right).

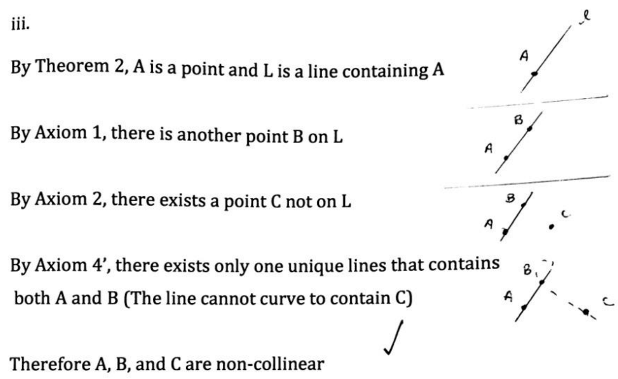
The second draft turned in by Alexis has the same data and claim as her draft. On this draft, however, she clarifies the contradiction with axiom 4' that would occur if point A was on line L. Following this amendment, her warrant becomes the structural axiomatic proof scheme. After spending some time relying on the reasoning of others and processing the information, Alexis progressed her reasoning to the deductive proof scheme. She continued to improve her reasoning as she spent more time working in the Neutral Geometry Axiom System. On the NG 6 assignment, the warrant started at the deductive proof scheme and progressed to the structural axiomatic proof scheme.

Although her warrant for her first assignment was perceptual, once Lindsey started working in the Neutral Geometry Axiom System, her proof scheme warrant became the structural axiomatic proof scheme. For the NG 6 assignment, Lindsey turned in two drafts, and her first draft is comparable to the second draft produced by Alexis. The data for Lindsey's first draft is her written argumentation, and the claim is that there exists a line not containing a given point. Lindsey crafts a correct, deductive argument based on the axioms. While her explanation for why line M does not contain point A could be clearer, the first wording she produces does not hinder the understanding or validity of her argument. Her warrant for this draft is then the structural axiomatic proof scheme.

Midterm Problem 3biii (Problem 3biii). This assignment took place during week 12 of 15. Students were asked to prove, using the NG axiom system including axiom 4', that for any given point there exist two other distinct points such that the collection of points is non-collinear. While all other assignments were allotted class time and students worked in groups, on the Midterm, students worked individually outside of class.

Alexis' data for Problem 3biii is her written argumentation, and she claims that for a given point there exist two other different points such that the points are non-collinear. In this argument, her warrant is the structural axiomatic proof scheme. Alexis produces a clear argument formed from logically applies theorems and axioms.



iii.

By Theorem 2, A is a point and L is a line containing A

By Axiom 1, there is another point B on L

By Axiom 2, there exists a point C not on L

By Axiom 4', there exists only one unique lines that contains both A and B (The line cannot curve to contain C)

Therefore A, B, and C are non-collinear

Figure 10. Alexis Problem 3biii Draft 1

On the NG 6 assignment, the warrant for Alexis' first draft was the deductive proof scheme, and the warrant for her second draft was the structural axiomatic proof scheme. Continuing to work in the Neutral Geometry Axiom System, Alexis maintained a warrant of the structural axiomatic proof scheme in Problem 3biii.

Like Alexis, Lindsey produced a correct deductive argument based on the axioms for the Neutral Geometry Axiom System. Hence, her warrant for this argument is the structural axiomatic proof scheme. The warrant Lindsey used on the NG 6 assignment was the structural axiomatic proof scheme. Working independently of her group, Lindsey was able to maintain her reasoning at the structural axiomatic proof scheme on Problem 3biii.

Discussion

The purpose of this study was to determine to what extent students' geometry proof schemes became more axiomatic throughout a one-semester college geometry course. By assigning each of the proof schemes a number rank based on the level of axiomatic reasoning utilized and creating time series graphs to analyze the changes in students' proof schemes through the course, we discerned three proof scheme trajectories: the static participant, the peripheral participant, and the central participant. These proof scheme trajectories emerged as a reaction to the revision component of the IBL course design (Figure 11). The revision component forced students to reanalyze and revise their reasoning. Static participants resisted this revision process; peripheral participants withdrew from group participation but used this time to process ideas; and central participants invested more time analyzing ideas within their groups.

Regardless of prior proof experience all but one student in this study started with a perceptual proof scheme. This suggests that students may have had initial trouble linking prior formal proof training to a more familiar content area. After receiving extensive feedback on their initial attempts of the viewing tubes lab, participants had three different responses to the need to revise their work, two of which were successful.

The static participants were Jeremy and Kayla, and they relied on prior ideas such as their perceptions or beliefs about what a proof should look like to form their reasoning. Jeremy and Kayla struggled with beliefs many pre- and in-service possess such as an inclination to accept perceptual arguments as proof, and the belief that the validity of an argument depends on its formatting (Knuth, 2002a; Goetting, 1995; Dickerson, 2008). However, since they were reluctant to reassess these prior beliefs, their proof reasoning improved minimally.

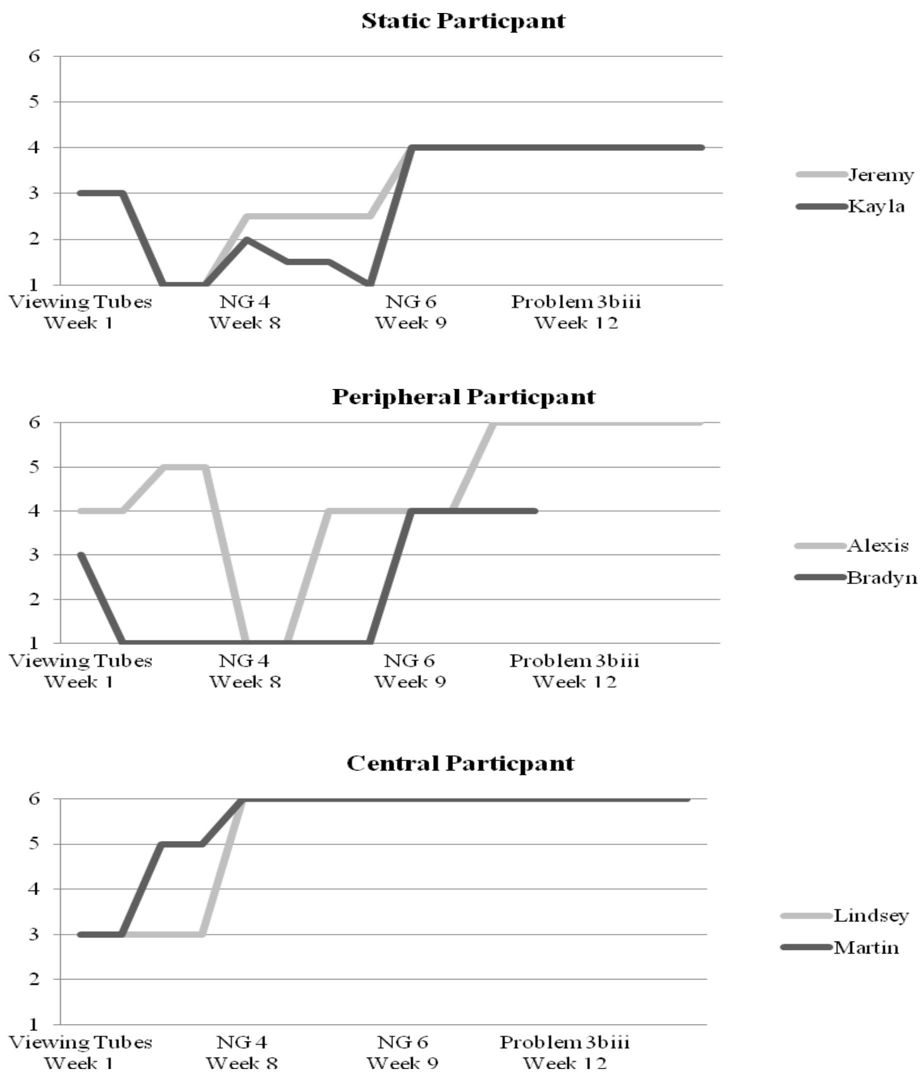


Figure 11. Proof Scheme Trajectories

Alexis and Bradyn were the peripheral participants, and their response to revising arguments that were outside a familiar context was to become seemingly passive group members. This passivity occurred when these students had limited knowledge of the content and context they were asked to prove in because teachers exhibit difficulty in proof when they lack content knowledge (Ko, 2010). On the Viewing Tubes assignment, Alexis had a strong understanding of the content within the Euclidean context and was able to exhibit axiomatic reasoning. When the proofs left the Euclidean context and moved into unfamiliar content in NG 4, Alexis' reasoning relied solely on others and she employed the authoritarian proof scheme. Bradyn did not possess a strong understanding of the content in Viewing Tubes, so this move to the authoritarian proof scheme occurred earlier in the semester for him. Since Bradyn did not have a thorough understanding of the Euclidean content before moving into other contexts, he utilized the authoritarian proof scheme longer than Alexis. Observing this period where Alexis and Bradyn relied on the authoritarian proof scheme, they appeared to play the role of a spokesman paraphrasing the ideas of others (Krummheuer, 2010). However, the data analysis revealed that these students were successful after watching their peers. This indicates that they were actually partaking in what research refers to as legitimate peripheral participation (Krummheuer, 2010). Hence, peripheral participation proved to be a successful reaction to revision for improving proof reasoning.

The central participants, Lindsey and Martin initially encountered difficulties experienced by Jeremy, Kayla, and other teachers – the willingness to accept empirical arguments in the form of diagrams as proof (Knuth, 2002a; Goetting, 1995). This is apparent in both students initial use of the perceptual proof scheme in Viewing Tubes. However, instead of clinging to their prior beliefs, Lindsey and Martin responded to the need for revisions by investing more time discussing ideas and the questions posed by the instructor within their groups. By NG 4, both students were employing the structural axiomatic proof scheme. Unlike Jeremy and Kayla who resisted the IBL course design, Lindsey and Martin fully embraced it. They essentially took full advantage of the availability of student-student and student-teacher interactions built into the course design. These are the interactions literature suggests would be successful for inducing logic and proof techniques in students (Selden & Selden, 2008; Harel & Sowder, 1998). Since they centered their time on investigating and critiquing one another's ideas, their proof reasoning improved quickly. It should, however, be noted that Lindsey and Martin were also quite talented as students.

These proof scheme trajectories were not a phenomenon of group structure or proof training. Groups typically contained the following pairs: Kayla and Bradyn, Jeremy and Alexis, and Lindsey and Martin. Although the central participants were paired together for the majority of the assignments, the static and peripheral participants were seldom in the same group. The trajectories exhibited by the static and peripheral participants occurred across the groups. Furthermore, these proof scheme trajectories were not a result of proof training. Kayla was the most experienced with proofs and started the class having completed two proof courses; however, Kayla struggled to utilize deductive reasoning to formulate her arguments. Particularly, Kayla was hindered by the belief that a valid proof had to adhere to a particular format. This is an idea that was perhaps even cultivated by her prior proof training. Lindsey, conversely, had no prior proof training, and she rapidly moved into the structural axiomatic proof scheme. Hence, these proof scheme trajectories that emerged were neither a result of the group structure nor a product of proof experience.

The success exhibited by the peripheral participants following their passivity was unexpected. Since these students relied solely on the authoritarian proof scheme for a time, it did not appear they were developing their own logical and deductive reasoning. Yet, their sudden improvement in proof reasoning demonstrates that they were actually partaking in what literature refers to as peripheral participation (Krummheuer, 2010).

Although completing other direct instruction proof courses was not sufficient for pre-service teacher to be adept at geometry proof, the findings of this study indicate that developing a proof course consisting primarily of student-student and student-teacher interactions helped all students improve their geometry proofs. This course design was achieved through an inquiry-based learning environment, and the revision component of the course was pivotal. The way students chose to revise and reanalyzed their arguments in these forced revisions is what formed the three proof scheme trajectories and informed students' successes. In analyzing the proofs formed in an IBL course such as a modified Moore method course, it is imperative to gather both observation data and the documents students produce. Since the proof scheme trajectories were informed by students' reactions to the revisions, it is essential to observe how students participate in their groups as well as the actual arguments they produce.

Limitations to this study arise from the fact that there were a small number of students enrolled in the course. Due to the limited number of participants, there was little ethnic and first language diversity as well as minimal diversity in prior proof experience. There may also be other proof scheme trajectories that were not observed in the small sample of students.

While teachers and students have long struggled with geometry and proof, geometry is under-researched in mathematics education (Speer & Kung, 2016). However, this study provides insight into how to structure a course aimed at instructing geometry and proof. Findings depict the impact of an IBL geometry course on the proof schemes utilized by students as they form geometry proofs. As the revision element of the course design proved to be an integral component due to students' reactions, this study also portrays some reactions students could exhibit and their successfulness.

In future studies, we suggest copying students' drafts as they are turned in throughout the course. We had students assemble a portfolio that we made a copy of at the end of the semester. However, some students did not turn in a complete portfolio and this diminished the amount of usable data. Copying drafts as students complete them would also reduce confusion about what was on the draft when it was turned in versus what may have been a note that the student added at a later time.

There are several ways that the results of this study may be extended in further inquiry. Since it was observed that completing direct instruction proof courses did not translate to successful proof reasoning in this study, further research should follow these students through their next proof course to determine the usefulness of this type of course design. The standards of evidence table developed in this study could also be used to analyze the proof scheme trajectories of students in other courses differing in structure and content. Applying this type of analysis to other courses could identify other possible proof scheme trajectories as well. Furthermore, due to the rapid transition to the structural axiomatic proof scheme for the student with no prior proof experience, Lindsey, this type of course design should be applied to an introductory or transition to proof course that follows the participants through following proof courses.

Developing Student Understanding: The Case of Proof by Contradiction

Darryl Chamberlain Jr.
Georgia State University

Draga Vidakovic
Georgia State University

Proof is central to the curriculum for undergraduate mathematics majors. Despite transition-to-proof courses designed to facilitate the transition from computation-based mathematics to proof-based mathematics, students continue to struggle with all aspects of mathematical proof. In particular, research suggests that proof by contradiction is an especially difficult proof method for students to construct and comprehend and yet, there are no satisfactory instructional models for how to teach the method. The purpose of this paper is to discuss preliminary results of a teaching experiment on student comprehension of proof by contradiction within a transition-to-proof course. Grounded in APOS Theory, this paper will illustrate that a student's conception of mathematical logic, and quantification in particular, plays an important role in their comprehension of proof by contradiction.

Keywords: Proof by Contradiction, Teaching Experiment, Transition-to-proof course

Proof is central to the curriculum for undergraduate mathematics majors. Indeed, the *2015 CUPM Curriculum Guide to Majors in the Mathematical Sciences* contains the following recommendation: "Students majoring in the mathematical sciences should learn to read, understand, analyze, and produce proofs at increasing depth as they progress through a major" (Schumacher & Siegel, 2015, p. 11). Despite transition-to-proof courses designed to facilitate the transition from computation-based mathematics to proof-based mathematics, students continue to struggle with all aspects of mathematical proof (Samkoff & Weber, 2015). In particular, research suggests that proof by contradiction is an especially difficult proof method for students to understand and produce (Antonini & Mariotti, 2008; Brown, 2011; Harel & Sowder, 1998). In order to address students' understanding of proof by contradiction, we examined the literature for what proof by contradiction means and what is known about how students develop an understanding of proof by contradiction. A short summary to these questions is provided below.

Proof by contradiction is based on the *law of the excluded middle*: either a statement is true or the negation of the statement is true. By showing the negation of the statement cannot be true (i.e., leads to a contradiction), the statement must be true. However, some scholars do not attribute the law of the excluded middle as the foundation of proof by contradiction. Indeed, Lin, Lee, and Wu Yu (2003) state that "the conceptual knowledge of proof by contradiction is the law of contrapositive" (p. 4-446). Other scholars do not always distinguish between proof by contradiction and proof by contraposition when describing how students understand indirect proofs. For example, Antonini and Mariotti (2008) state that the commonality of negating the thesis in both methods is enough to consider cognitive aspects of students' difficulties with both methods simultaneously. We consider the two indirect proof methods as having distinct underlying concepts: logical equivalence of an implication and its contrapositive (Contraposition) and the law of the excluded middle (Contradiction). These distinct underlying concepts require cognitive models to consider how students develop an understanding of each method separately.

The only current cognitive models of how students understand proof by contradiction have been proposed by Lin, Lee, and Wu Yu (2003) and Antonini and Mariotti (2008). Yet, neither of these cognitive models are satisfactory as they do not focus on how students develop an understanding of how the law of the excluded middle validates the contradiction proof method. Our larger study aims to address this deficiency in the literature by first modeling how students could come to understand proof by contradiction and then, using this model, develop instructional materials to teach proof by contradiction. The purpose of this paper is to discuss preliminary results on a part of this larger study; that is, to discuss preliminary results of a teaching experiment on a single student's understanding of proof by contradiction. In particular, this paper will address the following question: How does a student's conception of mathematical logic affect their understanding of proof by contradiction? What follows is a detailed discussion of the theoretical framework we will use to answer this question.

Theoretical Framework

Our theoretical framework of choice is APOS Theory – a cognitive framework that considers mathematical concepts to be composed of mental Actions, Processes, and Objects that are organized into Schemas. What follows are definitions of the mental constructions, along with examples within the context of proof by contradiction.

An *Action* is a transformation of mathematical objects by the individual requiring memorized or external step-by-step instructions on how to perform the operation. In the context of proof by contradiction, this may entail a list of steps (either written down or memorized) that a proof by contradiction of an implication statement follows. As an individual reflects on an Action, he/she can think of these Actions in his/her head without the need to actually perform them based on some memorized facts or external guide; this is referred to as a *Process*. Staying within the context of proof by contradiction, a student may interiorize the external list of steps that a particular type of proof by contradiction follows so that these steps become generalized to prove any statement by contradiction. In this way, the student would not need to write the proof in order to talk about what a step may look like in a specific proof. As an individual reflects on a Process, they may think of the Process as a totality and can now perform transformations on the Process; this totality is referred to as an *Object*. Again in the context of proof by contradiction, this could entail comparing proof by contradiction to similar methods such as proof by cases. Finally, a *Schema* is an individual's collection of Actions, Processes, Objects, and other Schemas that are linked by some general principles to form a coherent framework in the individual's mind (Dubinsky & McDonald, 2001). In the case of proof by contradiction, this may include an individual's general proof Schema, mathematical knowledge Schema, and mathematical logic Schema, as well as any steps (external and specific or internal and general) required to write or identify a proof by contradiction.

One of the central goals when using APOS Theory is to develop a series of hypothetical constructions students may need to make in order to understand a concept, referred to as a *genetic decomposition*. This cognitive outline is constructed based on an analysis of the historical development of the concept in question, a literature review of the concept, and the conception of the instructor or researcher. In addition to outlining the mental constructions a student should make in order to understand a concept, a genetic decomposition may include a description of prerequisite knowledge a student should possess in order to begin developing a concept (Arnon et al., 2014). A description of the prerequisite knowledge for proof by contradiction follows.

First, a student should have a general understanding of the propositional logic that underscores all proofs. In particular, a student should be able to perform and understand negations of the following types of statements: without quantification, implications, and single-level quantified statements. This is necessary as every proof by contradiction requires a negation of some statement. In addition to understanding the mathematical logic, a student should be able to move between semantic, symbolic, and algebraic representations of mathematical statements. For example, a student should be able to represent the statement 'If a is even, then $a + 1$ is odd' as the symbolic implication '$P \rightarrow Q$' as well as the algebraic representation 'If $a = 2n$ for $n \in \mathbb{Z}$, then $a + 1 = 2m + 1$ for $m \in \mathbb{Z}$'. Moving between representations of mathematical statements is necessary in any mathematical proof and thus is necessary before developing a notion of proof by contradiction. Finally, a student should be familiar with the direct proof method in a mathematical context as this is the basis of understanding any proof.

With this prerequisite knowledge in mind, we developed a preliminary genetic decomposition. We should be clear that a genetic decomposition need not be unique and so the genetic decomposition below may be one of several different ways in which students may develop an understanding of proof by contradiction.

Preliminary Genetic Decomposition for Proof by Contradiction

1. Students outline the propositional logic of a given proof to develop specific, step-by-step instructions to construct proofs by contradiction for the following types of statements: (i) implication, (ii) single-level quantification, and (iii) property claim.
2. Students interiorize each of the Actions in Step 1 into individual Processes by examining the purpose of statements of given proofs. These Processes become general steps to writing a proof by contradiction for statements of the form (i), (ii), and (iii).
3. Students coordinate the Processes from Step 2 by comparing and contrasting the general steps to determine the necessary steps for *any* proof by contradiction. This Process becomes general steps to writing any proof by contradiction and identifying a proof as a proof by contradiction.
4. Students encapsulate the Process in Step 3 as an Object by utilizing the law of excluded middles to show proof by contradiction is a valid proof method. Alternatively, students encapsulate the Process in Step 3 as an Object by comparing proof by contradiction to other, similar proof methods. Students can now comprehend proofs on a holistic level.
5. When necessary, students de-encapsulate the Object in Step 5 into a Process similar to Step 3 that then coordinates with a Process conception of quantification to prove multi-level quantified statements.

First, note that students' initial conception of proof by contradiction is through the specific steps to construct a proof by contradiction. That is, students think that each of these steps are necessary for a proof to be by contradiction. Students may also need the external cues from specific steps, such as seeing the word "contradiction" near the end of the proof. Students then reflect on these specific steps to considering the general procedure of proof by contradiction. Still, students conceptualize a proof by contradiction as a dynamic procedure that must be followed and thus their conception closely matches the steps to writing a proof by contradiction. It is only after encapsulating the dynamic procedure as a static proof method, by comparing the main idea of the method to similar methods, that students do not rely on the steps of a proof by contradiction to describe the method.

Once developed, a genetic decomposition is used as a guide to develop all instructional material. One pedagogical approach aligned with APOS Theory is the ACE teaching cycle; an instructional approach that consists of three phases: Activities, Classroom discussion, and Exercises. In the *Activities* phase, students work in groups to complete tasks designed to promote reflective abstraction. These tasks should assist students in making the mental constructions suggested by a genetic decomposition. In the *Classroom discussion* phase, the instructor leads a discussion about the mathematical concepts that the Activities focused on. For example, during this phase the instructor may formally state the theorem that was central in the Action phase and together with students write its complete proof. In the *Exercises* phase, students work on standard problems designed to reinforce the Classroom discussion and support the continued development of the mental constructions suggested by the genetic decomposition. The Exercises also provide students with the opportunity to reinforce and apply what they have learned in the Activities and Classroom discussion phases to related mathematical concepts (Arnon et al., 2014). We utilized the proof comprehension assessment model by Mejía-Ramos et al. (2012) to develop standard proof comprehension questions for the Exercises. As this assessment model was pivotal in the development of instructional materials, we will briefly introduce it below.

Mejía-Ramos et al. (2012) presented a multidimensional model for assessing proof comprehension in undergraduate mathematics. This model contains seven different aspects of proof split into two categories: local and holistic. *Local* types of assessment focus on only one, or a small number, of statements within a proof, whereas *holistic* types of assessment focus on student understanding of a proof as a whole. These seven types of assessment are reproduced below:

1. *Meaning of terms and statements:* items of this type measure students understanding of key terms and statements in the proof;
2. *Logical status of statements and proof framework:* these questions assess students' knowledge of the logical status of statements in the proof and the logical relationship between these statements and the statement being proven;
3. *Justification of claims:* these items address students' comprehension of how each assertion in the proof follows from previous statements in the proof and other proven or assumed statements;
4. *Summarizing via high-level ideas:* these items measure students' grasp of the main idea of the proof and its overarching approach;
5. *Identifying the modular structure:* items of this types address students' comprehension of the proof in terms of its main components/modules and the logical relationship between them;
6. *Identifying the general ideas or methods in another context:* these questions assess students' ability to adapt the ideas and procedures of the proof to solve other proving tasks;
7. *Illustrating with examples:* items of this type measure students' understanding of the proof in terms of its relationship to specific examples. (Mejía-Ramos et al., 2012, p. 15-16).

These assessment questions revolve around the reading and understanding of a presented proof. While the authors caution that all types of assessment questions may not be appropriate for some presented proofs, such as if the proof was too short to warrant breaking into modules, we choose proofs such that each type of assessment question could be applied.

In summary, we used APOS Theory to develop a hypothetical model (genetic decomposition) of possible mental constructions students may need to make in order to develop an understanding of proof by contradiction. We then introduced the ACE teaching cycle, an instructional method closely aligned with APOS Theory, which we used to develop lessons on proof by contradiction. We used the proof comprehension assessment model by Mejía-Ramos et al. (2012) to develop the routine exercise questions for the Exercise phase of the ACE teaching cycle. The methodology section will provide a detailed explanation of the lessons on proof by contradiction as well as provide the context of the study.

Methodology

In order to assess our preliminary genetic decomposition for proof by contradiction, we conducted a teaching experiment (Steffe & Thompson, 2000). Unlike a typical instructional sequence of the ACE teaching cycle that, in a regular classroom, usually lasts for a week, this teaching experiment consisted of 5 shorter, consecutive teaching sessions each mimicking the ACE teaching cycle. That is, each session consisted of: students working on the Activity worksheet focusing on a particular component of the genetic decomposition for proof by contradiction (A); a discussion about the concepts from the worksheet (C); and a typical series of proof comprehension questions related to the content of the worksheet (E).

Our teaching experiment was conducted at a large, public R1 university in the southeastern United States with students from a transition-to-proof course. This course, *Bridge to Higher Mathematics*, is the first course in which students at this university are formally introduced to mathematical proofs and their accompanying methods of proof. *Bridge to Higher Mathematics* has the following general learning outcomes:

- Basic Logic (e.g. truth tables, negation, quantification),
- Proof Methods (e.g., direct, contradiction, induction),
- Introductory Set Theory (e.g., union, intersection, power set, cardinality), and
- Introductory Analysis (e.g., least upper bound and greatest lower bound, open/closed sets, limit points).

We began with teaching episodes two weeks into the course, just after a review of basic logic and an introduction to direct proofs. *Bridge to Higher Mathematics* is a primarily lecture-based course where proof and proof methods are taught primarily through proof construction (i.e., asking students to replicate proofs). Thus, in both teaching style and assessment, the designed teaching experiment deviated from the regular classroom. However, the teaching episodes did correspond to the content and proofs that were normally covered in the course.

Data for this report was collected during Summer 2016 from teaching episodes with Chandler. Chandler was an untraditional student: he had already graduated once with a bachelor degree (in an unspecified topic) and was unsure as to whether or not he wanted to complete a bachelor's degree in mathematics. As a senior, Chandler had already taken courses beyond the prerequisites for *Bridge to Higher Mathematics,* including *Differential Equations, Probability Theory*, and *Vector Calculus*. However, none of these additional mathematics courses required proof writing and thus *Bridge to Higher Mathematics* was still Chandler's first experience learning how to read and write formal proofs. While Chandler initially consented to completing all five teaching episodes, he dropped the course before mid-semester. As such, Chandler only completed the first three teaching episodes.

We choose to focus on Chandler for this preliminary report for two primary reasons. First and foremost, Chandler's progression of understanding proof by contradiction is similar to the majority of other participants and thus can be considered representative of a general participant's understanding. In addition, Chandler was open to communicating, answering, and asking questions without any reservation. This provided us with rich data on his thought process. The next section will describe how we analyzed Chandler's thought process through the three teaching episodes he completed.

Data Analysis

All three teaching sessions were video recorded and then transcribed by the teacher/researcher. Transcripts of these three sessions went through multiple passes of analysis. First, we identified Chandler's conception of proof by contradiction, according to APOS Theory, for each teaching episode. Next, we identified Chandler's local and holistic understanding of proof by contradiction and proof in general, according to the proof comprehension assessment model by Mejia Ramos et al. (2012), during each teaching episode. We then open coded for other themes that affected Chandler's understanding of proof by contradiction, during which quantification emerged. Finally, we examined quantification's role in Chandler's understanding per teaching episode. What follows are the results from this analysis.

Results

For each episode, we will first present the statement and proof Chandler was asked to read as well as provide the comprehension questions he was then asked to complete. Afterwards, we will provide some of Chandler's responses that best illustrate his understanding of proof by contradiction in general and his understanding of the presented proof. When applicable, we will include a discussion of how mathematical logic, and quantification in particular, affected Chandler's proof comprehension.

Pre-Teaching Episodes

Before the first teaching episode, we asked Chandler a few basic questions to ascertain his background with mathematical proof. In particular, we were focused on determining whether Chandler possessed the following prerequisite knowledge necessary to begin developing a conception of proof by contradiction: mathematical logic (especially negating statements), how to transition between representations, and proof in general. Chandler exhibited at least an Action conception of mathematical logic as he was able to describe rules to use in order to negate propositional statements. Chandler was also able to answer questions that required him to transition between mathematical statements, their propositional representations, and their algebraic representations. Finally, with respect to his understanding of proof in general, Chandler gave the following definition:

An effort to show something is true or false based on real evidence and facts.

We see his definition as a dynamic procedure, i.e. an effort to show something, and so infer Chandler possesses a Process conception of proof. Based on his responses, we believe Chandler had the prerequisite knowledge to begin developing a conception of proof by contradiction.

We also wanted to know what conception, if any, Chandler had of proof by contradiction before the first teaching episode. When asked for a definition of proof by contradiction, he stated:

Demonstrating the opposite of a statement is false, so the statement is true.

Note there is no mention of an assumption or contradiction in terms of "demonstrating the opposite of a statement is false" and thus this is not a complete definition of proof by contradiction. At most, this is a definition for a general type of indirect proof that utilizes the tautological equivalence of a double-negated statement and the statement itself. We therefore do not believe Chandler has a conception of a mathematical proof by contradiction.

Teaching Episode 1

Teaching episode 1 began with Chandler converting a series of statements into propositional and predicate logic on his own. After checking his answers to these conversions, it was clear that Chandler was able to convert mathematical statements with a single quantifier into a logical form. Chandler was then asked to read the following statement and proof.

Statement 1: The set of primes is infinite.
Proof 1: Suppose the set of primes is finite. Let $p_1, p_2, p_3, \ldots, p_k$ be all those primes with $p_1 < p_2 < p_3 < \cdots < p_k$. Let n be one more than the product of all of them. That is, $n = (p_1 p_2 p_3 \ldots p_k) + 1$. Then n is a natural number greater than 1, so n has a prime divisor q. Since q is prime, $q > 1$. Since q is prime and $p_1, p_2, p_3, \ldots, p_k$ are all of the primes, q is one of the p_i in the list. Thus, q divides the product $p_1 \cdot p_2 \cdot p_3 \cdot \ldots \cdot p_k$. Since q divides n, q divides the difference $n - (p_1 \cdot p_2 \cdot p_3 \cdot \ldots \cdot p_k)$. But this difference is 1, so $q = 1$. From the contradiction, $q > 1$ and $q = 1$, we conclude that the assumption that the set of primes is finite is false. Therefore, the set of primes is infinite.

Chandler was then prompted to answer the following comprehension questions on his own.

1. Please give an example of a set that is infinite and explain why it is infinite.
2. Why does n have to have a prime divisor?
3. Why exactly can one conclude that q divides the difference $n - (p_1 \cdot p_2 \cdot p_3 \cdot \ldots \cdot p_k)$?
4. What is the purpose of the statement "Let $p_1, p_2, p_3, \ldots, p_k$ be all those primes with $p_1 < p_2 < p_3 < \cdots < p_k$."?
5. Summarize in your own words the main idea of this proof.
6. What do you think are the key steps of the proof?
7. In the proof, we define $n = (p_1 p_2 p_3 \ldots p_k) + 1$. Would the proof still work if we instead defined $n = (p_1 p_2 p_3 \ldots p_k) + 31$? Why or why not?
8. Define the set $S_k = \{2, 3, 4, \ldots, k\}$ for any $k > 2$. Using the method of this proof, show that for any $k > 2$, there exists a natural number greater than 1 that is not divisible by any element in S_k.

Considerable attention was given to local comprehension questions 1-4 as Chandler was not able to discuss questions 5-8. We highlight his most enlightening responses to the Activity and these comprehension questions below.

After reading the statement and its proof, Chandler was asked to describe or define proof by contradiction. He said:

> *Aren't you supposed to show not the conclusion, or try to prove not the conclusion and try to come up with something that is?*

While this definition discusses the final steps of a proof by contradiction, it focuses on "showing not the conclusion" rather than discussing how the initial assumption and contradiction relate to the original statement. Thus, we believe Chandler exhibited a PreAction conception of proof by contradiction.

Chandler was able to describe the meaning of key words and phrases, such as when he described infinity as:

> *Every time it [a real number] goes up, you can still go up by 1.*

However, Chandler was unable to describe the purpose of statements and provide justification for lines in the proof. For example, he initially wrote that the purpose of the statement 'Let $p_1, p_2, p_3, \dots, p_k$ be all those primes with $p_1 < p_2 < p_3 < \cdots < p_k$' was:

> *To construct an infinite number of possibilities for number* n*, since numbers are composites of primes* p *and* n *is not a particular natural number.*

When the teacher asked Chandler to clarify his written response during the discussion, he said:

> *Infinity. Uh, well the set of primes is infinite. [long pause] Is it,* n *is composed of a finite number of parts?*

In both cases, Chandler did not recognize the statement as defining the assumed finite set of primes so that they may be used to produce a new prime. When the teacher asked Chandler to provide justification for the line 'q divides the difference $n - (p_1 \cdot p_2 \cdot p_3 \cdot \dots \cdot p_k)$', Chandler realized that he wrote multiple answers and even expressed confusion on what he was thinking:

> *I wonder what I decided… there's several things boxed in.*

All of the answers Chandler initially provided involved rewriting statements in the proof without further clarification. Even after an extended discussion considering the statement with a small number of primes, Chandler was unable to provide justification for the line. These examples suggest that while Chandler could understand what individual statements meant, he did not know how these statements logically or mathematically followed from one another. Thus, we believe Chandler showed some local understanding of the presented proof.

When asked to summarize the main idea of the proof, Chandler restated the statement. When asked what the key steps of the proof were, he said:

> *Supposing the contradiction is true, that the set of primes is finite and showing how to prove that by reducing an infinite number of primes down to the number 1… I don't know what that means.*

When asked whether the proof would still work if we changed $n = (p_1 p_2 p_3 \dots p_k) + 1$ to $n = (p_1 p_2 p_3 \dots p_k) + 31$, he said that it would "Because the difference is 31, so q is 31 and q is still greater than 1. I don't know." In the questions above, Chandler does not exhibit any holistic understanding. Yet, Chandler does show some holistic understanding in his attempt to show that for any $k > 2$, there exists a natural number greater than 1 that is not divisible by any element in $S_k = \{2, 3, 4, \dots, k\}$. Chandler was able to identify the previous construction of n as being necessary for the new proof and began his proof by appropriately modifying the new number $n = (2 \cdot 3 \cdot 4 \cdot \dots \cdot k) + 1$. Rather than showing that this number is not divisible by any element in S_k, Chandler tried to mimic the presented proof. It is likely that Chandler was unsuccessful in writing the proof because he did not understand the multi-level quantified statement and, in particular, did not know how to negate this statement. Consider the following discussion between Chandler and the teacher about his proof:

T: Any idea how to negate this statement?
C: And I thought of that but I just, it didn't seem following along, and I sure didn't [know] how to get it following along like this one. I think the contradiction would be: for all natural numbers greater than 1, wait [pause, mumbling to self] for all natural numbers greater than 1… I don't know.
T: Okay, let's try to rewrite this in symbols, maybe.
[After prompting, Chandler writes $\forall k > 2, \exists n > 1 \in \mathbb{N}\ s.t.\ s \nmid n \ \ \forall s \in S_k$*]*
T: Can you negate this now?
C: I think, piece by piece. There's a whole string of these, I don't know. I think for all n less than or equal to 1, or yeah, is that right?
T: We also do the, for every k greater than 2, so maybe it's "there exists a k greater than 2" so there is actually one of them.
C: Or, wait, which part? You don't negate this [points at $n > 1$*], you negate this [points at* $\forall$*]. The quantifier?*
T: Yes, yes.
C: So you don't negate the [trails off].
[After more discussion on negating parts of the statement.]
C: I'm trying to remember [pause] such that for some s, s divides n, for s in the set. Is that the entirety?

While Chandler was unable to negate the multi-quantified statement (either as a mathematical statement or in algebraic notation), he did say

> *And I thought of that [negating the statement] but I just, it didn't seem following along, and I sure didn't how to get it following along like this one…*

which indicates that he may have been able to complete proof had he been able to negate the multi-quantified statement. We also see phrases such as "I'm trying to remember…" and errors such as "I think [the negation would be] for all n less than or equal to 1…" that indicate Chandler may need an external guide or table to negate quantified statements even single-quantified statements. At least in this case, it is possible that Chandler's conception of quantification was inhibiting his holistic comprehension of the proof.

Teaching Episode 2

Teaching episode 2 began with Chandler examining the following statement and proof, after which he was asked to provide a definition of proof by contradiction based on the presented proof.

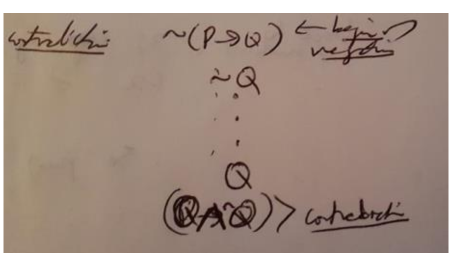
> *Statement 2:* If every even natural number greater than 2 is the sum of two primes, then every odd natural number greater than 5 is the sum of three primes.
> *Proof 2:* Assume that every even natural number greater than 2 is the sum of two primes and that it is not the case that every odd natural number greater than 5 is the sum of three primes. Then there exists an odd natural number greater than 5 that is not the sum of three primes, call it k. Then $k = 2n + 1$. Since $k > 5$, $2n + 1 > 5$ and so $n > 2$. Rewriting k, we have $k = 2(n-1) + 3$. Since $n > 2$, $2(n-1) > 2$ and so is the sum of two primes: p and q. Thus $k = p + q + 3$. This is a contradiction as we assumed k was not the sum of three primes. Therefore if every even natural number greater than 2 is the sum of two primes, then every odd natural number greater than 5 is the sum of three primes.

After a discussion on the underlying structure of the presented proof and how this related to proof by contradiction in general, Chandler was asked to answer the following comprehension questions on his own.

1. Please give an example of a prime number and explain why it is prime.
2. Why is every even natural number greater than 2 the sum of two primes?
3. Why exactly can one conclude that $k - 3$ is the sum of two primes?
4. What is the purpose of the statement "Since $k > 5$, $2n + 1 > 5$ and so $n > 2$."?
5. Summarize in your own words the main idea of this proof.
6. What do you think are the key steps of the proof?
7. In the proof, we rewrite $k = 2(n-1) + 3$. Would the proof still work if we instead rewrite $k = 2(n-2) + 5$? Why or why not?
8. Using the method of this proof, show that: if every odd natural number greater than 5 is the sum of three primes and 3 is one of those primes, then every even natural number greater than 2 is the sum of two primes.

Unlike teaching episode 1, Chandler was able to talk more about the holistic questions than he could previously. We highlight his most enlightening responses below.

After discussing the specific structure of the presented proof, Chandler came up with the following step-by-step guide for a general implication statement:



<u>Contradiction</u> $\sim (P \to Q)$ ← <u>begin negation</u>

$\sim Q$

$\vdots$

Q

$(Q \wedge \sim Q)$ > <u>contradiction</u>

Figure 1: Chandler's written structure (left) and his recreated structure (right)

First, note that the logical connection between the assumption, $\sim (P \to Q)$, and the next line, $\sim Q$, is omitted as well as the logical connection between the assumption and contradiction in order to conclude the proof. Also, there is no mention of the role of P in the proof. These omissions indicate that the structure above is meant to *write* a complete proof by contradiction and not to outline the logical structure of the method. In other words, Chandler focus is on the procedure and not in understanding why the procedure works. Thus, we believe he exhibits an Action conception of proof by contradiction.

After reading the first line of the proof and before attempting any of the comprehension questions, Chandler said:

> *I'm not sure when something contradicts, if you begin with 1, step 1. The assumption, or the given, was that P and [sic] Q. If you begin with P and not Q, it's already a contradiction, isn't it? No?*

Once the teacher explained the logical equivalence between the hidden initial assumption step, $\sim (P \to Q)$, and the first statement of the proof, $P \wedge \sim Q$, Chandler was able to understand the logical relation between the statement and the first line of the proof. However, rather than include this equivalence in his proof by contradiction steps above, he only included $\sim Q$, the consequent of $P \wedge \sim Q$ the proof uses to move forward and end up with a contradiction. While his steps may now avoid attending to local understanding of the statement and assumption, we see an instance in which Chandler, unprompted, attended to the local understanding of a particular proof by examining the propositional logic.

When writing his proof for comprehension question 8, Chandler had difficulty negating statement Q (a key step in his current conception for proof by contradiction) without first translating the statement into propositional logic and using rules to negate the propositional logic. An excerpt of what transpired is provided below:

> *T: Do you have any ideas on how to approach this proof? [Long pause]*
> *C: Not Q would be 'every even natural number greater than 2 is not the sum of two primes'? No, all? I don't know.*
> *[Teacher prompts Chandler to write the statement in propositional logic]*
> *T: Alright. So for every n here, that's how you said it to me. So parentheses for all n, in the natural numbers, if n is greater than 2, then n is p + q. So what would be the negation of this statement?*
> *C: There is a natural number…*
> *T: There is a natural number.*
> *C: n greater than 2 that is not equal to p + q.*

We see Chandler utilizing his general procedure for implication statements by starting with negating statement Q. Once he wrote the statement in propositional logic, Chandler was able to recognize the negation of a 'for all' statement as 'there exists' and continue using his procedure to complete the proof. This suggests that Chandler's conception of quantification still inhibited his holistic understanding of the proof.

Teaching Episode 3

Teaching episode 3 began with Chandler examining the following statement and proof, after which he was asked to provide a definition of proof by contradiction based on the presented proof.

Statement 3: There is no odd integer that can be expressed in the form $4j-1$ and in the form $4k+1$ for integers j and k.

Proof 3: Assume it is not true that there is no odd integer that can be expressed in the form $4j-1$ and in the form $4k+1$ for integers j and k. Then there is an odd integer that can be expressed in the form $4j-1$ and in the form $4k+1$ for integers j and k. Let n be that integer; that is, $\exists n \in \mathbb{N}$ such that $n=4j-1$ and $n=4k+1$ for $j,k \in \mathbb{Z}$. Then $4j-1=4k+1$ and so $2j=2k+1$. Note that $2j$ is an even number and, since $2j=2k+1$, $2j$ is an odd number. A number cannot be both even and odd and thus this is a contradiction. Therefore, it is not true that it is not true that there is no odd integer that can be expressed in the form $4j-1$ and in the form $4k+1$ for integers j and k. In other words, there is no odd integer that can be expressed in the form $4j-1$ and in the form $4k+1$ for integers j and k.

Chandler was then asked to compare and contrast Proof 2 and Proof 3. After a discussion on the similarities and differences of the underlying structures of these proofs how this related to proof by contradiction in general, Chandler was asked to answer the following comprehension questions on his own.

1. Please give an example of an integer that is odd and explain why it is odd.
2. What kinds of numbers can be expressed in the form $4j-1$?
3. Why exactly can we assume "$\exists n \in \mathbb{N}$ such that $n=4j-1$ and $n=4k+1$ for $j,k \in \mathbb{Z}$." ?
4. What is the purpose of the statement "Note that $2j$ is an even number and, since $2j=2k+1$, $2j$ is an odd number."?
5. Summarize in your own words the main idea of this proof.
6. What do you think are the key steps of the proof?
7. In the statement, we have $4j-1$ and $4k+1$. Would the proof still work if we instead have $4j-3$ and $4k+3$? Why or why not?
8. Using the method of this proof, show that there is no odd integer than can be expressed in the form $8j-1$ and $8k+1$ for integers j and k.

The teacher/research focused Chandler's attention on the holistic comprehension questions as Chandler was able to give quick, confident answers to the local comprehension questions. We provide some of his most enlightening responses below.

As mentioned above, Chandler was asked to compare Proof 2 and Proof 3 in their presented form. An excerpt of this comparison is provided below, along with a recreation of Chandler's two proof structures that he eventually compared in place of the semantic representations of the proofs.

C: They are both contradiction, proof by contradiction, and [pause] I don't know.
T: Well, maybe… let's see. You have the structures of both proofs, right?
[Teacher prompts Chandler to examine the structures he already developed.]

T: So you were saying something before you started talking about the $\sim Q$; you were pointing at [steps] 5-7.
C: Yeah. Those are similar – [steps] 4-7 are similar to this, [steps] 4-6, of course.

Table 2: Recreation of Chandler's proof structures for implication (left) and nonexistence (right) statements.

$P \rightarrow Q$	$(\nexists x)(P(x))$
1. $P \wedge \sim Q$ 2. $\sim Q$ 3. $\sim Q \rightarrow R_1$ 4. $R_1 \rightarrow R_2$ 5. $R_2 \rightarrow R_3$ 6. $R_3 \rightarrow Q$ 7. $Q \wedge \sim Q$ 8. $\sim (P \wedge \sim Q) = P \rightarrow Q$	1. Assume $\sim (\nexists x)(P(x))$ 2. $\sim (\exists x)(P(x))$ [sic] 3. $P(n)$ 4. Algebra until contradiction: $4j - 1 = 4k + 1$ means $2j = 2k + 1$ 5. $\sim (\sim (\nexists x)P(x))$ 6. $(\nexists x)P(x)$

What Chandler is talking about here is the role of parts of the proof. In particular, he is considering how each structure arrives at the contradiction and uses this contradiction to complete the proof (Note: although he initially excludes step 8 in the implication structure as seen in Table 2, he clarifies the role of this step later in the discussion). Chandler uses this insight when he developed a general set of steps for any kind of proof by contradiction, replicated below:

1. *Assume the claim is false.*
2. *Rewrite the assumption.*
3. *Do algebra until contradiction.*
4. *The assumption is false, so the original claim is true.*

Chandler leveraged the propositional and quantified logical structure of the proofs to produce a general, non-logical list of steps for *any* proof by contradiction and thus we believe he developed a Process conception of proof by contradiction.

Chandler used of the general steps above to identify the purpose of single statements in the presented proof. When asked why the proof can assume 'there is an odd integer n such that $n = 4j - 1$ and $n = 4k + 1$ for $j, k \in \mathbb{Z}$', Chandler responded:

Because we are claiming the negation of "there is no odd integer n such that $n = 4j - 1$ and $n = 4k + 1$" which is "there is an odd integer n…"

We see that Chandler recognized 'there is an odd integer n*…'* as a rewrite of the assumption without needing to refer to the logical equivalence of the statements. In addition, Chandler identified that the purpose of the statement 'Note that $2j$ is an even number and, since $2j = 2k + 1$, $2j$ is an odd number' was to identify the contradiction. In both cases, we see Chandler relating the logical status and justification of statements to the general steps he has developed for a proof by contradiction. In doing so, he no longer needed to refer to the underlying structure of the proof in order to locally comprehend the presented proof.

Unlike teaching episodes 1 and 2, Chandler was able to describe the key steps of the presented proof and stated:

C: Rewording it, I think. Rewording the claim into a negation and the algebra.
T: That makes sense. Alright.
C: For this one. I mean… I don't know.

What Chandler is describing as the key steps for this proof are steps 2 and 3 for general proofs by contradiction that he constructed during the Discussion of this teaching episode, though he clarifies that these may only be the key steps for this proof. Based on the previous steps he has listed as key steps, it seems that Chandler conceptualized the key steps of a proof as the steps in which he found to be most difficult. With this in mind, his clarification that the key steps of another proof may be different likely refers to the idea that the *difficult steps* of another proof may be different and not that the *general steps* of another proof by contradiction may be different. Thus, we believe Chandler exhibits holistic understanding of the presented proof based on his general understanding of proof by contradiction.

Discussion

It was evident that logic, and quantification in particular, played an important role in Chandler's understanding of particular proofs and proof by contradiction in general. First, he leveraged propositional logic to develop specific steps for a particular kind of proof by contradiction as well as considered the logical connection between the statement and assumption of a particular proof. We also observed that Chandler's initial difficulties with negating quantified statements inhibited his ability to transfer the methods of a particular proof into a similar context. By the end of the teaching experiment, Chandler developed a list of general steps any proof by contradiction should contain through the comparison of two different logical structures of particular proofs by contradiction. These steps not only aided Chandler in transferring the method of one proof to similar proof, but they aided Chandler in recognizing the logical status and justification of statements in a particular proof.

Chandler's conception of mathematical logic seemed to, at times, inhibit his proof comprehension. In particular, Chandler exhibited a need to convert statements into propositional or predicate logic in order to either negate the statement or recognize the logical relation between pairs of statements. This is especially important to highlight for proof by contradiction as students are not convinced of the validity of the proof method (Brown, 2011). However, by exploring the logical relation between the assumption, contradiction, and original statement, students may become convinced and thus more accepting of the method. At the very least, we found that prompting Chandler to explore the logical relation between statements in a proof and to develop key steps aided him in developing a robust understanding of proof by contradiction.

Future Plans

Overall, the teaching experiment seemed to aid Chandler in developing a robust understanding of proof by contradiction by focusing on the logical relationships within proofs. These results further a growing belief that attending to the logical relationship of statements may greatly improve proof comprehension (Brown, 2013; Hodds et al., 2014). Before we consider the teaching experiment useful to a general student at the university, we need to consider more case studies. Five more students from *Bridge to Higher Mathematics* volunteered and participated in at least 3 teaching episodes during Fall 2016. We plan to analyze these students' understanding of proof by contradiction in terms of APOS Theory and their understanding of specific proofs via the proof comprehension assessment model by Mejía-Ramos et al. (2012) in a similar fashion to Chandler. Positive results from these cases would strengthen our claim that the teaching experiment would be useful for general transition-to-proof students and allow us to examine the role of mathematical logic in understanding proof by contradiction.

Using Women of Color's Intuitive Examples to Reveal Nuances about Basis

Aditya P. Adiredja
University of Arizona

Michelle Zandieh
Arizona State University

Research and surveys continue to document the underrepresentation of women of color (WOC) in mathematics. Historically, their achievement in mathematics has been framed in a deficit way. Following the broader call for more research concerning WOC's learning experiences in STEM, we interviewed eight WOC about their understanding of basis in linear algebra. We documented diverse ways that these women creatively explained the concept of basis using intuitive ideas from their everyday lives. These examples revealed important nuances and aspects of understanding of basis that are rarely discussed in instruction. These students' ideas can also serve as potentially productive avenues to access the topic. Our results also challenge the existing broader narrative about the underachievement of women of color in mathematics.

Key words: student thinking, basis, linear algebra, equity

Women of color continue to be underrepresented in most areas of science, technology, engineering and mathematics (STEM), and more research is needed to understand the experiences of women of color in those areas (Ong, Wright, Espinosa, & Orfield, 2011). Their underrepresentation is also situated in the national call for more graduates in those fields in the U.S. (PCAST, 2012). In this study, we centralize the mathematical sense making of these students to counter the common colorblind approach to studying cognition. This focus has the potential to construct counter-narratives about women of color's achievement in STEM (Adiredja, in preparation). Research has historically positioned students of color as struggling or underachieving (Harper, 2010).

Research in post-secondary mathematics education has uncovered useful insights into the process of learning of advanced topics by focusing on students' individual cognition. However, scholars have noted the tendency of cognitive studies to deemphasize equity concerns (Martin, Gholson, & Leonard, 2010). Studies of mathematical cognition often take a colorblind approach in which students' background information is omitted (Nasir, 2013). There is a broader call for research at the post-secondary level to focus on addressing inequities, which include exploring ways that studies of student thinking can engage with issues of equity (Adiredja & Andrews-Larson, under review).

Theoretical perspectives on the nature of knowledge and how it develops directly impact the way we assess students' understanding and their contributions in mathematics. Studies of cognition share the power to determine what counts as productive knowledge, how learning is supposed to happen, and what kinds of students benefit in the process (Adiredja, 2015; Apple, 1992; Gutiérrez, 2013). For example, if we believe that mathematical knowledge can only be built upon prior formal mathematical knowledge, then it would be reasonable to privilege such knowledge in learning. However, one implication of this stance is that students who do not have the requisite formal knowledge would then be positioned as "not ready" or "less able," while students who do are seen as "smart," and are allowed to move forward (Gutiérrez & Dixon-Roman, 2011; Herzig, 2004). This deemphasizes the reality that such knowledge has been more available to some groups than others (Oakes, 1990). Cognitive studies can challenge some of these assumptions, and broaden what counts as productive ways of thinking and who counts as successful learners.

One way this is occurring at the undergraduate level is through research that focuses on building from students' informal knowledge and intuitions. For example, the instructional design theory, Realistic Mathematics Education (RME) (Freudenthal, 1983) has inspired some researchers to design curricula that build from experientially real start points (e.g., abstract algebra, Larsen, 2013; differential equations, Rasmussen & Kwon, 2007; geometry, Zandieh & Rasmussen, 2010; linear algebra, Wawro, Rasmussen, Zandieh, Sweeney, & Larson, 2012). Others focus on students' intuitions or conceptual metaphors to make sense of formal mathematics (Adiredja, 2014; Oehrtman, 2009; Zandieh, Ellis, & Rasmussen 2012). Most of these studies focus on using students' intuitions/ informal knowledge as building blocks for the more formal mathematical knowledge. In this paper, we explore ways that students' intuitive explanations can reveal nuances about a formal mathematical topic.

We explore students' explanations about the concept of basis in linear algebra using everyday ideas. Linear Algebra is a critical course for engineering and mathematics majors, and the concept of *basis* is a central topic. There has not been much research done about the concept of basis, though some researchers suggest that it is challenging for students (Stewart & Thomas, 2010). Stewart and Thomas (2010) found that students struggle in identifying span and linear independence in their description of basis. Moreover, they also struggle to define each of those terms, and tend to explain those concepts in terms of procedures. However, the authors found that students who received instruction that emphasized "geometry, embodiment and linking of concepts" (p. 177), were much better in describing the concepts compared to those whose instructions solely focused on symbolic algebra and isolated concepts. Students from the former group were also able to draw richer concept maps about basis than students from the more traditional class. These findings further support the approach of building from experientially real starting points (geometry and embodied ideas) to support students' understanding.

In this paper, we want to explore the diversity of ideas used by eight women of color to describe the concept of basis. We are less interested in identifying students' struggles with the concept of basis. Later we argue for the importance of adopting an anti-deficit perspective in analyzing students' ideas. In particular we explore the following research questions:

1. What everyday contexts do these women use to explain the concept of basis?
2. What do their explanations reveal about nuances in the concept of basis?

In this paper, we position these women as informants into their mathematical thinking and what it reveals about the nuances of the concept of basis.

Conceptual and Theoretical Frameworks

The "Anti-deficit Achievement Framework" from higher education research (Harper, 2010) guides the design and analysis of this project. Instead of perpetually focusing on examining deficits or struggles of students of color in STEM, Harper's framework focuses on understanding the success of these students despite existing inequities. For example, instead of asking the question, "Why are Black male students' rates of persistence and degree attainment lowest among both sexes and all racial/ethnic groups in higher education?" This deficit-oriented question can be reframed with the Anti-deficit Framework as, "How did Black men manage to persist and earn their degrees, despite transition issues, racist stereotypes, academic underpreparedness, and other negative forces?" (p. 68). The Anti-deficit Framework focuses on challenging a particular narrative about underachievement of students of color in STEM, which is also attached to women *of color* (e.g., Why are women dropping out of computer science?). While the author's work focuses on inequities in STEM higher education, some researchers in undergraduate mathematics education share similar perspectives in their study of students (e.g., successful Black mathematics majors, Ellington & Frederick, 2010).

In this paper we focus on countering the narrative of underachievement of women of color in mathematics, particularly with regards to their participation. The principle of "centralizing without essentializing" experiences (Bell, Orbe, Drummon, & Camara, 2000) provides an alternative to *essentializing* experiences of women of color (e.g., "all women of color struggle with basis in this way"). Centralizing instead leads to a focus on understanding the richness of their knowledge and sense making without attributing particular ways of sense making to all students in these groups.

The two authors of this paper come from different theoretical traditions, which guide our joint analysis. The first author comes from Knowledge in Pieces (KiP) (diSessa, 1993) perspective, and the second author has used RME (Freudenthal, 1983) and conceptual metaphors (e.g., Lakoff & Johnson, 1980) to productively analyze student thinking. The commonality of the different perspectives is that they view students' knowledge in an anti-deficit way. These perspectives highlight the use of intuitive ideas to explain mathematical and scientific ideas, and ways that they can be productive in building on students' existing understandings. In laying out our perspectives we position ourselves as being open to students' intuitions and non-normative language.

Methods

Given the desired depth and detail of analysis, this study favored the use of a small number of research subjects and videotaped individual interviews (diSessa, Sherin, & Levin, 2016). Participants were 8 undergraduate female students of color at a large public research university. The university's mathematics advising center shared contacts of mathematics majors and minors who identified as women of color. We invited students via email, and through personal contacts of the authors of this paper. The breakdown of racial and ethnic backgrounds and their past mathematics courses are presented in Table 1. This information was drawn from a student background survey that was administered at the end of the interview. With the exception of one student who is a Biomedical Engineering major (Morgan), all the other students were mathematics major or minor. All pseudonyms were selected to reflect the origin of students' names.

Each interview lasted for 90 minutes. We developed the protocol to explore student understanding of basis. Students started the interview by solving four linear algebra problems that did not mention basis but for which basis could be relevant. We then asked them about basis, which included the way they would define it, and everyday ideas that were useful to explain the concept. In this paper, we focus specifically on students' discussion of everyday examples. These occurred most often in response to questions Q2a and Q2b below, but also sometimes in response to other questions later in the interview.

Q2a. Can you think of an example from your everyday life that describes the idea of a basis?
Q2b. How does your example reflect your meaning of basis? What does it capture and what does it not?

Table 1. *Students' Racial/Ethnic Background and Mathematics Course History*

Student	Racial/Ethnic Background	Linear Algebra Completion	Grade	Other Mathematics Courses
Leonie	African American	Spring 2016	A	Calculus I, II, and III

Morgan	Asian/Asian American	Spring 2016	A	Calculus I, II, and III, and Differential Equations
Annissa	Hispanic/Latin@	Fall 2014	B	Calculus I and II
Eliana	Hispanic/Latin@	Spring 2014	C	Calculus I and II
Nadia	Hispanic/Latin@	Fall 2015	A	Calculus I, II, and III
Jocelyn	Hispanic/Latin@	Spring 2015	B	Calculus I, II, and III
Stacie	Hispanic/Latin@	Spring 2016	C	Calculus I, II, and III
Liliane	Hispanic/Latin@/White	Fall 2015	B/C	Calculus I, II, and III

We transcribed the interviews following guidelines from Ochs (1979). Transcripts were organized by turns, marked by changes in speaker. Transcripts use modified orthography (e.g., wanna, gonna, cus) to stay close to the actual students' utterance. Our analysis first focused on identifying the everyday context and the details associated with that context (e.g., how does the student think about a vector, a vector space, or scalar multiple?). We then differentiated between utterances that had to do with characteristics of the basis vectors, and those that had more to do with roles of the basis vectors in relation to the larger space. The next step of the analysis is developing codes through open coding (Strauss & Corbin, 1994) to capture nuances of students' understanding of basis.

Results

Students' Everyday Examples

We found that the majority of the students discussed at least one everyday context to explain the concept of basis. Table 2 provides a summary of the different contexts. We elaborate on the details of some these contexts in a later section.

Table 2. *Everyday contexts used to explain basis and vector spaces*

Student	Context (for basis and vector space)
Leonie	friendship
Morgan	driving in a city (on a grid), Legos, cooking, groups of pens
Annissa	set of solutions (no actual everyday example)
Eliana	least amount of myself I need to cover the space of the room, storage room, dimension, skeleton, outline of a paper
Nadia	floor, universe and earth, syntax in programming
Jocelyn	fashion, recipe, art sculpture, collage
Stacie	walking to places in a room, floor as a plane, marching band
Liliane	religious teachings

Characteristics and Roles of Basis Vectors

Students discussed characteristics of the basis vectors in their everyday examples. While many of the ideas they brought up can be associated with the notion of linear independence, their ideas reveal nuances about linear independence and its role in defining basis. The first set of codes below capture these characteristics of basis:
1. Minimal/maximal focuses on the required number or amount of vectors needed for the basis. Minimal focuses on the fact that the basis is the least amount of vectors necessary. Maximal focuses on the need to include all the basis vectors and that more would lead to redundancy.
2. Essential focuses on the quality of the vectors being the core and necessary.

3. Representation focuses on naming or identifying the smaller set as the structure or representation of the larger space.
4. Non-redundant focuses on not wanting extraneous information in a set, or the act of reducing or removing the extraneous information.
5. Different/sameness focuses on comparing items (vectors) based on their difference/similarity for the sake of keeping or removing items from the basis.

Prior to conducting the interviews we had noticed that basis vectors are sometimes emphasized in mathematics lessons as a way to *generate* a space of vectors. This is an emphasis on the basis vectors as a spanning set. Other situations might emphasize the role of basis vectors to describe the vector space, e.g., the basis for the null space of a non-invertible matrix serves as a short hand to *describe* that space. We asked students directly about this idea of generating and describing through Q5 and Q6, which ask, "Can you see a basis as a way to [generate/ describe] something?" But even before we asked students directly, they spontaneously brought up the idea of generating and describing in their description of basis, suggesting resonance of this idea. Lastly, related to the code of representation, students also brought up the role of choosing the particular vectors to represent the larger space.
1. Generating: To create the larger space from the basis vectors.
2. Describing: To describe the space using the basis vectors.
3. Sampling: To choose the particular basis vectors as representatives of the larger space.
In the next section we share our analysis of one student, Jocelyn to illustrate how we operationalize these codes.

Illustrative example of analysis. We illustrate our analysis and codes with one student, Jocelyn. Asking students to assess the validity of their everyday example turned out to be very informative of aspects of basis to which students were attending. Jocelyn's case illustrates ways that some of the codes emerged in our analysis. Jocelyn described basis in the context of fashion/creating an outfit. Jocelyn saw basis as minimum number of clothing pieces that "allows you to make all those outfits." In this turn, she was explaining what aspects of basis her example captured. We used bold texts to mark the codes in the write up of our analysis.

Interviewer: In the way you think about this sort of outfit idea to describe basis, um, what aspects of your understanding of basis is captured with your example and what part of it is not captured?

Jocelyn: Um it's minimal. To pick one pair of heels and one pair of tennis shoes. So when I think of my idea of a basis, my mind goes to minimal. Um, what doesn't it capture? Well, ok, so it's weird cause I guess you can use one pair of shoes for different outfits. But like if I'm trying to make...it's harder to kind of have like a casual outfit and in a formal outfit there's not a whole lot of like overlap you end up having each piece in each outfit in the basis. So it's like. How do I explain this? I feel like the basis I'm making, all of the pieces aren't as like they're not all the same. Like you have shoes, tops and pants. You can't make an outfit with just shoes. But if you have a basis, you can pick just some of the vectors, combine them and make something and leave all the rest out. Cause you can't just put on shoes and pants. So that's where it kinda...that's one of the ways that doesn't really [captures it].

Jocelyn attended to the **minimal** aspect of a basis. In addition to using the word minimal, she explicitly identified the need for the specific quantity of one pair of heels and tennis shoes. The particular pair of shoes serves as a **representation** for formal shoes and casual shoes respectively, and you end up with "each piece in each outfit in the basis." Earlier in the interview she discussed the necessity of one pair of heels for a formal outfit and one pair of tennis shoes for a casual outfit. It was also important to Jocelyn that the basis vectors were **different** ("they're not all the same"), and as a set was **non-redundant** (lack of "overlap" in the pieces). She also highlighted the **essential** nature of each element of the basis. She explained this in the way that an outfit needs shoes, pants *and* tops. She asserted, "you can't make an outfit with just shoes," or "just put on shoes and pants."

In addition to attending to particular aspects about the basis vectors, Jocelyn also attended to the roles of the basis vectors in the larger space. In particular she attended to the role of the basis vector in **generating** the larger space, and the necessity of choosing or **sampling** the particular basis vectors to represent the larger space. We coded the phrase "combine them and make something" as highlighting the **generating** relationship. We coded "to pick one pair of heels and one pair of tennis shoes" as also highlighting the **sampling** relationship. This is not to be confused with the representation code, which focuses on the basis vectors as representatives of the larger space.

Jocelyn's assessment also revealed a unique concern that we did not observe with other students about the ability to choose some of the vectors in the basis but not all of them. Jocelyn argued that with basis vectors, one could use a subset of them to generate a vector in the space. In the context of fashion, she could take a subset of the pieces to generate an outfit. The fact that she needed a top, a bottom and a pair of shoes meant that her example required that she had one piece from each category of clothing. She saw this as a limitation to her example. In the next section we explore the extent to which students in the study brought up roles of the basis vectors.

A focus on the generating relationship. In the process of analyzing students' everyday examples we found a wide range of examples of generating, a smaller number of examples of describing, and some examples of sampling. We focus now on most common code on the role of the basis vectors: **generating**. Each student had at least one example of what we label as generating.

Common verbs for the generating code were variations of "to make" or "to build." For example, Morgan talked about building in terms of Legos, "you're given like the 3 by 2 Lego [pieces] and you have like a 2 by 2 Lego [piece] you can just like *build* on to that to create that I guess space that you have." Nadia spoke about computer programming syntax, "Syntax is like stuff so you can *make* a program that doesn't give you an error." Other variations include "add," "expand", and "come from that," which Liliane used in her description of basis using religious teachings:

> So I'm very religious and so the teachings that I that we share with each other and that we read about and all that stuff. Like, there are a lot of things that you can *add* to and be like here's an application and here's the things, and this *expands* to this and this and this. But there's like the most basic teachings and like it all comes back to that. And this is the basic thing like you have the Ten Commandments. You have the Scriptures and you have like the prophets and you have your connection with God and, like all of the decisions and all of things that *come from that* and you can reach all of the other points with this basis.

These examples illustrate the different ways students brought up the notion of generating, and these women's creativity with the everyday contexts.

Discussion and Implication

The two main components of our results illustrate (1) the creativity and breadth of the everyday contexts used to describe basis by these female students of color, and (2) the nuances in understanding of basis that have come out of our open coding of this student data. The range of examples that students used was particularly interesting and useful. Most of these were not examples we had thought of ourselves prior to beginning the study. We are mindful of not gendering or racializing these examples, which would lead to essentializing the students. Students did discuss basis in the context of fashion, cooking and religion, but they also brought up other contexts like driving, skeleton, and the universe. These contexts are likely inspired by the students' experiences, and not their background characteristics. Future studies can further explore the range of contexts to explain basis, and the details of their differences. One can also investigate if there are shared learning experiences among these women that contributed to their flexibility to come up with these examples. Moskovich (2012) asserted that there is nothing inherently different about the cognitive processes of students of color in mathematics. However, there is a difference in their "conditions of learning" (p. 96). We conjecture that the different conditions for learning might have contributed to the creativity of these students.

These women were also fairly sophisticated in judging their own examples in terms of what aspects of the examples worked well for their understanding of basis and what aspects of the context were harder to line up with their understanding of basis. For example, Jocelyn did not think her outfit example captured the idea that you can create vectors in the space by just using one or two of the basis vectors, whereas in her outfit example, one would need to use all three basis vectors (shoes, tops and pants) to create a wearable outfit. In grappling with what aspects of their context worked well and which did not, the students revealed many nuances of basis that we might not have discovered using strictly formal mathematical questions. Together, these students' creativity and sophistication in assessing their examples challenges the narrative of underachievement of women of color that Harper (2010) has noted.

We argue that this paper makes contributions both to research on student cognition in addition to equity research. From a cognitive point of view, this is the only study that we know of that focuses on students' everyday examples of basis. In fact, there have been very few studies done on student understanding of basis and also few studies on students' ability to create everyday examples of mathematical constructs at the undergraduate level. For these reasons, this paper adds to the literature on student mathematical cognition and reasoning at the undergraduate level. In addition, we argue that the paper adds valuable data to the corpus of research in undergraduate mathematics education in that few studies have been written about the mathematical thinking of women of color. Sometimes this is because women of color have not been included in data sets (perhaps because there were not many women of color in the population from which the data was drawn). Other times we simply do not know whether or not women of color were in the data sets because, as one can see from a review of the papers in recent proceeding of the Conference on Research in Undergraduate Mathematics Education (RUME), it is not common in the RUME community to report data on gender and particularly on ethnicity.

This work may have implications for curriculum design. As an example, consider the experientially real starting points emphasized in the curriculum design framework of RME. Our analysis challenges us to reflect on what counts as an experientially real starting point for our students. Creating these experientially real starting points requires us to know our audience. In our past work we may have focused on certain types of students more than others in imagining what is experientially real to this audience. Making sure to interview and listen to the thinking of students who are not as often interviewed in RUME studies is vital to making sure we are reaching all students in instruction and also with our curriculum design.

Comparing Expert and Learner Mathematical Language:
A Corpus Linguistics Approach

Lara Alcock[1], Matthew Inglis[1], Kristen Lew[2],
Juan Pablo Mejía-Ramos[3], Paolo Rago[1] & Chris Sangwin[4]

[3]Rutgers University, [4]University of Edinburgh

Corpus linguists attempt to understand language by statistically analyzing large collections of text, known as corpora. We describe the creation of three corpora designed to enable the study of expert and learner mathematical language. Our corpora were formed by collecting and processing three different genres of mathematical texts: mathematical research papers, undergraduate-level textbooks, and undergraduate dissertations. We pay particular attention to the method by which our corpora were created, and present a mechanism by which LaTeX source files can be easily converted to a form suitable for use with corpus analysis software packages. We then compare these three different types of mathematical texts by analyzing their word frequency distributions. We find that undergraduate students write in remarkably similar ways to textbook authors, but that research papers are substantially different. These differences are discussed.

Key words: corpus linguistics, mathematical language, proof

Understanding the nature of mathematical language is a goal for at least three research communities. Sociologists and philosophers have long been interested in the practices of intellectual communities, and mathematics, with its uniquely deductive mode of inquiry, has attracted particular attention (e.g., Larvor, 2016). Mathematicians increasingly recognize that novices need to learn not only the content of mathematics but also the practices of mathematicians. Transition-to-proof courses are therefore common, and a growing number of textbooks directly address logical norms of mathematical communication (e.g., Vivaldi, 2014). Mathematics educators at all levels aim to support learners in developing sophisticated modes of thinking: a commonly-stated goal is that learners should engage in authentic mathematical activity that involves reasoning, proving, and communicating their arguments with others in the classroom and in written work (e.g., Stylianides, 2007).

These communities – sociologists and philosophers, mathematics educators, and mathematicians – therefore share an interest in understanding the norms of mathematical practice and communication. To date, however, there are relatively few empirical studies of this practice, and those that exist indicate less homogeneity among mathematicians than is typically portrayed in introspective accounts (e.g., Inglis, Mejía-Ramos, Weber & Alcock, 2013). In particular, to our knowledge, there have been few large-scale attempts to study the authentic mathematical communication of research mathematicians, or to compare this to the communication of undergraduates.

One method of studying language is to use the techniques of corpus linguistics, a branch of linguistics that statistically interrogates large collections of naturally occurring text, known as corpora. Methods developed by corpus linguists can be used to investigate many different types of linguistic question, and have revealed important and surprising findings (e.g., McEnery & Hardie, 2011).

Our goal in this project was to compare three distinct types of mathematical written language: that used by mathematicians when writing research papers, that used by mathematicians when communicating with undergraduates for pedagogical purposes, and that used by undergraduates when writing for assessment. By collecting and processing naturally occurring mathematical texts of these three types we aimed to understand the similarities and differences of these three genres of mathematical language. A subsidiary goal was to compare all these versions of mathematical language with general (non-mathematical) written English. We first discuss the process involved in creating our three corpora.

Collecting the Texts

The first task for a researcher who wishes to create a corpus is to collect examples of the language that they wish to study. We adopted two largely pragmatic criteria:

1. We collected only text in LaTeX format to enable consistent processing (discussed below).
2. We collected only text that had been published non-commercially or, in the case of student projects, where the author agreed to assign us copyright.

Subject to these criteria, we collected texts for the three corpora in different ways.

To create the learner corpus we invited undergraduate students to submit their final-year projects or dissertations. Such dissertations are common in the UK (where students specialize to study three subjects at age 16 and to one or two when at university) and degree programs vary in their dissertation criteria. But students commonly have the opportunity to undertake an individual project – which might be expository or applied– accounting for approximately one sixth of their final-year credit. We invited submissions from such students via project coordinators at 15 universities, who sent on an email directing interested students to a Facebook page that explained how to process their dissertation LaTeX file to remove personal identifiers, and how to submit this along with a copyright transfer form. Each student who submitted received a £5 (approximately $7) Amazon voucher and was asked to encouraged their friends to submit too. By this method we collected 50 student dissertations, which contained a total of 419,965 words.

To create the pedagogic text corpus we located online undergraduate-level open textbooks using the Open Textbook Library, the College Open Textbooks site, and the American Institute of Mathematics Approved Textbook list. Topics included abstract algebra, analysis, linear algebra, complex analysis, and textbooks designed to support the transition to proof. If the textbooks were not available in LaTeX format we contacted the author and asked for permission to access their source files. This approach left us with the source files for 21 complete undergraduate textbooks, which contained a total of 1,518,932 words.

To create the expert corpora we first downloaded all papers that had been uploaded to the arXiv in the first four months of 2009. The arXiv is an online repository that is routinely used by research mathematicians to share their research articles. The majority of articles on the arXiv are available in LaTeX format, and can be bulk downloaded using a command line tool. We then sorted the articles using their primary subject classification (e.g., mathematics, physics, etc.) and further sorted them using their secondary subject classification (e.g., algebraic geometry, algebraic topology, etc.). This left us with a total of 5087 mathematics articles, containing 30,892,695 words.

Processing the Texts

Collecting mathematical language and converting it into a form that can be processed using the standard software packages used by corpus linguists presents a challenge. Unlike most texts, mathematical language contains numerous atypical characteristics, such as inline mathematical notation. Most mathematics is written using the LaTeX markup language, not plain text. Our first goal was therefore to create a method of converting LaTeX source code to plain text in a way that preserved the natural sentence structure of the language, but which removed non-linguistic features of the source code (the code for bold or italic text for instance).

An important question for the would-be creator of a mathematical corpus concerns how to deal with inline mathematical notation. For instance, a typical mathematical sentence might be "Let $f: X \to Y$ be a bijection." How would we want the "$f: X \to Y$" to appear in a plain text corpus? One approach would be to leave the LaTeX source code intact and to analyze the code as if it were natural language. The difficulty with adopting this option is that there are several different ways in which one could encode "$f: X \to Y$" in LaTeX. For instance, `$f:X\rightarrow Y$` and `\(f:X\rightarrow Y\)` produce identical output, and `$f\,:\,X\longrightarrow Y$` only differs stylistically. We therefore felt that this approach would be unhelpful for the majority of questions a researcher would wish to answer using a mathematical corpus (although our code does allow this approach as an option, as a researcher who wished to primarily focus on the semantic content of papers might wish to retain these markup codes).

A second option would be to delete all mathematical code entirely, and simply record the example above as "Let be a bijection". We rejected this option as it seemed not to preserve the logical structure of sentences, which would influence certain analyses (those that investigate the collocation of words, for instance). Instead we opted to replace all occurrences of inline mathematics with the string "inline_math" (although this decision can be altered by the researcher if desired). The scripts we used to convert LaTeX to analysis-ready plain text are freely available for the research community at:
`https://github.com/sangwinc/arXiv-text-extracter`

As our corpus of general written English we used the combined Lancaster-Oslo/Bergen corpus (commonly referred to as the LOB corpus; Johansson, 1986) and Brown corpora. The Brown University Corpus of Standard American English (commonly referred to as the Brown corpus; Francis & Kucera, 1961) is formed of 1 million words of American English from texts published in 1961. The LOB corpus consists of written British English created to mirror the structure of the Brown corpus (i.e. texts were taken from similar sources in similar proportions). Thus our combined Brown/LOB corpus consisted of 2 million words of British and American written English.

Analyzing the Corpora

Having created the corpora, our primary goal was to understand the extent to which they were similar: is it the case that the language used in mathematical textbooks, mathematics research papers, and undergraduates' final year projects is consistent? If not, where are the differences between these genres, and how can these differences be characterized?

Kilgarriff (2001) proposed a variety of measures that aimed to assess the similarity of different corpora. All his approaches relied upon the so-called 'bag of words' model of text construction. This model ignores the order in which words occur and instead focuses on understanding texts by assessing their distributions of word frequencies. The basic idea is that two texts are likely to be a similar genre, and focus on a similar topic, if they have broadly similar word frequency distributions. Of the measures he studied, Kilgarriff concluded that a chi-squared approach performed best. Suppose one wishes to calculate the similarity of corpora A and B. Kilgarriff proposed determining the most frequent n words in the supercorpus formed of $A \cup B$, and then calculating the test statistic for a chi-squared test of goodness of fit. Since these n words were selected to be the most frequent, and not sampled randomly from the population of words, it would be inappropriate to actually perform the chi-squared hypothesis test, but Kilgarriff reasoned that the test statistic would serve as a suitable measure of similarity (with lower values represent more similarity).

Unfortunately Kilgarriff's (2001) chi-squared method would not suffice for our purposes, as it requires that we are comparing corpora of the same size. We therefore modified his proposal as follows. We first determined the 100 most frequent words across our four corpora, where each corpus was weighted as representing 25% of the supercorpus (we needed to perform this weighting because our expert arXiv corpus was considerably bigger than the others). We did not include "inline_math" as a word for this analysis, as clearly it did not appear at all in the Brown/LOB corpus. We then calculated the proportion of each corpus consisting of each word. For instance, the word "the" represented 6.08% of the arXiv corpus, 6.72% of the textbook corpus, 6.62% of the learner corpus, and 6.69% of the Brown/LOB corpus.

For each pairwise combination of corpora, A and B, we then calculated

$$S_{AB} = \sum_{i=1}^{100} \left(\frac{(a_i - b_i)^2}{a_i} + \frac{(a_i - b_i)^2}{b_i} \right)$$

where a_i represents the proportion of corpus A formed of word i, and b_i represents the proportion of corpus B formed of word i. While this is not a true chi-squared value (which would be calculated with frequencies rather than proportions) it fulfils a similar role. Therefore if $S_{AB} < S_{AC}$, we can conclude that corpora A and B are more similar than corpora A and C. The S_{AB} values for each pairwise combination of our four corpora are given in Table 1, and plots of the frequencies of the top 100 words are shown in Figure 1 (so, a point at (x,y) in the bottom left graph indicates that the same word formed x% of the arXiv corpus and y% of the textbook corpus).

The results shown in Table 1 and Figure 1 paint a consistent picture. We found that the textbook and learner corpora had remarkably similar word frequency distributions, that the arXiv corpus formed of mathematical research papers was somewhat different, and that all three mathematical corpora were substantially different to the regular written English of the Brown/LOB corpus. Before exploring the differences between the arXiv and textbook corpora below, we first make some remarks on these findings.

	Textbook	Learner	Brown/LOB
ArXiv	0.105	0.097	1.215
Textbook		0.011	1.317
Learner			1.320

Table 1: The similarity measures, S_{AB}, for each pairwise combination of our four corpora.

Although our analysis was exploratory in the sense that we did not have strong hypotheses about the results in advance, we were somewhat surprised by these findings. We anticipated there would most likely be a gap between the language used by experts and novices. After all, mathematicians have typically had many years of enculturation into the discipline, whereas the undergraduates who provided the texts for our learner corpus had only had three or four years of university-level study. However, we found something quite different. Our learners seemed to produce very similar written language to that found in textbooks written by experts, at least in the sense that their word frequency distributions were close to identical. One hypothesis that might account for this similarity would be if the two corpora had similar balances of mathematical topics. For instance, two corpora focused on linear algebra might be expected to have similar word frequencies for “kernel”, “matrix”, and so on. But we do not believe that this suggestion can account for our data. Because we only considered the 100 most frequent words, few were highly domain specific: in fact, only “theorem” and “proof” were words in the overall top 100 which had fewer than 100 occurrences in the Brown/LOB corpus.

Instead our conclusion is that the undergraduate students who provided the texts for our learner corpus did successfully produce written mathematics that was consistent with that found in undergraduate textbooks written by expert mathematicians. At least in the sense that it shared a similar distribution of word frequencies.

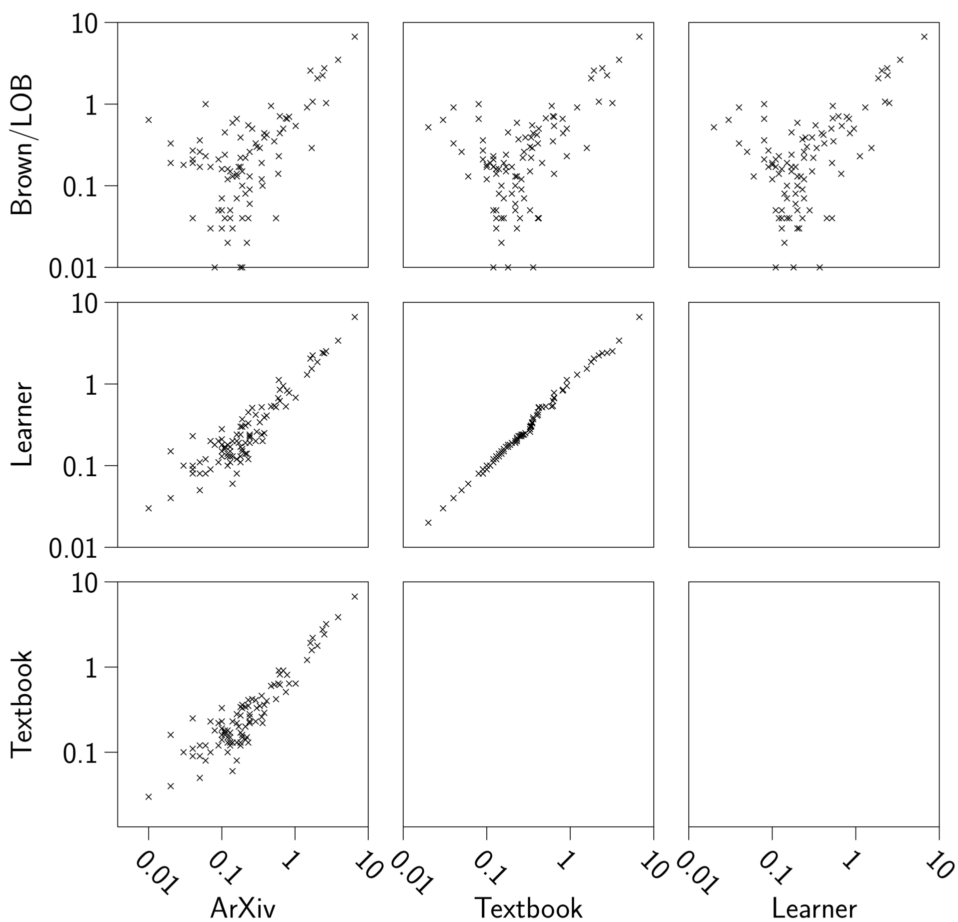

Figure 1. Scatterplots showing the frequencies of the top 100 words (as percentages) for each pairwise combination of our four corpora. Axes have logarithmic scales (therefore words with zero frequency in one corpus are not shown).

The main difference we found between the mathematical corpora concerned the word frequency distributions of the textbook and arXiv corpora. We can explore this difference in more detail by considering the keywords for each corpus – those words which occur disproportionately in one corpus compared to the other. These are shown in Table 2, which is ordered by chi-squared value (i.e. the contribution of the word to S_{AB} defined earlier).

Some of these key words are unsurprising: for instance, ‘example’, and ‘solution’ occur proportionately more often in the textbook corpus than the arXiv corpus. The textbook corpus also contains proportionately more instances of verbs such as ‘find’, ‘show’, ‘do’, and ‘prove’ – than the arXiv corpus. Indeed, the only verbs appearing in the right-hand side of Table 2 are ‘let’ and ‘see’. Although one might attribute this to the inclusion of exercises in textbooks, this explanation would not account for the extremely similar frequencies for these words found in the textbooks and the undergraduates’ final-year projects: although clearly textbooks normally contain exercises, student projects do not.

One further difference between the mathematical corpora concerned the frequency of mathematical notation. The arXiv corpus had considerably more instances of “inline_math” per 100 words (11.1%) compared to the textbook (8.8%) or learner (7.6%) corpora.

Further analyses are required to understand the significance of some of the other differences between the corpora. For instance, ‘by’ occurs disproportionately often in the arXiv corpus (1.02% of words) compared to the textbook corpus (0.64%) , but why? Investigating the most common clusters of words that include ‘by’ in the arXiv corpus indicates that the word is used to both name (“defined by”, “denote by”) and assert (“given by”, “obtained by”, “generated by”). By systematically studying such cases we can begin to understand the differences between research-level and undergraduate-level mathematical language.

Conclusion

Our main goal in this paper has been to describe the creation of three mathematical corpora designed to aid researchers understand mathematical language. The tools we used to construct these corpora are freely available for the research community to use. Having constructed the corpora we presented an analysis of word frequency distributions which suggested that undergraduate students are, by the end of their courses, surprisingly successful at writing in a manner consistent with the language used in undergraduate textbooks. The developmental trajectory by which students develop mathematical language skills would be a worthy topic of future study. In contrast to the similarity observed between textbooks and final year dissertations however, the language mathematicians use in research papers is different to both.

In this paper we have focused on comparing the word frequency distributions of four different corpora, but there are a great many other techniques that can be used to analyze corpora which go well beyond this approach (e.g., McEnery & Hardie, 2011). Given the interest shown by mathematics educators and other researchers in mathematical language, we believe that corpus linguistics is a potentially useful, but currently under used, research technique.

Mathematics instruction leadership in undergraduate departments

[1]Naneh Apkarian, [1]Chris Rasmussen, & the Progress through Calculus team*
[1]San Diego State University

Many universities have begun to coordinate their introductory mathematics courses to handle multiple sections of the same course, a situation necessitated by the large numbers of students taking precalculus and calculus. Robust coordination systems consist of two major elements: uniform course elements (e.g., common text; exams) and regular instructor meetings. These regular meetings may turn calculus instruction into a joint enterprise, potentially engendering a community of practice. Of particular importance are those who act as leaders (formally and/or informally) within these coordination systems – these people have the potential to influence and "nudge" instructors towards improving their practice (Rasmussen & Ellis, 2015). This study combines case study findings with social network data to investigate instructional leaders at five diverse institutions, considering both formal and informal coordination phenomena, and hypothesize about their potential to influence practice in their departments.

Key words: Coordination, instructional leadership, social networks, change

Many universities have begun to coordinate their introductory mathematics courses to handle multiple sections of the same course, a situation necessitated by the large numbers of students now taking precalculus and single-variable calculus (Precalculus to Calculus 2, P2C2). Robust coordination systems consist of two major elements: uniform course elements (e.g., common text; exams) and regular instructor meetings. These regular meetings can have the effect of turning calculus instruction into a joint enterprise, potentially engendering a community of practice (Rasmussen & Ellis, 2015). P2C2 instruction has been identified as one of the culprits in the mass exodus of college students from STEM majors, and many calls for improvement hint at the need for collaborative work: "all faculty, including tenure-track faculty and the teaching/pedagogy faculty, should engage collaboratively in undergraduate curriculum and teaching reform" (TPSEMath, 2015, p. 10). Coordination systems provide a venue for this collaboration to take place. Of particular importance are those who act as leaders (formally and/or informally) within these coordination systems – these people have the potential to influence and "nudge" instructors towards improving their practice (Rasmussen & Ellis, 2015).

To better understand the nature of coordination systems and instructional leaders, this study combines case study findings with social network data to investigate mathematics departments at five diverse institutions, considering both formal and informal coordination phenomena. This work is guided by the following questions:

1. Who in the department influences instructional practice?
2. To what extent do leaders identified using social network analysis coincide with those in formal leadership positions (e.g., coordinators; chair)?
3. How do leadership roles and influences vary?

Theoretical Perspective and Literature Review

Leadership is a concept with many definitions, though all involve influence. A review of definitions over the last century emphasizes that it is relational, situated, and can be formal

* The Project through Calculus PI team consists of Linda Braddy, David Bressoud, Jessica Ellis, Sean Larsen, Estrella Johnson, and Chris Rasmussen. Graduate students include Naneh Apkarian, Dana Kirin, Kristen Vroom, and Jessica Gehrtz.

and/or informal (Carter, DeChurch, Braun, & Contractor, 2015). By *relational*, we mean that leadership involves relationships between people: for someone to lead, their influence must be felt by others. By *situated*, we mean that a person who leads in some situations may follow in others, it is not an unchanging characteristic of an individual. A key element of the situational nature of leadership is that different characteristics and expertise have different value in different contexts – a person who is considered a leader in one domain (e.g., pedagogy) may not be seen as a leader in another domain (e.g., research). Finally, leadership involves formal and/or informal influence. That is, leadership can originate from positional power (e.g., manager, chairman), or from personal power (e.g., respect, trust), and the two are not exclusive (Carter et al., 2015).

In this study, we focus on *instructional leaders*, whom we conceptualize as those with the ability to influence the practice of instructors in the classroom. This influence may be explicit (e.g., providing advice) or implicit (e.g., conversation partners), and may relate to particular elements of a course (e.g., exams, homework) or be a more diffuse influence on general approaches to instruction. Those in formal positions of leadership can certainly influence the choices others make, but many without formal titles have informal influence. While in some organizations it is possible to mandate actions, instructors at institutions of higher education enjoy a remarkable amount of autonomy, particularly those with tenure. However, even those with complete independence can be nudged toward making certain decisions.

The idea of *nudging*, increasing the chances of a certain decision being made, comes from the work of behavioral economists Thaler and Sunstein (2009). They describe how the moves of choice architects, those who organize the context of decision making, can strongly influence the actions of others without removing their ability to make their own choices. The general principle they recommend is to make it easy for individuals to make "healthy" decisions, and more difficult (though not impossible) to select alternatives. This often comes in the form of setting desired options as a default, providing feedback to choosers, mapping out courses of action, and providing information about others' actions. As detailed by Rasmussen and Ellis (2015), many of these roles are within the purview of course coordinators. This report builds on that previous analysis to include a more diverse set of institutions, some with less formal coordination systems, and instructors of a more diverse set of introductory mathematics courses.

The notion of leadership also necessitates conceptualizing the community of those involved. Toward this end we draw on the communities of practice literature (Wenger, 1998). In particular, we take the point of view that norms and practices related to instruction are part of a continuously developing, shared repertoire which develops through mutual engagement surrounding a joint enterprise. Central members of a community of practice are those perceived as the most expert, and exert stronger influence over the group than newer or more peripheral members. While the departments being studied are not necessarily true communities of practice, they (at least officially) refer to undergraduate instruction as one of the purposes of the department, and one of the responsibilities of instructors and faculty.

Bringing these literature bases together directs our attention to the nature of instructional leadership, the scope of its potential to influence others through social interactions, and the conduits through which people engage and negotiate normative practice and beliefs. We next turn to data sources and how the methods of social network analysis offer an approach for using these data to assess leadership and identify conduits for influence.

Data Collection Methods

Data for this report comes from two research projects, *Characteristics of Successful Programs in College Calculus* (CSPCC) and *Progress through Calculus* (PtC). The CSPCC project surveyed faculty and students across the nation to identify those whose Calculus 1 implementations were more relatively more successful, where success was defined in terms of affective changes, passing rates, and persistence rates. Case studies of these more successful programs led to the articulation of common features, at least at the research universities (Bressoud, Mesa, & Rasmussen, 2015; Bressoud & Rasmussen, 2015). Follow-up surveys and interviews were also conducted at several case study sites, when possible, to further explore the themes and surrounding context. These, and other project findings, influenced the design of the PtC census survey, which investigated P2C2 courses at departments that offer a graduate degree in mathematics (Apkarian et al., 2016; Rasmussen et al., 2016). The five departments investigated in this report come from sites that were selected in the CSPCC study, had follow-up investigations, and participated in the PtC census survey.

Of particular interest to this study are data and findings related to course coordination. From the original CSPCC case studies come interviews with faculty and course coordinators of Calculus 1. From the PtC survey comes information about the coordinated elements, coordinators, and instructor meetings for each P2C2 course. From the follow-up social network surveys comes information about social interactions and relationships between instructors and faculty at each department. Social network surveys are used to ascertain the ties, and strength of those ties, between people by asking participants to identify others with whom they have a particular relationship (Daly, 2010; Kadushin, 2011; Scott, 2012). Our follow-up survey asked about five types of interaction: seeking advice about teaching, seeking instructional materials, discussing instructional matters, friendship, and instructional influence, supplemented with demographic information and Likert scale questions to characterize the actors between whom ties exist or do not exist (Coburn & Russell, 2008; Daly, 2010; Scott, 2012).

Data Analysis Methods

Graph theoretic techniques common to social network analysis were used to identify those with influence over instructional matters (Borgatti, Everett, & Johnson, 2013; Daly, 2010; Kadushin, 2011; Scott, 2012). Table 1 explains the interpretations of participant A selecting participant B for each of the four instruction-specific networks. This interpretation was used to determine what network measures were appropriate for each relationship. This proposal discusses only degree though other more complex measures are being used to ensure the validity of interpretation and to identify more nuanced differences. *Degree* refers to the number of ties that an actor in the network has. An actor's *in-degree* refers to the number of nominations they receive, while their *out-degree* refers to the number of nominations they provide, in a given network. High and low degree values are determined based on the distribution of degrees across all actors in a particular network, rather than in absolute terms.

Table 1. Interpretation of social network survey responses.

If A chooses B for…	…this means that:	The instructional influence being passed is:	An influential actor is identified by:
Advice	A believes B has worthwhile advice	Specific; explicit; primarily from B to A	High in-degree
Materials	A believes B has useful materials	Specific; implicit; primarily from B to A	High in-degree
Influence	A has been influenced by B	Nonspecific; explicit; primarily from B to A	High in-degree
Discussion	A and B have discussed a topic	Nonspecific; implicit; direction indeterminate	High total degree

In addition to identifying actors with high degree values, it is informative to compare an actor's in- and out-degrees to determine their level of involvement (higher degree values = more involved) as well as their perceived function. When someone receives many nominations but provides very few, they function as an authority; when they provide many but receive few, they function as an apprentice (Borgatti et al., 2013).

The social network data was used to determine who in these departments has functional influence on their colleagues' instructional practice. This information was then combined with data from our other sources to understand where positional leadership overlapped with instructional leadership, where it did not, and (to a certain extent) why. Actors with positional authority were identified through their titles, either from official records or interview data. The formal setup of coordination systems (see Table 2) was identified through the PtC census survey data. Interview data from CSPCC case studies reveal nuances about the coordination system, including characterizations of coordinators, attitudes towards the coordination system, and the extent to which cooperation with the coordination systems is enforced.

Results

A first step in this project was to identify basic facts and features of each institution, department, and P2C2 coordination system. Table 2 gives a brief overview of each site, including institutional descriptors, the individuals identified as having positional power related to undergraduate instruction (other than chairpersons), and selected information about the coordinated elements and meetings of P2C2 courses.

Table 2. Characteristics of each institution, department, and P2C2 coordination system.

Instructor meetings	2-4 per term	Weekly	Calc 1 weekly; 1-4 per term for other	1-4 per term	1-4 per term for pre-calculus(es)

**Carnegie Classifications (Indiana University Center for Postsecondary Research, 2015)*

As we begin to describe the results of this project, we remind the reader that leadership is *situated*, and that someone with influence in one domain may not have the same level of influence in other contexts. We reinforce this idea to clarify that if we identify a chair as *not* exerting instructional leadership, this does not mean that there are no contexts in which they are highly influential. Bearing that in mind, we first consider some common features across all five institutions, followed by a more detailed treatment of three sites. Full reports of the remaining two sites have been omitted from this proposal due to space constraints.

General results

At each of the five institutions examined in this study, a few individuals emerge from the social network analysis as instructional leaders with regard to undergraduate mathematics courses. Their formal roles vary, as do the networks in which they appear important, but across all institutions it appears that these individuals are not simply the "most popular" members of the department. Justification comes from usage of the friendship network question – as their position in the friendship network is not extreme, it appears that they are sought out for advice because of perceived expertise or authority, not simply because they are nice to talk to.

In these five institutions, which were identified in the CSPCC study as having relatively successful Calculus I programs, there is overlap between those with formal leadership titles and those who function as leaders via the social analysis. This may be an indication of a "healthy" environment, wherein department members trust in the expertise of those in power. While trust was not one of the explicit questions participants were asked to comment on, looking at those who are sought out for advice and those who are identified as influential can serve as a proxy in the context of instruction.

Large Public University - LPU

This institution's mathematics department has three course coordinators, each specializing in a particular course. While their specific assignments rotate through Precalculus, Calculus 1, and Calculus 2, these three are permanent coordinators and work together as a unit to manage the courses. These three individuals emerged as instructional leaders from the social network analysis. They function as authorities in advice, material, and influence networks, and are highly involved in the discussion networks. In practice, this means that these three are the most likely to be asked for advice or sample materials (thus influencing specific practices explicitly); very likely to be involved in informal conversations about instruction (thus influencing practice implicitly); and considered by many instructors to be the most influential on their teaching practice. Thus we see that the positional authority of all three coordinators is supplemented with real instructional influence, indicating that at LPU the coordination system is functioning as intended. We note that at LPU, the department chair had very low involvement in every network, implying that his/her positional authority does not extend to matters of undergraduate instruction. No other actors appeared to exert significant influence over instructional matters.

Interview data are consistent with the network-based findings. These coordinators are appreciated by other instructors as reliable resources for advice about content as well as teaching. They maintain websites to host instructor resources and sample materials, which are widely used by others. While these three were viewed by their colleagues as leaders, it was noted that they do not insist on every detail, thus allowing instructors independence, even within a coordinated system. At this institution, P2C2 courses are only coordinated during the on-sequence terms of instruction, but many instructors note that they use the coordinated materials no matter which term they are teaching a course, freely choosing to act under the coordinators' influence.

Public Technical University - PTU

This institution has three course coordinators and a lab coordinator, each a multi-year, semi-permanent position. One course coordinator, the lab coordinator, and (to a lesser extent) the department chair emerged from the social network analysis as instructional leaders. The coordinators function as authorities with regards to advice, materials, and influence and are highly involved in the discussion networks; the chair is an authoritative figure in the influence network but does not appear highly involved in advice or materials. In practice, this means that these two coordinators are the heaviest influences on explicit elements of practice (via advice and material sharing); are involved in many conversations about instruction (a more general, implicit influence); and the chair joins them in generally influencing instruction. These three actors appear to have positional power backed up with real influence over instruction, representing a good match between theory and practice. Two other faculty members in the department had high involvement in discussion networks, but not in any of the direct influence networks. They also appeared highly in the friendship network, perhaps indicating that these two are friendly, but not perceived as having any particular expertise in instructional matters.

The CSPCC interview data provides some context and explanation for the result that only one of the three coordinators has real influence over instruction. The influential coordinator frequently takes the helm and provides default options to those working under her; the other coordinators project less authority and consider themselves to be “organizers” rather than supervisors of the coordinated courses. Their decision to operate “on the same level” as the other instructors is apparent from their interviews as well as interviews with instructors, and may explain why they do not exert significant influence over instructional practice in the department.

Private Technical Institute - PrTI

PrTI has one course coordinator and a calculus committee to oversee introductory courses, and the calculus committee is managed by a chairperson. This institution, which is smaller than LPU and PTU, has more distribution of degree than some other places – a sign that leadership is somewhat distributed. However, instructional leaders do emerge from the analyses, coinciding with the course coordinator and the calculus committee chair. Neither appear to function as authorities, but they are the most influential in terms of advice and discussion networks. The committee chair was also identified as a major source of advice. No actors emerged as particularly influential with regards to course materials; no other actors emerged in leadership roles; and the department chair has low involvement in the instructional networks. In practice this indicates that while instructional materials are not influenced by particular members of the department, the positional authority invested in the coordinator and chair of the calculus committee is reinforced by personal power and influence – another instance of a good match between title and role. As with LPU, the department chair’s positional authority does not appear to extend to influence over instructional practice.

It is worth noting that the network analysis identified the committee chair as having influence before his/her position was known. Follow-up investigation of the available data revealed that they did, in fact, have a position which carries some inherent power. The fact that no actor, not even the coordinator, is a major source of instructional materials is made less surprising when we note that this department does not have many uniform course elements – homework and non-final exams are at the discretion of the instructor. This is further supported by the CSPCC interview data, which indicated that the coordinator organizes meetings and provides feedback to instructors, but does not insist on the usage of pre-specified elements.

Public Master’s Universities – PU1 & PU2: A Brief Overview

At both PU1 and PU2 the calculus committee chair and department chair have instructional influence as well as positional authority. Also at each, instructors do not feel particularly restrained by the recommendations of the committee, but there is evidence of collaboration, cooperation, and some informal coordination through the influence of leaders. Moreover, at each the networks are somewhat distributed and the leaders, though they have influence, do not stand out as much as they do at the doctoral institutions we studied.

Discussion

One overarching message from our work is that, despite having significant pedagogical autonomy, university instructors are influenced by their colleagues. Note that pedagogical autonomy is distinct from academic freedom – the former refers to instructional practice in the classroom while the latter refers to research. Our results lend themselves to two related implications: one for the study of leadership in undergraduate departments and one for the potential of social network analysis to inform the change process. We present some hypotheses and questions for future research in this area.

We have discussed the nature of leadership as being relational, situated, and both informal and formal. The theoretical premise and empirical results of this paper lead us to extend these ideas to consider larger systems. The relational nature of leadership lends weight to the consideration of *people* and their interactions within a department, and we highlight again that leadership comes from and is embedded in relationships – it is not an inherent trait of particular individuals. While our work identifies relationships between instructors and faculty members, we have little evidence of relationships connecting members within the department to those outside. We see that centers for teaching and learning are not heavily utilized (when they exist), and there is not much coordination between departments. While administrators (e.g., deans) have some positional power over department activities, they did not appear to be involved in interactions related to instruction. The situated nature of leadership implies that in different contexts, or when considering different domains, the traits that coincide with influence are varied. Our work here focuses on instructional leadership rather than administrative or research leadership, but there are other contextual factors to consider. How does institution size and/or mission affect the nature of leadership? What about institutional or departmental culture? Considerations of departmental culture lead to the nature of leadership as both informal and formal. While formal meetings are held with some regularity in many departments, we do not know the extent to which instructors meet informally with each other. Having identified influence and interactions related to instruction at schools without regular instructor meetings, we believe that informal interactions have some impact on the development of influencing ties. Furthermore, the literature and our data support the idea that titles are neither necessary nor sufficient conditions for instructional leadership.

We believe that this work has implications for those interested in studying or planning change at the undergraduate level. Understanding the readiness of a department for change involves understanding the context and community, without which efforts may well fail (Lee, Hyman, & Luginbuhl, 2007). Identifying those with influence and those with positional authority may go some way to explaining the success or failure of a particular effort – when the two do not coincide there is the potential for subversion via misaligned influences. We may go so far as to recommend social interventions prior to the implementation of change efforts, in the event that the organization (in this case department) is fractured or heavily influenced by an opposition leader – something which can be revealed through social network analysis (Carolan, 2014; Daly, 2010; Lee et al., 2007). We see great promise in coordination systems for instructional improvement. Not only do these systems provide more uniform experiences for students, but a coordinator with both positional and personal instructional influence is in a position to be a choice architect. That is, the default options they set for their colleagues is likely to be accepted and their recommendations are likely to have real implications for instructional practice. Their ability to nudge others makes them a high-priority ally for change agents interested in making a difference (Kezar, 2014; Rasmussen & Ellis, 2015; Thaler & Sunstein, 2009).

Using learning trajectories to structure teacher preparation in statistics

Anna E. Bargagliotti
Loyola Marymount University

Celia Rousseau Anderson
University of Memphis

As a result of the increased focus on data literacy and data science across the world, there has been a large demand for teacher preparation in statistics. Project-SET constructed two hypothetical learning trajectories for teacher learning and subsequently used the hypothetical learning trajectories to structure a professional development curriculum. We illustrate how the utilization of learning trajectories to design professional development allowed participating teachers to develop several aspects of Statistics Knowledge for Teaching (Groth, 2013).

Key words: Learning trajectories, statistics, professional development, teacher preparation

Large-scale research provides some indication of the key characteristics of effective teacher training (Doerr, Goldsmith, & Lewis, 2010; Garet, Porter, Desimone, Birman, & Yoon, 2001; Heck, Banilower, Weiss, & Rosenberg, 2008). These include a focus on content knowledge, opportunities for active learning, and coherence with other learning activities (Garet et al., 2001).

The purpose of this article is to report on how using teacher learning trajectories (TLTs) to design teacher training offers a structure to develop teacher content knowledge in deep and meaningful ways. This study is based on the implementation of Project-SET, a project funded by the National Science Foundation to develop professional development curriculum to enhance teachers' content knowledge of two statistics topics – sampling variability and regression. Project-SET first developed TLTs for these two topics and then designed a professional development curriculum around the trajectories. In exploring the outcomes of the implementation, we recognized the important role that the TLTs played in creating opportunities for teacher participants to achieve different aspects of Statistical Knowledge for Teaching (SKT).

We aim to answer the following research question: *How did the use of learning trajectories to design professional development curriculum support the development of teachers' statistics knowledge for teaching?* Our findings suggest that TLTs offer a promising structure for aiding professional development design.

Learning Trajectories

The idea of a learning trajectory (LT) was initially introduced by Simon (1995) as a way to conceptualize how students might progress through a learning sequence. He stated that a LT included "the learning goal, the learning activities, and the thinking and learning in which the students might engage" (pp. 133). Originally grounded in constructive theory, LTs connect students' thinking and learning for specific mathematical content with a conjectured pathway to move students through a developmental progression (Clements & Sarama, 2004). While all learning trajectories essentially organize learners' thinking and learning, how a learning trajectory is built and the scope for which it is used differs in the literature.

For example, Confrey and Maloney (2010) describe LTs for a several of topics as "a researcher-conjectured, empirically-supported description of the ordered network of constructs a student encounters through instruction (i.e. activities, tasks, tools, forms, of interaction and methods of evaluation), in order to move from informal ideas, through successive refinements of representation, articulation, and reflection, towards increasingly complex concepts over time" (Confrey, 2008; Confrey et al., 2008, 2009). Clements and Sarama (2004) instead focus on early childhood mathematics and describe LTs for narrow sequences of topics.

The LTs constructed by Project-SET differ that those discussed in the literature as they are focused on teachers. In other words, the Project-SET LTs were build and designed to conceptualize *teacher* content knowledge in statistics. Project-SET adapted the definition of a learning trajectory as that of Clements and Sarama (2004): "learning goal, developmental progression of thinking and learning, and sequence of instructional tasks." The learning goal for the trajectories was to address teacher content knowledge on the topics of sampling variability and regression. This goal was coupled with a progression and instructional tasks.

Theoretical Framework

The Project-SET teacher learning trajectories (TLTs) served to guide and develop a professional development for teachers. In applying the LTs to teachers, we intersect LTs with frameworks of teacher knowledge. In particular, we draw upon the Mathematical Knowledge for Teaching (MKT) framework and the Statistical Knowledge for Teaching (SKT) framework (Groth, 2013).

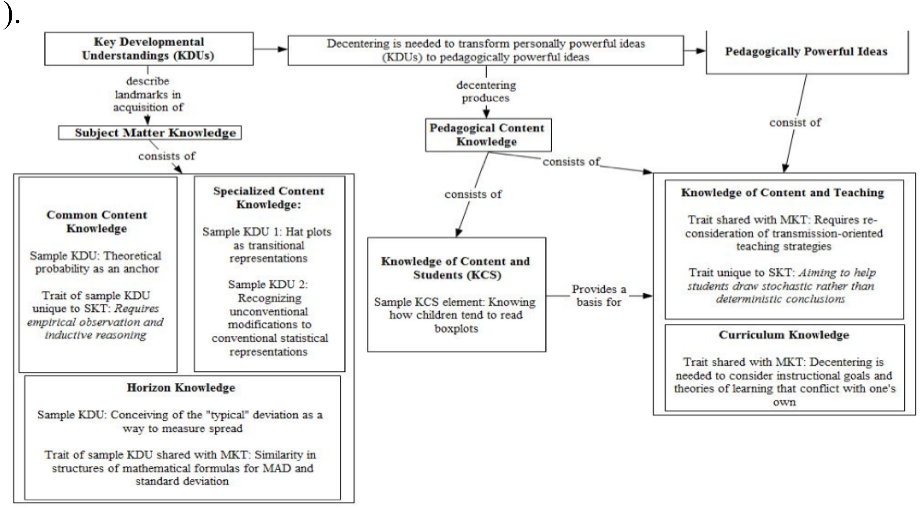

Figure 1 SKT Framework (Groth, 2013, pp. 143)

Groth (2013) identified Key Developmental Understandings (KDUs) as landmarks in the teachers' development of subject matter knowledge. Building from the work of Simon (2006), Groth describes KDUs as significant conceptual shifts. According to Groth, these landmarks or conceptual shifts can occur in each of the three types of subject matter knowledge in his framework (common content knowledge, specialized content knowledge, and horizon content knowledge). Groth's SKT framework also incorporates ideas outlined by Silverman and Thompson (2008) regarding the development of pedagogical content knowledge. In particular, Silverman and Thompson assert that teachers' development of KDUs with regard to subject matter knowledge are a necessary, but perhaps insufficient, first step with regard to improving student learning.

The purpose of the Project-SET professional development was to develop teachers' content knowledge. These TLTs served as guides for the structure of the professional development. Figure 2 represents the relationship between teacher learning trajectories, professional development, and SKT. This study focuses on understanding how this process might work.

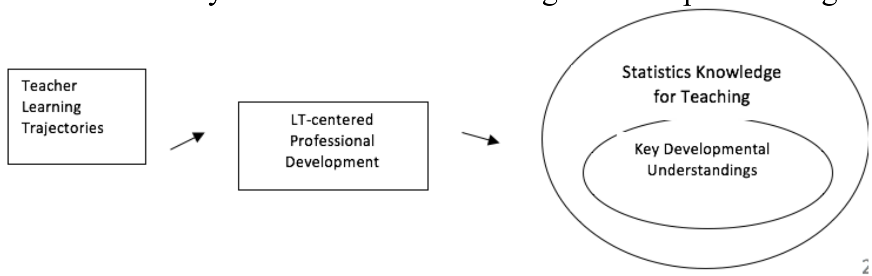

Figure 2. Project-SET Conceptual Framework

Methods

Participants

Nine secondary teachers completed the first implementation of the professional development. Seven of the 9 teachers taught in the local public school district. Two of the teachers taught in a private school within the city. Their average number of years teaching statistics was 2.4.

Data Sources

End-of-Loop Assessment Tasks. Assessment tasks were completed by the teachers at critical points of the LT in order to measure understanding with respect to the content included in the LT. The scoring of each part was modeled after the AP Statistics scoring of: E (Essentially Correct); P (Partially Correct); or I (Incorrect). The assessment tasks were scored each week by two scorers who were part of the research team but not present during the professional development session. The scorers graded the papers separately and then discussed their scores to come to a consensus on the final scores.

End-of-LT Assessment. At the completion of the content of each LT, teachers were assigned as homework an assessment intended to bring together the content of the entire trajectory.

Video of Class Sessions. Each class session of the professional development was videotaped. Outlines of the videos were created and portions of the videos were transcribed. The videos provide a means to confirm and elaborate on the observed patterns of teacher learning documented from the teachers' written work.

Analysis

A two-phase process was used to investigate how the use of TLTs supported the development of SKT, with a particular focus on KDUs. The first phase took place during the analysis of teachers' written work on the End-of-Loop Assessment Tasks and the end-of the LT projects. This analysis provided insight into which ideas were pivotal to teacher understanding thus permitting the research team to identify a preliminary list of KDUs.

In the second phase of the data analysis, these prospective KDUs were then examined through the analysis of classroom interactions. During this phase, the videos were examined in order to determine how teachers' SKT developed as they progressed through the LTs.

Results

We present illustrative examples of the KDUs that we identified along with supporting evidence consisting of samples of teacher work or transcript segments.

Example 1 Common Content Knowledge KDU: Sample Size and the Sampling Distribution

One of the most persistent ideas that surfaced in teachers' work and discussion involved the relationship between sample size and the shape and spread of the sampling distribution. We have identified this as a KDU reflecting Common Content Knowledge in Groth's framework insofar as this is not a concept specific to the domain of teaching.

Teachers repeatedly made statements alluding to the fact that when repeated samples were taken and a sample mean was computed, then the shape of the sampling distribution should become more bell-shaped and the variability of the sampling distribution should decrease. For example, an assessment task for sampling variability asked teachers to compare three different approximate sampling distributions taken with samples of n=5, 15, and 30 according to their shape, variability, and center. There is evidence at this point that the nine teachers developed an understanding of the effect of the sample size on the spread, even if they were not yet clearly articulating the relationship to shape. Three samples of teacher responses are provided:

Table 4. Sample Answers to Loop 3 Task
Assessment task question: Compare the three distributions that you constructed. What can you say about the shape of the distribution as the sample size, *n*, increases? What can you say about the mean? What can you say about the standard deviation?
Teacher Example 1: As *n* increases, the data gets more "compact" around the population mean $27,000 – thus the variation decreases. The mean income was closer to the population mean when n=15 than when n=30, but still both close to $27,000. The standard deviation decreases as *n* increases.
Teacher Example 2: As the sample size increase, the distributions are becoming less spread out. There is less variability in the distributions as the sample size increases.
Teacher Example 3: The shape of the distribution is more unimodal and symmetric, becoming more approximately normal. There is less variation as the sample size n increases. The mean got smaller and then bigger as the sample size increased. However, the mean stayed in the same interval between 25,000 and 30,000. The standard deviation decreased as the sample size n increased. I would expect that trend to continue, but the standard deviation was decreasing at a slower rate as n increased.

The videos of the class sessions provide further support for the assertion that this was a KDU for teachers that the loop design of the LTs fostered. After investigating these ideas over a period of time, teachers expressed different "aha" moments around the effect of the sample size. For example, the activity for Loop 3 engaged the teachers in sampling from four populations with vastly different distributions (bimodal distribution, skewed distribution, roughly normal distribution, and scattered distribution). The teachers took samples of size n=5, n=10, and n=25 and generated approximate sampling distributions for each sample size. They compared the sampling distributions of different sizes and noted the similarities in the effect of the sample size on the sampling distribution.

Instructor: So, tell us what you've got there from Jamal [the bimodal distribution] and what happened with the samples of different sizes? Teacher 6: As you can see, as you increase the sample size, the variability gets smaller and smaller, if you look you are going from 20 to about 110, versus the spread going from 20 to about 80 where for size 10 you are going about 52 to 66, your variability is decreasing.

As the discussion continued, several teachers also compared the sampling distributions to the corresponding population distributions, noting the way in which the distributions with the larger sample sizes behaved in a similar manner, regardless of the distribution of the population. In particular, even when the population had a non-symmetric or bimodal shape, as the sample size increased, the variability of the sampling distribution decreased. During this comparison of the different distributions, one of the teachers, focused on the behavior of sampling distributions of the bimodal population distribution, began to talk through the reasons behind what she had observed.

Teacher 5: No matter what the population looked like, there was a mean. And our data, or our samplings, were samplings of the average. So, they all should have been near the average of the population. No matter what [the population] looked like.

Another teacher builds on this idea and offers an argument for why the variation of the sampling distribution should logically decrease with an increase in the sample size:

Teacher 7: I guess they can't do this because they are obviously...cards, but if we had done N=60, a.k.a. all the cards, it would have just been a straight line at 60... So that like N = 60 literally is just 60, 60, 60, 60 [the mean of the sample] over and over again, just a straight line of 60, *but that would have been a good thing to compare to n = 4, n=10, n = 30*. [Note: The example to which she was referring had a population mean of 60 and a population size of 60.]

In this segment, the teachers appear to not only recognize the effect of the sample size on the spread of the sampling distribution (as with their written work, their descriptions of the shape are not as explicit at this point). They also appear to be creating corresponding mental images of why this makes sense, no matter what the shape of the population is.

The significance of this idea as a KDU is reflected in their own comments a few minutes after the observations from Teacher 5 and 7 described above.

Teacher 3: You know...I'm not sure that I ever understood that...I'm serious. Teacher 5: The light did come on, in terms of understanding what was happening in this activity.

Example 2 Specialized Content Knowledge KDU: Line of Best Fit Counterexamples

Specialized content knowledge, defined in the SKT framework as knowledge of content needed in the practice of teaching, may include teachers' ability to comment on student work and strategize ways they can address student errors. One way to illustrate to students their errors would be to provide students with examples for which their solution will not work. The ability to develop such counterexamples is knowledge specific to teaching.

In the regression LT, the teachers were asked to examine a scatterplot of drop heights versus bounce heights of a golf ball and place a piece of spaghetti on the scatterplot in such a way that they believed represented a line of best fit. Teachers also had to explain what their criterion was for the placement of the line and why they chose to place it there. This same activity had been given to 8^{th} grade students. A second component to the teacher activity was then for the teachers to comment on the 8^{th} grade students' work and, if the work showed a misunderstanding, then provide a counterexample scatterplot that would illustrate to the student that their placement criterion would not be successful in general.

During part one of the activity, all of the teachers created criteria that matched that of the previously collected student data. For example, one teacher asked "do you assume it [the spaghetti] goes through (0,0)?" She noted that in the context of the problem, dropping balls, if you dropped the ball from 0 height, you would get a 0 bounce height. She thus concluded that her line of best fit must go through the origin. This same reasoning was also seen in the student work. Another teacher stated that she placed her line in such a way that "there are 4 dots above and 4 dots below and so it is in the middle." Again, similar reasoning was uncovered in the student work with a student stating that they wanted to "split" the points.

When teachers were given the student results to analyze, they were asked to evaluate whether the criteria the students used to place their line was one that would work for *any* data set. If not, then the teachers were to give an example scatterplot for which their student criteria would not work. This proved difficult for the teachers. For example, one student had the origin criteria similar to one of the teachers. Looking at the student work, she stated: "I think that is a good idea." However, teacher 8 responded by saying "in this case, it [going through the origin] is ok but not all the time." At this point, a conversation emerged as to whether the criterion the student applies must work for any set of linear data or just the golf ball data in front of them. After a short deliberation about what defining a criterion means and how it should be applied, it was accepted that a criterion must work for any set of data. Then, the teachers created the counterexample of a data set that had a negative association and thus would require a line to have a negative slope so it would not enable the line to go through the origin. Although the teachers were able to develop counterexamples to help guide student misunderstandings in the context of the line of best fit, the work was non-trivial.

Discussion & Conclusion

As noted by Simon (2006), for someone to develop a KDU, one must have repeated exposure to the concept. Additionally, according to Simon, students without a KDU "do not tend to acquire it through explanation or demonstration" (p. 362); instead a KDU must emerge through discovery. In this way, a person would be able to shift their understanding and gain a Key Understanding. We gathered evidence to show that the Project- SET LTs offered a platform for teachers to develop KDUs by scaffolding more complex ideas and repeatedly looping for each topic. Due to limitations in space, only two examples were presented above. We assert that the design of the Project-SET activities to progress teachers through the TLT facilitated the development of SKT and the emergence of KDUs. In addition, the TLT also allowed for the conceptual unpacking necessary to develop teachers' knowledge.

The TLTs' mapping created clearly-defined conceptual boundaries that allowed us to recognize when inadequate connections were begin made to horizon content knowledge. Thus, although this is a small study with nine teachers, we see promise in the use of TLTs in the design of teacher preparation curriculum to support the growth of teachers' knowledge. The SKT construct asserts that teacher statistical knowledge for teaching consists of both content knowledge and pedagogical knowledge. We found evidence that building professional development using TLTs can help teachers advance both their content knowledge and their pedagogical knowledge. In addition to the development of subject matter knowledge, we evidenced the translation of this subject matter knowledge into pedagogically powerful ideas.

The goal of this paper was to analyze the affordances of TLTs in the design of professional development. In particular, we sought to understand how the use of TLTs might support the development of SKT, with a particular focus on the KDUs that emerged. Doerr et al. (2010) have identified this type of small-scale study as making important contributions to our understanding of professional development. In particular, through the description and analysis of the "critical elements" (Borko et al., 2008) of the program, it is possible to better understand the teacher learning process and the potential of the program for sustained success.

We view the findings in this paper contributing to the advancement of knowledge and literature base in three ways. First, this study provides small-scale evidence that learning trajectories can not only be used to map student curriculum and learning, but also can be used as maps for teacher curriculum and learning.

A second contribution of this study is the connection of learning trajectories to existing teacher learning constructs such as SKT, KDUs, and Pedagogically Powerful Ideas. This study provides evidence that TLTs offer a means to observe and develop such constructs with teachers.

The analysis of the use of TLTs as a "critical element" of a professional development program suggests that TLTs can offer similar structures for teacher learning that mirror those previously documented for student learning. In particular, the TLTs offered a framework for identifying and achieving KDUs and making instructional decisions based on the KDUs. The TLTs gave the research team a way to see how KDUs were directly related to the development of SKT. Furthermore, the TLTs provided a means for teachers to achieve KDUs due to their repeated exposure while moving through the loop structure of the TLTs. By construction, the TLTs provided scaffolding for KDU development. The repeated exposure illustrated when cognitive shifts were occurring in teachers' knowledge. In addition, this repetition allowed teachers to transform KDUs into pedagogically powerful ideas.

While Project-SET has a specific focus on teachers' statistics knowledge, we submit that the implications for mathematics teacher training are broader than this teacher population. In particular, by focusing on a "critical element" of Project-SET– the use of LTs for teacher knowledge – we assert that the model has potential for other content within mathematics teacher professional development. The use of LTs for teacher learning offers a potentially powerful strategy for developing teachers' knowledge of other concepts within the larger mathematics curriculum.

Interaction, Activities, & Feedback: A Taxonomy of GTA Professional Development

Daniel Bragdon	Jess Ellis	Jessica Gehrtz
Colorado State University	Colorado State University	Colorado State University

In this report we present a taxonomy of mathematics graduate student teaching assistant (GTA) professional development (PD) programs. This taxonomy is based off of the characterization of GTA PD programs from 120 mathematics departments, and is informed by the framework developed by Ellis (2015) based on case studies of four GTA PD programs. A cluster analysis revealed nine distinct models of GTA PD within the 120 programs. These nine models vary with respect to the amount of interaction the GTAs have through the PD, the amount of activities involved in the PD, and the level of feedback given to GTAs involved with the PD. We present a characterization of one of the nine models using Ellis's framework.

Key words: GTA, professional development, taxonomy, institutional change

Graduate teaching assistants (GTAs) are playing an increasingly integral role in the education of undergraduate students at major universities in the United States, serving as both primary instructors of introductory courses and as lab or recitation assistants. Although many of the GTAs coming in to these teaching roles in mathematics departments are likely well-versed in the content of the course they are teaching, this may not be enough (Ball, Thames, & Phelps, 2008). Shulman (1986) and Ball, Thames, and Phelps (2008) argue that teaching also requires an additional type of understanding and knowledge, that of the "organizing principles and structures and the rules for establishing what is legitimate to do and say in a field" (Ball, Thames, & Phelps, p. 391, 2008). Thus, it is essential that GTAs receive adequate training in order to help them to be successful in their roles as teachers.

There are numerous case studies and journal articles (such as Alvine et al., 2007; Belnap, 2005; Barry & Dotger, 2011; Harris, Forman & Surles, 2009; Luft, Kurdziel, Roehrig & Turner, 2004; Wayne et al, 2008) about improving GTA training programs at single universities across the nation. This is further corroborated by a recent national survey in which about 33% of the 210 PhD or Masters granting institutions that responded said that changes to their GTA teaching preparation program are either being discussed or changes have recently/currently been implemented (Ellis, Speer, & Deshler, 2016). One difficulty in evaluating current GTA professional development programs is that there is not an agreement on how this training is defined (Shannon, Twale, & Moore, 1998). Consequently there is a need to create a taxonomy of GTA professional development (PD) programs and an accompanying metric for determining the effectiveness of these programs. The overarching question that guides the analysis in this paper is: *What models of GTA PD are currently being implemented in US mathematics departments where GTAs are tasked with teaching?*

In order to help us characterize the existing GTA training programs, we can gain insight from the PD programs at the secondary level. Graduate students often receive training before they teach (similar to pre-service teachers) and ongoing training while they teach (similar to in-service teachers). In order to develop a characterization of the current GTA PD programs we will also elaborate on the framework given by Ellis

(2015). Ellis's framework "can help direct attention to important components to consider [for a GTA training program], as well as provide a visual representation of the many components" of such a program (p. 12, 2015). Figure 1 provides an outline of the framework and the main components of the framework.

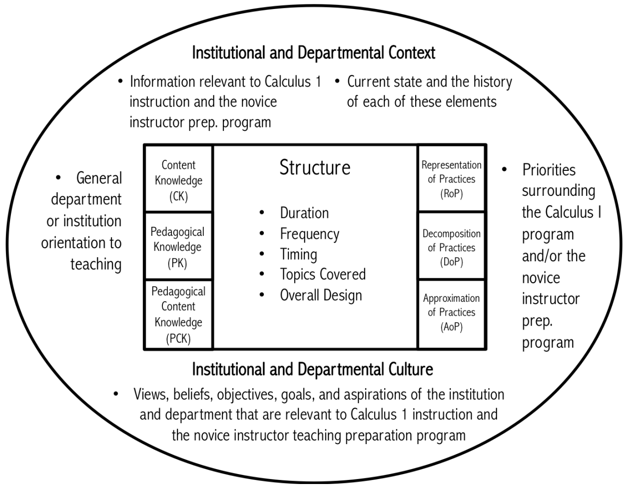

Figure 1. GTA PD framework (Ellis, 2015)

It will be beneficial to test and expand (if needed) Ellis's proposed framework to GTA PD programs across the nation as this framework is currently based on models used by only four universities. The process for collecting the data used to characterize these models was very intensive. In the characterization that we propose, the information that went into categorizing the training programs came from national survey data and did not require site visits and interviews, although these could be helpful in further classifying GTA PD programs. In the discussion section we consider the applicability of the framework based on the data available through the survey.

Methods

The aim of this research is to investigate how graduate-degree granting mathematics departments are training their GTAs, and more broadly refine a systematic classification of such programs. To understand what models of GTA PD currently exist in graduate degree granting mathematics departments, we analyze survey data from the Progress through Calculus (PtC) Census Survey. This survey was sent to every masters and doctoral degree granting mathematics department in the US, and was comprised of questions related to many aspects of the Precalculus through Calculus II (P2C2) sequence, including student placement, what courses the school offers in the sequence, and who teachers these courses and how these courses are taught.

We focus on the section of the survey dedicated to graduate student teaching involvement in the sequence, and the GTA PD involved. The PtC research group (NSF DUE-1430540) and the College Mathematics Instructor Development Source (CoMInDS) (NSF DUE-1432381) research group jointly developed this section of the survey. Overall, the response rate for the survey was 68%. There were 223 schools that completed the GTA section of the survey. Of the 223 schools, we focus primarily on schools who had a department wide training. Only 148 of the 223 schools responded that they had department wide training that was required. Of the 148 schools with department specific training, 120 indicated that their GTAs primarily served as the sole instructor of a P2C2 course. The breakdown of the 120 schools can be found in Table 1.

Table 1. Overview of institutions involved in analysis

Degree Awarded	Undergraduate Population	Number of Schools	% of Schools	% within Degree
Masters	<20,000	29	24%	83%
	>20,000	6	5%	17%
PhD	<20,000	55	46%	65%
	>20,000	30	25%	35%

To understand the main components of the GTA PD programs currently being implemented, we started by looking at each school's responses to five questions on the survey (as shown in Figure 2) related to the structure of the GTA PD.

1. WHEN do GTAs participate in the department's teaching preparation program? Mark all that apply.
- ❑ Before teaching for the first time (e.g., pre-term orientation)
- ❑ During their first term of teaching
- ❑ During their second term of teaching
- ❑ At some point later (e.g., an on-going series of teaching seminars, activities later in the graduate program)
- ❑ Other (please explain)

2. Which of the following best describes the FORMAT of your main activity in the GTA teaching preparation program? Mark all that apply.
- ❑ Short workshop or orientation (1-4 hours)
- ❑ One-day workshop
- ❑ Multi-day workshop
- ❑ Term-long course or seminar
- ❑ Occasional seminars or workshops
- ❑ Other (please explain)

3. Which of the following activities, related to providing feedback on GTA's teaching, does your program FORMALLY include? Mark all that apply.
- ❑ GTAs practice teaching and receive feedback on their teaching
- ❑ GTAs are observed by an experienced instructor while teaching in the classroom and receive feedback on their teaching
- ❑ New GTAs are observed by experienced GTAs while teaching in the classroom and receive feedback on their teaching
- ❑ New GTAs teaching in the classroom are videotaped for review and discussion with a mentor or experienced instructor.
- ❑ GTAs are paired with a mentor to discuss teaching
- ❑ Other (please explain)

4. Which of the following activities, related to evaluating GTAs' teaching, does your program FORMALLY include? Mark all that apply.
- ❑ GTAs are observed by a faculty member while teaching in the classroom
- ❑ Student evaluations required by the institution or department
- ❑ Student evaluations gathered specifically for the purpose of evaluating GTAs (in addition to or separate from those required by the institution or department)
- ❑ Other (please explain)

5. Which of the following other activities does your program FORMALLY include? Mark all that apply.
- ❑ GTAs watch or read cases of others teaching and discuss the teaching
- ❑ Experienced GTAs are observed by new GTAs while teaching in the classroom
- ❑ GTAs develop lesson plans
- ❑ GTAs learn classroom assessment methods
- ❑ GTAs learn about what research tells us about how students learn mathematics
- ❑ Other (please explain)

Figure 2. Survey questions used for analysis

To prepare for the analysis, some of the response options were combined. For instance, we combined responses from schools that indicated their GTAs participate in training before teaching and during their first term of teaching with schools that indicated their GTAs participate before teaching and also at some point later. We felt these two groups could be combined because they both had a pre-teaching training and follow up training. Similar combinations were made to reduce the large number of variables. Our main goal in the analysis was to group schools together based off of their responses to the five questions, with essentially 25 binary yes or no questions.

To help guide us with the grouping we used SPSS to perform a hierarchical cluster analysis. We used Ward's method and, since the data was binary, a squared Euclidean distance and focused our analysis on the dendrogram. From this dendrogram we were given initial groupings of schools. One thing that became quickly apparent was that across the groups the type(s) of evaluation did not significantly vary. We concluded this would not be a deciding factor of our groupings, and thus question four (concerning evaluation) was dropped from our cluster analysis to help make more clear groupings.

Running the analysis again resulted in more distinct groups that we felt we could describe based on the institutions' responses to the remaining four questions. Nine distinct groups emerged from the cluster analysis and were illustrated by the dendrogram. After identifying these nine groups, we determined that the important factors were the amount of interaction (based off of question one and question two) and the amount of activities they were conducting (question five), and that the amount of feedback (question three) seemed to be a function of the level of interaction and the amount of activities involved in the training.

Results

The cluster analysis produced nine groups based off the amount/type of interactions and the amount/type of activities involved in the GTA PD programs. Table 4 has the breakdown of those groups based on the interaction level (low, medium, or high) and the amount of activities involved in the professional development (low, medium, or high).

Table 2. Nine models of GTA PD delineated by interaction level and activities

Model Name	Interaction Level	Activities	Number of programs
Model 1	Low	Low (0-1)	9
Model 2	Low	Medium (2)	13
Model 3	Low	Medium (3)	11
Model 4	Medium-Mixed	Low (0-1)	15
Model 5	Medium-One Semester	Low (0-1)	27
Model 6	Medium	Low (1-2)	15
Model 7	Medium	High (4-5)	9
Model 8	High	Medium (2-3)	11
Model 9	High	High (4-5)	10

The programs that are categorized as *Model 1* have GTAs participate in professional development before teaching their first course, with this training primarily consisting of a short workshop or orientation (1-4 hours) or a one-day workshop. The GTAs do not participate in any of the activities listed on the survey during training. This is considered a model with a low level of interaction and a low level of activities. The type of feedback that the GTAs receive was split between practice teaching with feedback and being observed by an experienced instructor with feedback.

The programs categorized as *Model 2* primarily have their GTAs participate in professional development before teaching their first course with this training either lasting one day or multiple days. Schools using this model include two activities (on average) into the training with the creation of lesson plans and assessments being the most common activities. Model 2 is considered to have a low level of interaction, but a medium level of activities. The feedback for GTAs primarily came from practicing teaching and being observed by an experienced instructor and/or an assigned mentor.

The programs that are categorized as *Model 3* have GTAs participate in training before teaching their first course and lasting either multiple days or continuing for one semester, thus having a low interaction level. Schools using this model incorporate an average of three activities (medium level of activities). The predominant activities are creation of lesson plans, creation of assessments, and the discussion of case studies. Model 3 incorporates several ways of providing feedback to GTAs, including feedback from practice teaching and being observed by an experienced instructor while teaching.

The programs that are categorized as *Model 4* have GTAs participate in training before the first course they teach with ongoing training during their first semester of teaching. Over half of the schools using this model also have training taking place during the GTAs second semester of teaching. The format of these trainings varied across schools ranging from only a few hours of PD and then follow up training that met as a semester course, occasional seminars/workshops, or a meeting schedule that went longer than one semester. Schools using this model are considered as having a medium level of interaction, but use a minimal number of activities as identified by the survey. All of the schools in this group gave feedback to their GTAs by having observations by an experienced instructor and/or an assigned mentor.

The programs that are categorized as *Model 5* have GTAs participate in training before the first course they teach with the training continuing for one semester. This model has a medium level of interaction, with minimal activities conducted during the training. Feedback for the GTAs is primarily from practice teaching and receiving feedback from an experienced instructor and/or an assigned mentor.

The programs that are categorized as *Model 6* have a very similar structure of GTA training and style of feedback as those categorized as Model 5; however, the schools using Model 6 incorporated at least one activity (often two) into the training. The most prominent activities used are the creation of lesson plans and the creation of assessments.

The programs categorized as *Model 7* have GTAs participate in training before teaching their first course and during their first and second term of teaching which is categorized as a high level of interaction. During these trainings, GTAs are involved in a high number of activities (4-5) with the most common among schools categorized in this model being creating lesson plans, creating assessments, and reading research on how students learn mathematics. The amount of feedback given is also high with it coming in the form of feedback from practice teaching, teaching while being observed by an experienced instructor, and one of the following: being videotaped while teaching, being observed by experienced GTAs, or having a mentor.

The interaction level of GTA training of schools categorized as using *Model 8* is similar to that of Model 7, but the level of activities incorporated is considered medium (2-3 activities). The major activities included are creating lesson plans, creating assessments, and discussing case studies or research on how students learn mathematics. The main method of feedback used in Model 8 is practice teaching and being observed by an experienced instructor, with the level of feedback classified as medium.

The schools that are categorized as using *Model 9* have GTAs participate in training before the first course they teach with most school having the training continue through their first semester of teaching. GTAs engaged with a high number of activities (4-5) with all school having GTAs create lesson plans, create assessments, discuss case studies, and observe experienced GTAs and/or discuss research about how students learn.

In Table 4 we present a graphical depiction of the nine models, with the x-axis representing the amount of activities involved in the GTA PD program, and the y-axis the amount of interaction involved. We represent the amount of feedback involved in the PD by the size of the circle in this graphical depiction. This visualization helps to illuminate the apparent positive correlation between the amount of feedback and the amount of interaction and activities. In other words, GTA PD programs that have the GTAs participate more often in the professional development and where the PD involves more activities (represented by the programs in the upper rand hand corner) also provide GTAs more feedback on their teaching. This is worth noting as feedback is beneficial for improving teaching skills, and is thought to be correlated with more effective teaching (Shannon, Twale, & Moore, 1998).

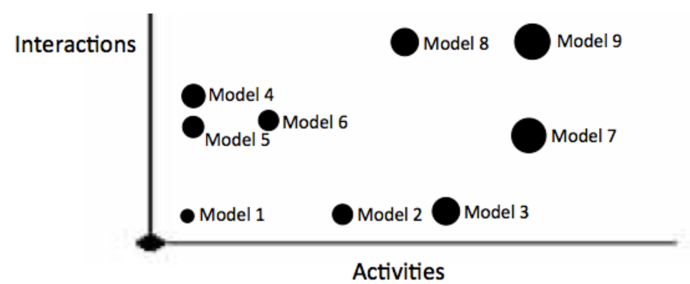

Figure 3. A graphical representation of the nine GTA PD models

Figure 3 helps to identify clusters of models. Model 1 is the least robust, while models 7-9 are the most robust. Models 4-6 have more interaction but less activities involved than Model 1, while Models 2 and 3 have less interaction but more activities. Based on these nine models, it appears that the amount of activities involved may be more related to the amount of feedback provided to the GTAs compared to the amount of interaction (as evidenced by Model 3 compared to Model 4).

Discussion

In this study we set out to determine how graduate-degree granting mathematics departments are currently preparing their GTAs for teaching. We approached this problem scientifically by developing a taxonomy of the characteristics of GTA PD programs. This taxonomy was informed both by Ellis's (2015) initial work to this end, and by the structure that emerged through the cluster analysis illustrated through the dendrogram. After identifying the nine models of GTA PD that currently exist across the country in graduate-degree granting mathematics departments based on this taxonomy, we can begin to explore a metric for comparing GTA PD programs and to aid in the development and improvement of such programs. In this discussion, we briefly explore the applicability of Ellis's (2015) framework to the models identified through the cluster analysis and based on survey data.

When Ellis (2015) initially began work on the taxonomy she created a framework to characterize GTA PD programs based on in-depth case studies of four programs. These case studies provided a large amount of information, but were time and resource intensive. We wondered if the information provided by the census survey would be sufficient to characterize our nine models using her framework. To do this, we identified relevant questions in the census survey and conducted basic descriptive statistics to determine the average responses for each cluster of schools per model. We attended to the structure of the program, the types of knowledge and pedagogies of practices emphasized in the structure, and the institutional and departmental context and culture, as described in Figure 1. We were happy to find that we were able to characterize each aspect through survey questions, though there is inherent bias in the survey based on the subjectivity of who answered the survey, whereas with case study data collection it is possible to triangulate findings. Due to space limitations, we characterize only Model 8 in this representation, as shown in Figure 4.

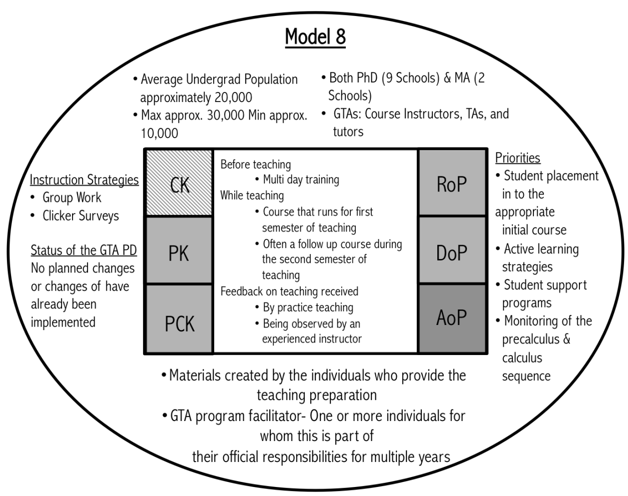

Figure 4. Characterization of Model 8 using Ellis's (2015) framework

In the presentation we will explain this characterization in depth, including the shading for the types of knowledge and practices, and compare this model to another using the oval representation. We will also explore what the taxonomy tells us about a metric for evaluating and comparing programs, and what the direct implications of this work are for mathematics departments seeking to improve their GTA PD program.

Difficult Dialogs About Degenerate Cases: A Proof Script Study

Stacy Brown
California State Polytechnic University, Pomona

Abstract: The purpose of the reported study is to explore students' reasoning about the "within argument contradictions" that arise from logically degenerate cases by analyzing the problematics noticed in students' proof scripts. The work proposes a framework for students' noticed proof problematics and explores the viability of the proof script methodology as a mechanism for identifying difficulties experienced by students but unseen by experts. In the case of logically degenerate cases, findings indicate students held conceptions of proofs by cases that inhibited students' reasoning about the encountered contradictions.

Keywords: Proof by contradiction; proof scripts; proof comprehension; proof by cases

Research on students' understanding and production of proofs by contradiction indicates that this form of proof is exceptionally difficult for students (Robert, & Schwarzenberger, 1991). In a reflective account of multiple teaching experiments, Leron (1985) proposed students' difficulties with proof by contradiction are rooted in a preference for constructive as opposed to destructive arguments, in part because the latter require learners to reason against that which is "real" to them. Harel and Sowder (1998) reported on multiple teaching experiments with undergraduates and observed that students don't use proof by counterexample and are not convinced by proof by contradiction. Like Leron, they argued students' difficulties are tied to ways of thinking in which ascertainment is reliant on constructive approaches; that is, students' reasoning with a constructive proof scheme. In contrast, in their study of young children playing the game Set, Reid and Dobbin (1998) reported observations of children spontaneously reasoning with informal contradiction arguments when convincing others of the validity of their solutions. And, Maher and Martino (1996) reported similar findings from their longitudinal studies of children's combinatorial reasoning. Hence, studies on students' views of indirect proof have offered disparate views. In work that bridges these conflicting reports, Antonini and Mariotti (2008) analyzed instances of students producing informal contradiction arguments but experiencing difficulties linking those arguments to formal proofs by contradiction. Thus, the conflicting reports may be related to the level of formalism expected.

Attending to the specific demands of indirect proofs, researchers have noted particular sources of difficulty. Taking a more syntactical approach, Wu, Lin, and Lee (2003) found that students were rather unsuccessful negating quantified statements. In relation to inferential practices, Antonini and Mariotti's (2006) analyses of interview protocols illustrated how, when students assume a true statement is false, they may experience difficulties understanding the ramifications of this assumption for they assume that other true statements may be false in this new "absurd world." And, Antonini and Mariotti (2008) documented how students' difficulties with indirect proofs (proofs by contradiction and proof by contraposition) can be tied to students' difficulties accepting the logical "theorems" that allow for indirect proofs; e.g., the tautologies $(P \Rightarrow Q) \equiv (\sim Q \Rightarrow \sim P)$ and $(P \Rightarrow Q) \equiv \sim (P \wedge \sim Q)$. Taken together these studies show that students may encounter a myriad of difficulties that are specific to proofs by contradiction.

One issue with the existing research, however, is that much of the research on students' understanding and production of proofs by contradiction has been generalistic in nature rather than focused. By this I mean that while researchers have argued that students dislike and are not convinced by proofs by contradiction, there is little empirical evidence related to the specific features students attend to which foster students' reactions and their subsequent lack of conviction or dislike of proof by contradiction, with the exception of the work of Antonini and Mariotti (2006, 2008). Indeed, their work has demonstrated connections between: (1) students' difficulties at the level of the logical theory and their lack of acceptance of proofs by contraposition; and (2) students' lack of conviction and students' confusion regarding which mathematical statements hold true and can be reasoned with when assuming a true statement is false. Yet, despite this progress, further research is needed on students' understanding and production of proofs by contradiction. There are two reasons for this claim. First, outside of research in geometric contexts, existing research has primarily focused either on basic conditional statements, "If n^2 is even then n is even" (Antonini & Mariotti, 2008) or non-compound statements, "there exists infinitely many primes" (Leron, 1985) and "$\sqrt{2}$ is irrational" (Tall, 1979). Yet, contexts that recurrently call for reasoning with contradictions have not been studied; such as, proofs of existence, nonexistence, disjointness, or those involving logically degenerate cases. Second, research on proof by contradiction has primarily involved interview protocols and assessments in which students' attention to and reasoning about proofs by contradiction are elicited by a knowledgeable other, whose questions provide a focusing effect. While both approaches are commonly taken by researchers and are of value, there is reason to question the types of difficulties students "see" when they are not engaged in communications that direct students' attention (e.g., structured interviews or comprehension tests). Stated another way, little is known about students' *problematics*; that is, "what students themselves see as issues of difficulty" (Koichu & Zazkis, 2013, p. 364). Indeed, as Koichu and Zazkis argue:

> As a rule, students' difficulties with constructing and understanding proofs are exposed by means of documenting and interpreting their (often poor) performance when coping with various proving tasks. This research approach implies that students' understanding of proofs and their difficulties are mainly examined from an expert point of view (p.364).

To move away from methodologies that necessarily employ preselected foci and assume the difficulties determined *a priori* by experts will coincide with those experienced by students, researchers have begun to build on the "lesson play" methodology developed by Zazkis, Liljedahl, and Sinclair (Zazkis, Liljedahl, & Sinclair, 2009; Zazkis, Sinclair, & Liljedahl, 2009; Zazkis, Sinclair, & Liljedahl, 2013) and the dialog methodologies of Gholamazad (2006, 2007) to develop techniques for examining students' proof "problematics" through students' *proof scripts* (Koichu & Zazkis, 2013; Zazkis & Zazkis; 2014). At the most basic level, the proof script methodology involves asking participants to write a dialog between characters in which the two characters discuss points of difficulty and resolve problematic issues. Building on Sfard's (2008) theoretical work, which views cognition as a form of interpersonal communication, researchers employing these methodologies have argued proof scripts provide an avenue by which participants may make "personal thinking salient."

The Study

The purpose of the reported study was to explore students' reasoning when confronted with within argument contradictions that arise from logically degenerate cases. A *logically degenerate case* is a case in which the case's assumption lead to a contradiction with the constraints of the mathematical statement or a definition, axiom, or property of the reference theory.[i] Such cases are not only common when proving basic properties of the real numbers (e.g., in proofs that use the Law of Trichotomy) but also occur in a variety of divisibility and topology proofs. Moreover, it was observed during prior teaching experiments that there are theorems for which one may produce a simple proof by contraposition or a direct proof involving logically degenerate cases. Among those seeking to avoid the Law of Contraposition, difficulties occurred interpreting the consequences of the contradictions encountered, when the overall structure (and the student's intention) was that of a direct proof. Building on prior work, the reported study aimed to document students' ways of reasoning about contradictions arising from logically degenerate cases by examining the *problematics* evident in students' proof scripts.

Data Collection

This research is part of a larger study on students' reasoning about and production of indirect proofs. For the purposes of this paper, we report on the *proof scripts* produced by 20 students randomly selected from two, inquiry-based "Introduction to Proof" courses at the end of the academic term. Students enrolled in these courses were either mathematics majors or minors, at a designated Hispanic-serving institution, where the majority are first generation college students and are eligible for need-based financial assistance. Collected proof scripts were blinded of students' names and scanned into a database, prior to the instructor's markings.

The scripting task instrument included instructions for the dialog and a line-numbered proof of the theorem "For every integer m, if $3 \nmid (m^2 - 1)$, then $3|m$". The scripting task (see Figure 1) was assigned as homework, so students had access to their texts, course notes and other resources.

Instructions: Create a 1-2 page dialogue that introduces and explains the theorem and its proof. Highlight the problematic points in the proof with questions and answers. In your submission:

- The dialogue should occur between two students, you and a mathematics student named Gamma, which you can denote with either Γ or γ.
- Start by reading the proof and identifying what you believe are the "*problematic points*" for a learner when attempting to understand the theorem/statement or its proof. List these "*problematic points*" in a bulleted list.
- **Write a dialogue** between you and Gamma in which you explain the theorem and the proof to Gamma, paying special attention to the *problematic points* you identified and listed in your bulleted list. In the dialogue you should both pose questions to Gamma and answer any questions Gamma might ask. (THIS IS THE MAIN PART OF THE ASSIGNMENT)
- You may add comments at the end or within the dialogue using [ ], explaining your questions or answers, if these are not obvious to the reader.

Theorem: For every integer m, if $3 \nmid (m^2 - 1)$, then $3|m$

1) *Proof*: Assume $3 \nmid (m^2 - 1)$.
2) Since $(m^2 - 1) = (m + 1)(m - 1)$, we can say $3 \nmid (m + 1)(m - 1)$.
3) By a previous theorem we know,
4) if $3 \nmid (m + 1)(m - 1)$ then $3 \nmid (m + 1)$ and $3 \nmid (m - 1)$.
5) Since $3 \nmid (m + 1)$, it follows from the Division Algorithm, that
6) $(m + 1) = 3k + 1$ or $(m + 1) = 3k + 2$ for some integer k.
7) *Case 1.* Let $(m + 1) = 3k + 1$
8) Then $m + 1 - 1 = 3k + 1 - 1$
9) $m = 3k$
10) Since k is an integer, $3|m$.
11) This is our desired result.
12) *Case 2.* Let $(m + 1) = 3k + 2$
13) Then $m + 1 - 1 = 3k + 2 - 1$
14) $m = 3k + 1$
15) $m - 1 = 3k + 1 - 1$
16) $m - 1 = 3k$
17) Since k is an integer, $3|(m - 1)$,
18) This is a contradiction.
19) It follows from *Case 1* and *Case 2*, that $3|m$. □

Figure 1. Proof Script Assignment [ii]

This particular proof was chosen for two reasons. First, one can either prove the statement directly, with the possibility of logically degenerate cases[iii] (as shown above) or one can write an indirect proof using use the Law of Contraposition. Since researchers have argued that students' prefer direct proofs, the selected proof afforded an opportunity to explore students' reasoning about the outcomes of their potential proving proclivities. Second, as mentioned above, the proof was produced by a group of students during a previous teaching experiment. Thus, it was an "authentic" student proof, by which I mean that it arose from students' mathematical activities, as opposed to an expert's. In that experiment, the authoring students asked to share the proof with the class, for they were uncertain of the proof's validity. Thus, there was reason to posit not only that students' might produce such proofs but that they might find them problematic. Indeed, during the prior teaching experiment the proof fostered an extensive debate about how to interpret the contradiction encountered. Thus, the proof was viewed as providing a fruitful venue for exploring students' reasoning about contradictions arising from logically degenerate cases.

Analytic Methods

Taking the perspective that asking students to produce dialogs around observed *problematics* is akin to asking students to share and elaborate on the difficulties noticed, the analytic methods employed in the study were heavily influenced by the construct of *noticing* (Mason, 2002; Jacobs, Lamb, Philipp, & Schappelle, 2011; VanEs, 2011). Building on Mason's work (Mason, 2002; 2011) it was hypothesized that noticing requires "a movement or shift of attention." Drawing on the work of Jacobs, Lamb, Philipp, and Schappelle (2011), it was posited that attending to noteworthy aspects and potential complexities is a sign of expertise. Thus, one can interpret "difficulties attending to difficulties" as indicative of one's need to grow expertise rather than as indicative of expertise. Drawing on the work of VanEs (2011), it was argued that noticing of complex phenomena is marked not only by *what* is noticed but *how* one notices; in particular, the extent to which one can accurately describe, focus on, or extend an observation is indicative of one's emerging level of expertise.

To analyze students' proof scripts, VanEs's (2011) "framework for learning to notice," which was developed to characterize teachers' noticing of classroom lessons, was adapted to examine two dimensions of students' noticing: what proof problematics students noticed and how students noticed those proof problematics. Specifically, three levels, which are defined in Table 1, were used to characterize the foci of students' dialogs and the depth of engagement with those foci.

FRAMEWORK FOR STUDENTS' NOTICED PROOF PROBLEMATICS			
Dimension	**Level 1**	**Level 2**	**Level 3**
1. What students noticed (i.e., students' identified problematics and other dialogical foci).	(*a*) Identifying (perceived) rudimentary errors, wording refinements, instances in which the naming or stating of definitions or theorems could add clarity, or (*b*) failing to attend to the proof by dismissing the proof in its entirety.	Addressing level 1 issues <u>*and*</u> potential points of confusion that are in need of clarification due to the application of content, theorems, or linkages between consecutive statements.	Addressing level 2 issues <u>*and*</u> identifying potential points of confusion across sets of statements or related to potential consequences of a sequence of statements or the logical architecture of a proof.
2. How students noticed (i.e, students' ways of attending to problematics and other dialogical foci).	Remarks are limited to correcting rudimentary errors, reiterations of lines of the proof in a "lecture-oriented" dialog or a single speaker monolog, or to assertions. (Note: Corrections may contain errors.)	Engaging with *problematics*, beyond the rudimentary level, to explore potential rationales or implications but in a perfunctory manner. (Note: Rationales or implications may include errors.)	Attending both holistically <u>and</u> locally to *problematics* so as to link the content and structure of the proof. (Note: Linkages may include errors.)

Table 1. The Framework for Students' Noticed Proof Problematics

What students' noticed (Dimension 1) was determined by comparing the student's bulleted lists to the students' written dialog, so as to produce a list of attended to proof problematics. *How* students' noticed (Dimension 2) was determined through analyses of the rationales, claims, and backing (if any) the student explicitly provided when attending to proof problematics.

Prior to data collection, it was anticipated that students would: (1) remark that a variable *m* is introduced but not defined; and, (2) experience difficulties determining the appropriate number of cases, i.e., incorrectly argue additional cases arise from the statement $3 \nmid (m - 1)$. In relation to the logically degenerate case, it was anticipated that students' might view the contradiction in Case 2 as implying the entire proof was a proof by contradiction and, therefore, that the original theorem was false. No other difficulties were anticipated prior to data collection.

Results

The coding of the students' noticed *proof problematics* indicates the majority of novices experienced a great deal of difficulty interpreting and attending to the given proof, for nearly half of the students (9 out of 20) produced *Level 1* proof scripts; that is, proof scripts focused on rudimentary errors or wording refinements, without attention to conceptual issues, linkages across statements, or the logical architecture of the proof. With regard to the given proof, typical characteristics of the Level 1 scripts included: (1) an extended discussion on the need to define the variable m; (2) incorrectly claiming cases were missing for the statement $3 \nmid (m - 1)$; and, (3) a verbatim reiterations of lines 12 – 18 coupled with a lack of attention to the role/ramifications of the logically degenerate case, which I will refer to as the *within-case contradiction*. The following written dialog excerpt illustrates a Level 1 response with characteristic (3):[iv]

<u>*Example 1*</u>

Student 1: (written dialog reiterates lines 13 – 18 verbatim)

Gamma: Damn, we got it wrong.

Student 1: No we didn't. This was our desired result, so in the end we got it right.

Gamma: Cool.

Student 1: So once we proved the cases, we can write this 'Since both cases had the desired results, we can say that $3|m$, therefore the statement is true.

Level 2 dialogs were produced by 8 of the 20 students. These responses differed from the *Level 1* dialogs in that beyond addressing rudimentary issues, the students' dialog clarified content and explained the application of theorems and/or linkages between consecutive statements. With regard to the given proof, common characteristics of *Level 2* scripts included: (1) specifically stating and clarifying the application of the "previously proved theorem;" (2) explaining how to apply the division algorithm and/or the meaning of "$a|b$"; and, (3) addressing the within-case contradiction in a perfunctory manner either by merely identifying the statement that was contradicted or by suggesting alternative proofs. Indeed, several students' remarks were limited to asking Gamma to find the contradicted statement; namely, $3 \nmid (m - 1)$. And, many either informed Gamma that the within-case contradiction implied the entire proof was a proof by contradiction (see Example 2) or told Gamma that "a stronger argument" would have been a proof by contraposition, with several providing the proof by contraposition.[v]

<u>*Example 2*</u>

Gamma: In Case 1, the statement is manipulated to show that $m = 3k$, then by definition 27 we write $3|m$, which is the desired result.

Student 2: We can see that the right idea is being established. In Case 2, the same process is used but results in a contradiction.

Gamma: Case 1 gives us the desired result but case 2 does not.

Student 2: Therefore, since Case 1 results $3|m$ but Case 2 results $3|m$-1, the original statement is false. [- *End of dialog* -]

Level 3 dialogs were produced by 3 of the 20 students. These responses differed from the *Level 2* dialogs in that beyond addressing rudimentary issues and clarifying definitions or theorems, *Level 3* students attended to the conjuctive structure (i.e., the logical "and") of the statement "$3\nmid(m+1)$ and $3\nmid(m-1)$" and attempted to address (either successfully or unsuccessfully) questions concerning the meaning of the within-case contradiction. Regarding the unsuccessful attempts, these students ($n = 2$) argued that the Division Algorithm resulted in "*or* cases" and, consequently, one case could be "false" or omitted. Example 3 illustrates responses of this form. Moreover, it should be noted that brief remarks indicative of similar reasoning were present in some *Level 2* dialogs (see Example 4), but these dialogs did not meet the criteria of the *Level 3* responses.

<u>*Example 3*</u>
Gamma: Case 2 has proven that $3|(m-1)$ which is the contradiction of $3|m$. Then does that mean the theorem is false?[vi]
Student 3: From line 6, it is stated that the remainders are 1 or 2, that means only one case is needed to be true for the $3|m$ to be true. Moreover, Case 2 is not quite necessarily needed when Case 1 is already proven to be true to make the theory true. [- *End of dialog* -]

<u>*Example 4*</u>
Gamma: … Case 2 ends in a contradiction, does that mean that the whole proof is wrong?
Student 4: Not at all! We were looking for only 1 case to be true, in terms of the value of *r*. We obtained our desired result in Case 1 already.

Regarding the successful attempt, the student argued that the contradiction arose from an earlier statement in the proof "$3\nmid(m-1)$" and that $m + 1 = 3k + 2$ could not occur under the theorem's given constraints. In so doing, the student moved beyond the Division Algorithm's disjunctive structure to make connections across statements and (correctly) conclude the case was logically degenerate (i.e., can't happen), under the conditions $3\nmid(m+1)$ *and* $3\nmid(m-1)$.

Discussion

The purpose of the reported study was to explore students' reasoning when confronted with *within argument contradictions that arise from logically degenerate cases* by examining the proof problematics students identified and attended to in their scripts. The aim of employing proof scripts, rather than clinical interviews or comprehension assessments, was to create a context within which students could make their "personal thinking salient" and articulate the *problematics* visible to students but potentially unseen by experts. Certainly, the findings suggest the methodology afforded these opportunities. Neither the students' beliefs related to "or cases" and nor the students' general lack of attention to the within-case contradiction were anticipated.

In regard to students' efforts to account for the contradiction by arguing it was a consequence of the disjunctive result of the Division Algorithm, it appears that many of the students incorrectly reasoned $[(A\vee B) \Rightarrow C] \equiv [(A\Rightarrow C)\vee(B\Rightarrow C)]$ rather than reasoning $[(A\vee B) \Rightarrow C] \equiv [(A\Rightarrow C)\wedge(B\Rightarrow C)]$. In other words, the students appear to have extended the logical "or" linking the statements derived from the Division algorithm ($m + 1 = 3k + 1$ or $m + 1 = 3k + 2$) to the (implicit) connective linking the cases. Consequently, the students viewed the cases as "*or*-cases." This response may explain why so few students attempted to relate the contradiction to the concomitant constraint $3\nmid(m-1)$. While difficulties making connections broadly across statements within a proof might not be unexpected when studying novices, and have been discussed by others (Selden & Selden, 2003), the students' views of proofs by cases (if prevalent) are unexpected. Moreover, they could suggest a serious misconception. Consideration of the ways such reasoning might manifest itself leads one to imagine a similar scenario in which when asked to prove, "if n is an integer, then $2|(n^2 - n)$," these students might (incorrectly) argue:

> By the Division Algorithm, $n = 2k$ or $n = 2k + 1$. If $n = 2k$, then $(n^2 - n) = 4k^2 - 2k = 2(2k^2 - k)$. Since $(2k^2 - k)$ is integer, $2|(n^2 - n)$. The result follows.

And, the instructor might note "you forgot the case $n = 2k + 1$" thinking the student was being absentminded, when in fact the student was acting on a conception of or-statements in proofs by cases. Indeed, such difficulties would be difficult to recognize from the experts' point of view.

In regard to the students' general lack of attention to the *within-case contradiction*, it is surprising that nearly half of the students produced *Level 1* dialogs in which the student avoided engaging with the contradiction. How might such low level responses be accounted for? One reason may be that the responses are reflective of the students' classroom experiences and the students are accustomed to *problematics* arising that are either ignored or are only given cursory explanations by their instructors. In such circumstances, the student may simply be attempting to follow the *modus operandi*. It is also possible that, despite the fact that the dialogs were graded (or perhaps due to their being graded), students avoided issues they felt inadequately prepared to address even though, in the students' eyes, they were *problematics*. In such situations, a lack of attention would indicate a higher degree of confusion rather than understanding. Such an account of the dominance of *Level 1* responses is reasonable, for as researchers (Mason, 2002; Jacobs, Lamb, Philipp, & Schappelle, 2011; VanEs, 2011; Sherin, 2001) studying noticing have argued, noticing of complexities requires expertise – a point cleverly illustrated by Sherin (p. 75):

> Imagine that you are standing at the site of an archeological dig. On your left, you see a large rock with a dent in the middle. Next to it you see a pile of smaller stones. Aside from this, all you see is sand. An archeologist soon appears at the site. What looked like just a rock to you, he recognizes as the base of a column; the small stones, a set of architectural fragments. And where you saw only sand, he begins to visualize the structure that stood here years before.

Thus, the prevalence of *Level 1* proof scripts might speak to the students' need to further develop their expertise. Indeed, the predominance of *Level 1* scripts coupled with the prevalence of students' incorrect conclusion related to the Division Algorithm and students' belief that additional cases were required for $3\nmid(m - 1)$, lead to significant concerns about the student reasoning that occurs when such proofs are presented in lectures and the opportunities required (but likely not afforded) for students to develop appropriate interpretations. Indeed, recent work by Lew, Fukawa-Connelly, Mejia-Ramos, and Weber (2016) on advanced mathematics lectures suggests that direct approaches (e.g., stopping to remark on such issues) might not be effective. And, as noted by Hemmi (2008), "Teachers' intentions of focusing on certain things in their presentation do not necessarily imply that these aspects become visible to students" (p. 424). Thus, future research is needed on how, within the various didactical constraints, students' proof *problematics* might not only be elicited but also productively addressed in classrooms, which seek to develop students' understanding of proof in advanced mathematics.

---

[i] In mathematics the phrase *degenerate case* is used to refer to a case that is qualitatively different from and often simpler than the other cases, for it belongs to a simpler class of objects or has some other features that distinguishes it from the class of objects. In line with this definition, the phrase *logically degenerate case* is being used to refer to cases that result in contradictions and are, therefore, qualitatively distinct from those cases by which one produces a desired result.

[ii] The previously proved theorem was "For any integers x and y, if $3 \nmid xy$ then $3 \nmid x$ and $3 \nmid y$.

[iii] I have used the phrase "with the possibility" because one may avoid degenerate cases by arguing after line 4 that the integers $m - 1$, m, and
$m + 1$ are consecutive integers and then prove that for any triplet of consecutive integers one member of the triplet must be divisible by three.

[iv] Due to space limitations, the discussion of students' dialogs will be focused on the primary research question of how students reasoned about the within-case contradiction.

[v] Examples of this type of response have been excluded due to their length.

[vi] Earlier in the dialog the student had argued that 3 could not divide two consecutive integers.

Stages of development for the concept of inverse in abstract algebra

John Paul Cook
Oklahoma State University

Rosaura Uscanga
Oklahoma State University

In this study, we conducted a teaching experiment with two students to investigate the development of a generalized concept of inverse in abstract algebra. In particular, we document the stages through which the students' reasoning progressed, initiating with an understanding of the additive inverse of an element as the result of a procedure applied to that element, and concluding with a generalized understanding of inverse that was broad enough to identify instances of inverses in various and unfamiliar algebraic structures. Of critical importance was the development of and coordination with a corresponding concept of identity.

Key words: student thinking, abstract algebra, Realistic Mathematics Education, teaching experiment

Introduction

The concept of inverse is prevalent in abstract algebra and is used to define such foundational algebraic structures as ring and field. Inverses are a key concept in secondary algebra as well and have been stated as a direct connection that pre-service teachers should make between their advanced coursework in abstract algebra and the algebra they will be teaching (CBMS, 2001). Accordingly, as abstract algebra is intended to be "the place where students might extract common features from the many mathematical systems that they have used in previous mathematics courses" (Findell, 2001, p. 12), the inverse concept – like the other properties that characterize rings and fields – is certainly familiar to abstract algebra students from previous courses. What makes inverse unique, perhaps, is the wide variation it exhibits across different contexts. Consider, for instance, the following examples of inverse from the undergraduate curriculum that reappear in abstract algebra:

- Inverse of a complex number: if $a + bi$ is nonzero, then $(a + bi)^{-1} = \frac{a}{a^2+b^2} - \frac{b}{a^2+b^2}i$.
- Inverse of an integer modulo n: if $\gcd(a, n) = 1$, then $a^{\phi(n)-1} \equiv a^{-1} \pmod{n}$.
- Inverse of a matrix: if $A = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$ and $ad - bc \neq 0$, then $A^{-1} = \frac{1}{ad-bc}\begin{bmatrix} d & -b \\ -c & a \end{bmatrix}$.

These few examples are widespread and varied, each largely dependent on its mathematical context. Without coordinating the binary operation with these examples of inverse and their respective identities, there are few surface-level indications that these are all direct implementations of the same overarching concept. The key notions of the generalized inverse concept – that the inverse of a given element is the element that, when combined with the given element, yields the identity – might be obscured within specific examples of inverses. Though students would likely recognize such examples of inverse within each context, research suggests that it might be challenging to recognize commonalities amongst these examples that reflect a generalized inverse concept. In particular, familiarity with algebraic properties prior to abstract algebra does not guarantee proficiency with these properties in abstract algebra (e.g. Larsen, 2010). Additionally, when working with examples, students attempt to overgeneralize in order to reduce the level of abstraction (e.g. Hazzan, 1999) and struggle to focus their attention on productive facets of the example structure (e.g. Simpson & Stehlikova, 2006). Thus, it is unclear if and how introductory abstract algebra students might identify these examples as instances of a general notion of inverse. This observation motivated our central research question: how might students in abstract algebra come to understand a generalized notion of inverse in a way that enables them to recognize instantiations of inverse within various structures? We propose that it is the coordination of the inverse concept with a corresponding concept of the *identity* that is critical to using and recognizing inverses in abstract algebra. Analyzing results from a ring theory teaching experiment, we document three stages of development for the inverse concept through which two undergraduate students progressed as we guided their reinvention of the concept of ring.

Literature

Much of the research pertaining to inverses provides characterizations of students' understanding of particular kinds of inverses, such as the reciprocal of a rational number (e.g. Tirosh, 2000), inverse functions (e.g. Even, 1992), and inverse matrices (e.g. Wawro, 2014). We focus on those papers describing student activity with inverse (1) across multiple contexts and (2) in abstract algebra.

Use of the Superscript -1 Symbol Across Multiple Contexts

Consistent with our observation above that the varied manifestations and contexts in which inverses arise might prevent students from noticing that each is an instance of the same underlying concept, Zazkis and Kontorovich (2016) pointed out a discrepancy related to potential interpretations of the superscript -1 symbol in a study of students' lesson scripts. For example, 5^{-1} can be interpreted as the reciprocal of the rational number 5, whereas f^{-1} refers to the inverse of the function f, a concept that itself admits various interpretations. For example, students might interpret f^{-1} algebraically (switching x and y and solving for y), graphically (reflecting the graph of f about the line $y = x$), or as the result of reversing or undoing the function f (Carlson & Oehrtman, 2005; Even, 1992). In accordance with these contextually varied interpretations, many students (15 of 22) described the superscript -1 as "the same symbol applied to different, unrelated ideas" (p. 103). All other students viewed the superscript as having "different but related" (p. 107) meanings, each depending on the context in which it is used. One of these students wrote that "we have an example of using the same symbol or same word in different contexts. Both are inverse … a multiplication inverse means 1 over, and an inverse function is when you switch x any y." There are no substantial commonalities amongst her descriptions; her use of the word "inverse" seems to be the only link between "1 over" and "switch x and y." Notably absent from any of the above interpretations of inverse is any mention of an identity element.

While Zazkis and Kontorovich noted the extent to which the students attempted to account for the apparent variation in meaning across different instances of inverse, their study left for future research the question of how students' might develop a generalized, coordinated understanding of the concepts of inverse and identity that enables them recognize instantiations of these concepts within various structures.

Students' Use and Understanding of Inverse in Abstract Algebra

Even though inverses are a familiar concept from school algebra, there is reason to believe that employing the inverse axiom in abstract algebra can be challenging for students. Research on student thinking about inverses delineates two lines of thinking that might explain these challenges. First, students might not carefully attend to closure and the binary operation(s) of an algebraic structure (Nardi, 2001). This could lead to determining inverse pairs by overextending the familiar operations of the real numbers (Hazzan, 1999) or identifying a potential inverse for an element but not verifying that the inverse is in the given set (Brown et al, 1997, p. 207). Second, students might not carefully attend to the algebraic properties on which their reasoning hinges. Indeed, there is evidence that students fail to verify or directly acknowledge inverses (Brown et al., 1997), even if they are implicitly invoking inverses by cancelling adjacent inverse pairs in a calculation (Larsen, 2013).

Theoretical Perspective

We adopted the perspective of Realistic Mathematics Education (RME) to guide our inquiry into how students might develop a generalized notion of inverse because of its view that mathematics can and should "link up with the informal situated knowledge of the students" (Gravemeijer, 1998, p. 279) in order to "enable them to develop more sophisticated, abstract, formal knowledge" (ibid). We leveraged the RME principle of *guided reinvention*, the goal of which is to design tasks that encourage students to "formalize their informal understandings and intuitions" (Gravemeijer, Cobb, Bowers, & Whitenack, 2000) en route to developing formal mathematical concepts themselves. The reinvention principle shaped both the overarching objective of the teaching experiment (to investigate how students might be guided to reinvent the concepts of ring, integral domain, and field) and also our specific objectives in this paper (to investigate how students might develop generalized, coordinated concepts of identity and inverse from their own intuitive understandings).

We propose that a robust understanding of the inverse concept necessarily involves coordination with the relevant binary operation and a generalized concept of identity. This is based upon suggestions in the literature (e.g. Brown et al., 1997) and also the hypothesis that such a coordination elucidates the common inverse structure across different binary operations and algebraic structures (as opposed to comparing the formulas or procedures to compute inverses across contexts). By *generalized concept of the identity*, we mean that a student should understand that an identity, if it exists, can only be conceptualized with respect to a particular binary operation (this is particularly important when studying rings, which have 2 binary operations and, therefore, two potential identity elements). An identity element, then, if it exists, is an element of that structure such that, when combined (in any order) with any element of that structure (under the relevant binary operation), leaves that element unchanged. That is, given an algebraic structure R with binary operation $*$, an identity is an element $I \in R$ for which $a \cdot I = a = I \cdot a$ for any $a \in R$. This understanding should be broad enough to accommodate instances of identity elements beyond the familiar 0 and 1 (such as an identity matrix or the element 8 in the ring $4\mathbb{Z}_{12}$). It should also be broad enough to employ in symbolic arguments for a general (unspecified) algebraic structure. Accordingly, a *generalized concept of inverse* depends not only upon a particular binary operation but also the aforementioned understanding of identity. Moreover, an inverse should be understood as an *inverse element* of the algebraic structure in question (as opposed to an inverse *operation*), and therefore the student needs to understand that, if an element a of an algebraic structure R with binary operation $*$ has a corresponding inverse element a^{-1}, then a^{-1} is also an element in R, and combining a with a^{-1} (in any order) yields the identity, i.e. $a * a^{-1} = I = a^{-1} * a$. This understanding should be broad enough to accommodate unfamiliar instances for which there is not a canonical procedure or formula that determines the existence of an inverse or produces the inverse element itself, and should also be broad enough to employ in symbolic arguments for an unspecified algebraic structure. A student must also understand that some elements in certain algebraic structures might not have a well-defined inverse, and that some elements might have an inverse that exists only outside the algebraic structure under consideration.

Freudenthal (1973), the founding father of RME, provided suggestions about how students might be guided to reinvent such generalized notions of algebraic structure. Arguing that there is a hierarchy of levels of mathematical activity, he noted that "the means of organization of the lower level become a subject matter on the higher level" (1973, p. 123). He defended this claim by describing the historical development of the concept of group. In the 19th century, he noted, groups were only implicit in mathematicians' intuitive reasoning, which led to explicit formulation of the group properties and, eventually, to the axiomatic abstraction of the definition of group. This characterization provides an operational, hypothesized model of how a student might abstract algebraic properties by leveraging his/her own activity:

(1) The property is implicit in the student's activity with an example structure;
(2) The property appears explicitly as a student's general description of his/her activity with the structure;
(3) The student uses the property as a lens to classify and investigate other structures.

Larsen (2013) verified that a learning trajectory proceeding in such a manner could indeed be leveraged to support students' reinvention of the group concept, and earlier studies provided similar evidence for the efficacy of this approach for reinventing rings (Cook, 2012). In this study, we hypothesized that students would be able to achieve the desired, coordinated understanding of identity and inverse by engaging in a task sequence informed by Freudenthal's characterization of the emergence and gradual formalization of an algebraic property in a student's activity.

Methods

We adopted the teaching experiment methodology (Steffe & Thompson, 2000) in order to construct models of students' thinking about the concepts of inverse and identity. We also sought to discern how their understanding of these concepts might evolve to a coordinated, generalized understanding of these concepts as they engage in mathematical activity in response to our teaching actions. It should be noted that such explanatory models of student thinking "may not, and probably cannot, account for students' mathematics" (Steffe & Thompson, 2000, p. 268), and instead reflect a researcher's best attempts to provide a rational frame of reference for a student's observable behaviors in response to a mathematical scenario. Thus, we deemed the models of student thinking that we constructed as valid insofar as they provided a viable explanation for students' utterances and written work.

Participants and Data Collection

Two undergraduate mathematics majors – Josh and Meagan (pseudonyms) – at a large Midwestern research university participated in this study. Both Josh and Meagan were juniors and had completed courses in linear algebra and number theory but had no prior exposure to concepts in abstract algebra. We selected these students for participation not only because their respective stages of mathematical preparation and abilities (as indicated by their own reports of their mathematical course experience and by a survey administered prior to participation) were suitable for this study, but also because of our perception of their enthusiasm for participating and willingness to openly articulate their mathematical thoughts. The teaching experiment consisted of 7 sessions of up to 2 hours apiece. The first author served as the interviewer and the second author served as an observer. We conducted two sessions per week to allow sufficient time for ongoing analysis (explained below). Each session convened on the campus of the students' institution. We recorded students' verbal utterances and written work using Microsoft Surface tablets, which recorded video-like capture of their written work with synchronized audio.

Data Analysis

We employed two methods for data analysis: ongoing and retrospective. The ongoing analysis occurred during and between sessions as we attempted to construct more stable models of student thinking in situations involving the concepts of inverse and identity. Ongoing analysis involved the first author's intuitive responses to students' activity in the form of asking questions or introducing tasks that would provide additional insight into their thinking and test the viability of our proposed explanations for their mathematical behavior. The models constructed during sessions were necessarily fluid and in need of additional refinement. Therefore, between sessions, we both viewed the videos from the previous session and, in particular, looked for evidence (in the form of the students' observable behaviors) that would either confirm or disconfirm the hypothesized models that we had developed during that session. Any additional hypotheses that arose would inform the instructional tasks administered in the next session. At the conclusion of data collection, we engaged in a retrospective analysis (Steffe & Thompson, 2000) in order to look for conceptual change across the entire teaching experiment.

Results

While it is beyond the scope of this proposal to comprehensively document the evolution of Josh and Meagan's understanding of the inverse concept throughout the entire teaching experiment, in this section we simply describe the first few stages of development:

Stage 0: Entrance Survey

Prior to selection for this study, Josh and Meagan, working independently of each other, answered the following questions as part of an entrance survey (the questions that appear here are only those that involved inverses; they have also been renumbered for easier reference):

- Consider the set $\{0, 1, 2, \ldots, 11\}$ with addition and multiplication modulo 12. To familiarize yourself with this set and its operations, construct an operation table for both addition and multiplication modulo 12, and then answer the following questions.
    - Q1: Does this set contain an identity with respect to addition? Explain.
    - Q2: Does this set contain an identity with respect to multiplication? Explain.
    - Q3: Does this set contain an additive inverse for 4? If so, identify it. If not, explain.
    - Q4: Does this set contain an additive inverse for 5? If so, identify it. If not, explain.
    - Q5: Does this set contain a multiplicative inverse for 4? If so, identify it. If not, explain.
    - Q6: Does this set contain a multiplicative inverse for 5? If so, identify it. If not, explain.
- Consider the set $\{0,4,8\}$ with addition and multiplication modulo 12. To familiarize yourself with this set and its operations, construct an operation table for both addition and multiplication modulo 12, and then answer the following questions.
    - Q7: Does this set contain an identity with respect to addition? Explain.
    - Q8: Does this set contain an identity with respect to multiplication? Explain.
    - Q9: Does this set contain an additive inverse for 4? If so, identify it. If not, explain.
    - Q10: Does this set contain a multiplicative inverse for 4? If so, identify it. If not, explain.

The results from this survey indicate that Josh and Meagan's understanding of inverse seemed more tied to notions of inverse as an *operation* (i.e. the inverse of addition is subtraction) or a *procedure* (i.e. take the reciprocal), as their additive inverses were initially negative numbers (Q3, Q4, and Q9), the multiplicative inverses were reciprocals (Q5, Q6, Q10). It appears that they both strongly associated the number 1 with multiplicative identity, and, moreover, there was no evidence that they coordinated these inverses with the respective identities. Had they been coordinating with an identity, we would have expected their explanation in response to Q10, for example, to focus on their assertion in Q8 that a multiplicative identity did not exist in the set.

	Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8	Q9	Q10
Josh	Yes; 0	Yes; 1	Yes; -4=8	Yes; -5=7	No; 1/4 not in set	No; 1/5 not in set	Yes; 0	No; 1 not in set	Yes; -4=8	No; 1/4 not in set
Meagan	Yes; 0	Yes; 1	Yes; -4=8	Yes; -5=7	No; 1/4 does not make sense	No; 1/5 does not make sense	Yes; 0	No; 1 not in set	Yes; -4=8	No; 1/4 does not make sense

Stage 1: Additive Inverse of a as $-1 \cdot a$

Notions of inverse first appeared in the teaching experiment in response to the first task, which prompted them to use addition and multiplication modulo 3 to determine the total number of distinct elements that could be generated, starting from $1 + 2i$. The task permitted them to add and multiply $1 + 2i$ by itself as many times as desired; they could also add and multiply results of any calculations they performed. The idea behind this task was that the algebraic properties that define a field would emerge implicitly in their activity as they acclimated to the elements and operations of what we knew to be the field $\mathbb{Z}_3[i]$. Soon after they generated the element -1, Meagan concluded that the existence of -1 enabled them to include the "opposite" of every element in their list because they could multiply any element by -1:

Meagan: So, like … if we … Isn't negative one, is negative one one of our numbers?
Josh: Yeah, because since negative one is one of our numbers …
Meagan: It's always going to be there.
Josh: Every one will have an opposite.

This characterization persisted unchanged into session 3, at which time they were completing operation tables to keep track of their calculations. In doing so, Josh and Meagan noticed that the addition table was a Latin Square (every element appears exactly once in each row and column). Following Larsen's (2013) recommendation regarding the role of proof in furthering students' reasoning, we prompted Josh and Meagan to prove this result, which essentially amounts to justifying (1) existence (that each equation of the form $a + x = b$ has a solution) and (2) uniqueness (that $ax = ab \Rightarrow x = b$). Their existence proof involved the cancelling of additive inverses. At this point, we prompted Josh and Meagan to articulate their "opposite" rule. Josh wrote:

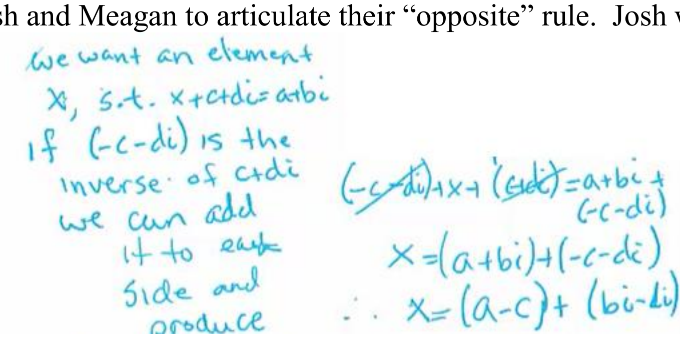

Figure 1: Josh and Meagan's initial characterization of additive inverse.

Notice that their demonstration of their use of this rule involves a cancellation, but does not acknowledge the role of the identity (or any of the other algebraic properties involved). We asked them to develop a "test for inverses" so that we could determine if cancelling featured prominently in their characterization of inverses or if it was just a consequence they derived from a stable $-1 \cdot a$ conceptualization:

Meagan: Multiply them by the negative, and then according to our mod three, um, determine if they're, equal. And you can do that with any equation.

Thus, their operational characterization of additive inverse still centered on $-1 \cdot a$.

Stage 2: Beginnings of a Coordination of $-1 \cdot a$ with the Additive Identity

It was not until Josh and Meagan proved the "uniqueness" component of the Latin Square property that the additive identity began to emerge in their discussions of additive inverses.

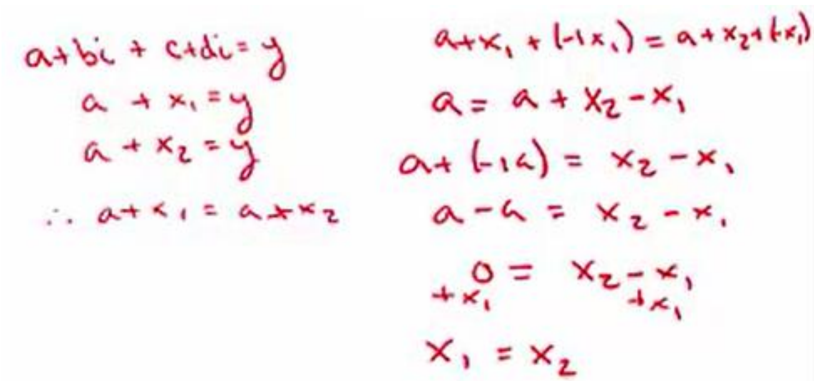

Figure 2: Josh and Meagan's proof of uniqueness for the Latin Square property.

Upon writing out the proof (Figure 2), I asked them to justify that $a + (-1 \cdot a) = 0$:

Researcher: Josh, what you've written there seems to be minus one times a?
Josh: Right.
Researcher: Ok, how do you know that minus one times a gives you zero? Is that true?
Meagan: I mean, it might be another rule. An inverse plus itself should always equal zero.
Right?
Josh: Yeah.

We asked Josh and Meagan to update their statement of the inverse rule:

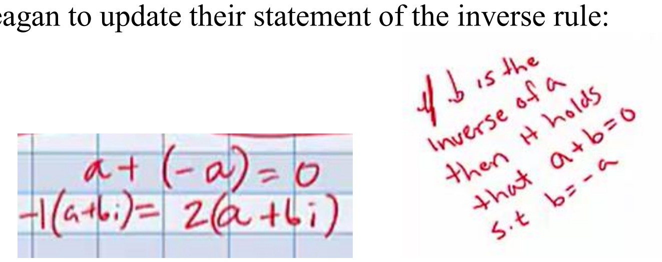

Figure 3: Josh and Meagan's statement of their additive inverse rule includes 0.

This concludes the results section, which is admittedly brief due to space constraints. The conference presentation (pending the acceptance of this proposal) will provide a much more comprehensive and detailed analysis of Josh and Meagan's understanding of inverse and identity and how it evolved throughout the teaching experiment.

Characterizing the Nature of Introduction to Proof Courses: A Survey of R1 and R2 Institutions across the U.S.

Erika J. David
Arizona State University

Dov Zazkis
Arizona State University

A number of institutions with mathematics programs offer introduction to proof courses in order to ease mathematics students' transition from primarily calculation-based courses to proof-centered courses. However, unlike most tertiary mathematics courses, whose mathematical content is directly implied by their course titles, introduction to proof courses may vary in terms of the mathematics content discussed. In this study we document the variation in content of introduction to proof courses. This is achieved by examining recent syllabi and other relevant course documents from introduction to proof courses at 179 R1/R2 universities across the United States. The various types of content used in these courses are discussed. We describe the 15 categories of ITP courses that emerged from the course information we collected and offer our categories as a framework for classifying ITP courses or students in future studies.

Key words: Introduction to Proof Courses, Syllabi, Survey, Categorization

Introduction

Undergraduate students taking introduction to proof (ITP) courses (also commonly called transition to proof courses), are a commonly studied population in mathematics education research on proof. However, what the courses that these students are drawn from look like across the United States is not well-known for several reasons. Unlike Calculus, Linear Algebra, Group Theory, Graph Theory, Topology, Combinatorics etc., ITP courses are one of the few undergraduate mathematics courses where the mathematical content covered is not specifically implied by the title of the course. Additionally, the possible mathematics content used to introduce students to proof is not well-defined. So, a number of mathematical topics may be the basis of an intro to proof course and the specific curriculum/texts used have not been documented. In spite of this lack of transparency, researchers interested in beginning proof students commonly make content-general claims from data of students working within a specific mathematics context (Dawkins and Karunakaran, 2016). Furthermore, students from ITP courses are often treated as if they are comparable regardless of the mathematics content used to introduce these students to proof. For example, the use of phrases like, "We present data on the reasoning of two students in a transition-to-proof course" (Alcock & Weber, 2010), without any further description of the course are fairly common. This language creates a false sense that intro to proof courses are compatible enough that the results of one study of ITP students is likely applicable to other ITP students. Such treatment also generates the impression that ITP courses are ubiquitous across mathematics programs. Both the ubiquity and comparability of ITP courses can be tested, rather than tacitly assumed, which is our goal in this manuscript.

Our goal in this study is to simply document the variability in ITP courses in order to facilitate researchers' descriptions of the particular ITP student population they are drawing from. This documentation will allow researchers to increase the specificity of the descriptions of the populations they study and will allow for comparison of courses across institutions. We achieved this by gathering syllabi and other relevant documentation from all 215 US universities that a) offer an undergraduate degree program in mathematics and b) are categorized by the

Carnegie foundation as either high research output (R2) or very high research output (R1). These syllabi provide a lens into what curricula ITP courses cover across the US.

Methods

The goal of this study was to collect and classify information on the nature of Introduction to Proof (ITP) courses offered at the undergraduate level across the United States. In order to gain a clear and accurate picture of the nature of these courses, the 215 of 221 R1 and R2 universities that offer undergraduate mathematics degrees were considered for this study. By examining a university's course catalog, math department website, and/or a list of course offerings, we determined whether an institution offered an ITP course. When this information was not available through online sources, we emailed instructors or administrators to acquire the needed information to make an ITP determination. For our purposes, a course was labeled an ITP course if the course description indicated an explicit emphasis on easing the transition to proof, bridging the gap between Calculus and higher level mathematics, and/or developing written mathematical arguments. To acquire an ITP label these emphases needed to be central to the course's content, as opposed to covered during a brief review period during the initial stages of the course.

Some courses functioned as ITP courses, but centered on a single mathematical topic, such as analysis or abstract algebra. In order to distinguish between these ITP courses and introductory courses on a mathematical topic that are not ITPs, we used schedules of content coverage in addition to course descriptions and listed objectives to make our ITP determinations.

For each of the 179 R1 and R2 schools that we determined offered ITP courses, we set out to collect one recent course syllabus per school through Internet searches and departmental websites. These Internet searches were typically of the form: "Course Code, Course Title, University Name, course syllabus." (Ex: MAT 300 Mathematical Structures Arizona State University course syllabus). When multiple syllabi were found, preference was given based upon precedence in search results, most recent date, and level of detail, in that order. If a course syllabus was not available through Internet searches or departmental sites, we emailed the department's administrative staff or a professor who had recently taught the course (when known) requesting a recent copy of the course syllabus. In all, 164 course syllabi were collected from 164 of the 179 ITP-offering institutions. Twelve of the remaining 15 schools had highly detailed course descriptions on their webpages. These descriptions were collected in lieu of course syllabi. Three schools with ITP courses did not respond to emails or provide enough detail online to sub-categorize them in terms of the mathematical content they covered. These three schools were excluded from the remainder of the analysis.

From these 176 ITP courses, (164 with syllabi, 12 with detailed online course information) the following information was collected in a spreadsheet: institution, location, course code, course title, textbook/author used, date, and course description/content covered. The vast majority of syllabi collected were from courses taught within the last 3 years (Fall 2013-Spring 2016) and only 6 syllabi were dated earlier than 2011. The results section below describes our analysis and sub-categorization of these courses based on their approach to introducing proof.

Results

Once we compiled all of the relevant information from each course, we looked for trends in types of courses, textbooks used, and topics covered in order to categorize these courses. From the beginning, there was striking variation, perhaps most noticeably in the number of textbooks used. Across the 176 courses, 63 different textbooks were used and 16 courses relied entirely on instructor or departmental lecture notes. The two most commonly used texts: *Mathematical Proofs: A Transition to Advanced Mathematics*, by Chartrand, Polimeni and Zhang, and *A Transition to Advanced Mathematics*, by Smith, Eggen and St. Andre were each used by only 16 and 15 of 176 of the courses surveyed, respectively. From the spreadsheet data collected for each course, we examined the types of courses in terms of topics covered and two broad categories of courses emerged: courses that followed a highly similar order of topics and courses that introduced proof in the context of a particular advanced mathematical topic. Of the 176 ITP courses, 144 (82%) of the courses were of the first type, which we categorized as Standard ITP courses and the remaining 32 (18%) we categorized as Topic-Based ITP courses. Once we separated the courses into these two categories, we looked for further trends and subcategories within each category. We will proceed to explain our categorizations, sub-categorizations, and provide examples of the two most common course type in each to illustrate how we made our determinations, as well as the frequency of each type of ITP course.

Standard ITP Courses

The 82% (144/176) of ITP courses we categorized as Standard ITP courses typically covered the following topics: symbolic/formal logic, truth tables, propositions, quantifiers, methods of proof (including contradiction and induction), number systems, sets relations and functions, infinite sets, and cardinality. Some of the Standard ITP courses covered additional topics from advanced mathematics towards the end of the course such as analysis or discrete mathematics topics. Courses that only covered these standard topics and did not include additional topics we categorized as Standard only ITP courses, which comprised 50% (72/144) of the Standard ITP Category. The other 50% (72/144) of Standard ITP courses contained introductions to topics beyond the standard topics, which we categorized as Standard+ Topic ITP courses.

Standard only: Within the Standard only ITP subcategory, which consists of 41% (72/176) of all ITP courses surveyed, 29 different texts were used, many of which are used for ITP courses in other categories. The most commonly used text, used by only 15% (11/72) of courses in this category, was *Mathematical Proofs: A Transition to Advanced Mathematics*, by Chartrand, Polimeni and Zhang. Additionally, 8% (6/72) of Standard only ITP professors use their own lecture notes or notes developed by their department. As described earlier, these courses cover what we take as the standard set of topics as a means of introducing proofs and do not introduce any other mathematical topics. We provide an example of an overview of topics from one such course:

Topics:

1. Symbolic logic (propositional calculus)
   - Logical Connectives and truth tables
   - Quantifiers
   - Tautologies
   - Relation to mathematical statements and proof
2. Foundations of mathematics
   - Set theory: union, intersection
   - Cartesian products, relations, partitions

Figure 1. Howard University, Mathematical Reasoning: Writing and Proof, Standard only ITP Course

Standard+ Topic: Any course that focused primarily on the same topics as a Standard only ITP course, but also introduced a certain mathematical topic or topics for a small portion of the course, we categorized as Standard+ Topic, according to which topic was introduced. These courses made up another 41% (72/176) of the ITP courses surveyed. Typically these courses covered formal logic, sets, functions, relations, etc. (the "standard" material) for the majority of the semester and then spent a few weeks on introducing a particular topic from a certain branch of advanced mathematics, often towards the end. The most common Standard+ Topic courses added on 2-4 weeks of discrete mathematics topics or introductory analysis topics. The breakdown of all of the Standard+ Topic ITP course subcategories that emerged is as follows: Standard + Discrete 35% (25/72), Standard + Analysis 15% (11/72), Standard + Combination 11% (8/72), Standard + Algebra 10% (7/72), Standard + Number Theory 8% (6/72), Standard + Algebra & Analysis 7% (5/72), Standard + Sampler 7% (5/72), and Standard + Other 7% (5/72).

Standard+ Discrete: Making up 35% (25/72) of all of the Standard+ Topic ITP courses, Standard+ Discrete courses usually spent the last few weeks of the course on several Discrete Mathematics ideas such as counting techniques, permutations, combinations, the Binomial Theorem, probability, graph theory, or possibly elementary number theory. Among the courses of this type, the most commonly used text, used by only 20% (5/25) of the category, was *Discrete Mathematics and its Applications* by Kenneth Rosen. We provide a sample course overview from a course in this category:

Overview:
This course is a rigorous introduction to many of the tools useful in higher mathematics and computer science. The major topics to be covered will be logic and proof techniques. Also included will be a brief introduction to set theory, number theory, relations, functions, complexity, combinatorics, and graph theory.

Figure 2. San Diego State University, Discrete Mathematics, Standard+ Discrete ITP Course

Standard+ Analysis: The second most frequent, Standard+ Analysis courses made up 15% (11/72) of the Standard+ Topic category. After the standard material, these courses covered introductory topics within Analysis such as sequences, limits, and continuity. Among these courses, 8 different texts were used. The most commonly used text was *A Transition to Advanced Mathematics*, by Smith, Eggen and St. Andre, and was used by only 27% (3/11) of Standard+ Analysis ITP courses. We provide two examples from course syllabi from this category. Note that while the additional Analysis topics are part of the course, the entire course is not centered on Analysis. Such ITP courses were categorized as Topic-Based ITP courses and will be discussed later in this manuscript.

Learning Outcomes

A successful completion of the course should permit the student to achieve the following skill levels:

- Develop a framework of widely used fundamental mathematical concepts;
- Understand the basic facts about sets, relations, functions, and structures;
- Formulate and prove mathematical statements using standard proof techniques;
- Learn the introductory concepts associated with the branch of mathematical analysis;
- Develop experience and confidence in the presentation of abstract mathematics.

Figure 3. George Washington University, Introduction to Mathematical Reasoning, Standard+ Analysis Course

Standard+ Algebra: Likewise, the courses that added several weeks of Algebra topics to the standard material in their introduction to proofs were categorized as Standard+ Algebra and made up 10% (7/72) of the Standard+ Topic category. The concluding topics for courses in this category include topics such as groups, subgroups, homomorphisms, cosets, rings, and fields. Each course in this category used a distinct textbook from other courses in this category, though some used the same text as courses in other categories.

Standard+ Number Theory: Six of the 72 courses in the Standard+ Topic category (8%) added number theory topics to the standard set of material. These courses are distinct from the Standard+ Discrete category since they only added number theory concepts specifically, and did not cover any other type of discrete mathematics such as counting, graph theory, or probability.

Standard+ Algebra & Analysis: Five of the 72 (7%) Standard+ Topic ITP courses added introductory ideas from Algebra and Analysis. These courses typically only added a few topics from each of Algebra and Analysis and do not have as much time to devote to each topic.

Standard+ Combination (other than Algebra & Analysis): While Algebra and Analysis were the most common two topics to add into standard material in an ITP Standard+ Topic course, 11% of courses (8/72) found in the Standard+ Topic category added different combinations of topics from two branches of mathematics to their course. The different combinations observed include: Discrete and Analysis, Geometry and Number Theory, and Algebra and Topology.

Standard+ Sampler: Five of 72 (7%) Standard+ Topic ITP courses added topics from more than two branches of advanced mathematics, which we classified as Standard+ Sampler ITP courses.

Standard+ Other: Five of the 72 (7%) Standard + Topic ITP courses did not fall under one of the previous categories were labeled Standard+ Other. These courses delved into more tangentially related topics, such as intermediate logic or certain software such as LaTex.

Topic-Based ITP Courses

Unlike courses in the Standard category, Topic-Based ITP courses introduce proof in the context of either a single mathematical topic, or occasionally through several topics. Such courses devote little, if any, time to the "standard" material that is the focus of Standard only and Standard+ Topic courses. These courses, through an introduction to a particular mathematical topic or topics, emphasize proof-writing and formal mathematical argumentation as a major goal of the course. Much less frequent, they comprise 18% (32/176) of the ITP courses surveyed and consist of the following subcategories, listed in order of prevalence: Analysis 38% (12/32), Discrete 25% (8/32), Algebra 16% (5/32), Sampler 9% (3/32), Combination 6% (2/32), Number Theory 6% (2/32). The following is a description of the characteristics of each subcategory.

Analysis*:* The most prevalent of the topic-based ITP courses, Analysis ITP courses have the goal of teaching mathematical proof in the context of Analysis topics and make up 38% (12/32) of the topic ITP category. Typically, these courses cover the real number system, limits, continuity, differentiation, integration, sequences, all in the context of single-variable functions. The most commonly used textbook for courses in this category, used by 25% (3/12) of Analysis ITP courses, was *Analysis with an Introduction to Proof*, by Steven Lay. Below is a description of one such course we placed in this category:

Strongly recommended for future math majors, this course covers calculus more thoroughly and more theoretically, giving an introduction to important mathematical techniques and results that give a foundation for further work in analysis. It serves as an introduction to the rigorous proofs and formal mathematical arguments needed in all upper division math courses.

Figure 4. Princeton University, Honors Analysis in a Single Variable, Analysis ITP Course

Discrete: These courses, which make up 25% (8/32) of the Topic-Based ITP courses have the goal of learning mathematical proof in the context of various topics in Discrete Mathematics including graph theory, probability, and combinatorics. These courses may include graphs, trees, Boolean algebras, cryptography, divisibility, permutations, combinations, binomial coefficients, and may include a sampling of number theory topics, although courses situated entirely in the context of number theory were divided into their own subcategory. Among these courses, the most frequently used text was *Discrete Mathematics with Applications* by Epp, employed by 50% (4/8) of the courses in this category. The following course description illustrates the nature of these types of courses:

2513 Discrete Mathematical Structures. *Prerequisite: 2423 or concurrent enrollment. A course for math majors or prospective math majors. Provides an introduction to discrete concepts such as finite sets and structures, and their properties and applications. Also exposes students to the basic procedures and styles of mathematical proof. Topics include basic set theory, functions, integers, symbolic logic, predicate calculus, induction, counting techniques, graphs and trees. Other topics from combinatorics, probability, relations, Boolean algebras or automata theory may be covered as time permits. (F, Sp, Su)*

Figure 5. University of Oklahoma, Discrete Mathematical Structures, Discrete ITP Course

Algebra: The third most frequent type of Topic-Based ITP course at 16% (5/32), the Algebra ITP courses have the goal of understanding mathematical proof in the context of abstract algebra topics. Typically, these courses cover groups, subgroups, normal subgroups, quotient groups, rings, homomorphisms, polynomials, subrings, cosets, isomorphism theorems, and sometimes include fields, integral domains, prime numbers and the division algorithm. Every Algebra ITP course surveyed used a different textbook.

Sampler: Three of the 32 (9%) topic-based ITP courses had the goal of learning mathematical proof in the context of a wide-array of mathematical topics, which we labeled as "sampler" courses. Often the goal of these courses is to introduce students to many different subjects in advanced mathematics. Courses in this category used the context of a minimum of four topics.

Number Theory: Distinct from Discrete ITP Courses, which typically sample various discrete mathematics topics, these courses, though rare, have the goal of learning mathematical proof in the context of Number Theory. In our study we only came across 2 such courses.

Combination: Courses in this category are topics-based intro to proof courses in the context of a combination of two different topics, and make up a very small portion (6% or 2/32).

The following table summarizes all of the ITP categories that emerged from the course information, as well as their prevalence.

Table 1
ITP Course Category Data Summary

Course Category (Percent of ITP Courses)	**Description**	**Subcategories (Percent of Category)**

Standard 82%	*Standard + ∅ ITP 41%*	Introduce proof through the following topics: symbolic logic, truth tables, propositions, quantifiers, methods of proof, number systems, sets, relations and functions, and cardinality. No additional topics covered.	N/A
	Standard+ Topic ITP 41%	Cover the same topics as a Standard ITP course for the majority of the course, but also include an introduction to a specific advanced mathematical topic or topics near the end, which typically lasts 2-4 weeks.	35% Standard+ Discrete 15% Standard+ Analysis 11% Standard+ Combination 10% Standard+ Algebra 8% Standard+ Number Theory 7% Standard+ Algebra & Analysis 7% Standard+ Sampler 7% Standard+ Other
Topic 18%	*Topic-Based ITP 18%*	Grounded in the context of either a single or several topics in combination. Majority of time on the topic and devote little to no time to formal logic and other "standard" topics.	38% Analysis 25% Discrete 16% Algebra 9% Sampler 6% Combination 6% Number Theory

Discussion

Our chosen focus on syllabi facilitated the collection of data across a fairly complete sample of R1 & R2 universities. This allowed for breadth rather than depth; syllabi offer a fairly accurate look into the material covered and textbook used but have little information regarding day-to-day classroom dynamics. Even with these limitations we were able to discover a wide variation in ITP courses. As discussed in the results section, ITP courses are not necessarily offered at all universities, meaning the universality of ITP student populations should not be assumed to exist within any tertiary mathematics program. We observed that no single textbook had more than 9% market share and most textbooks designed for ITP courses were used at only 2-3 institutions. Furthermore, when categorizing ITP courses we generated 15 different categories to describe the differences in mathematical content covered. These results point to the high variability in how students across the United States are introduced to proving, and highlight the importance of taking this variability in content into account when studying students enrolled in ITP courses. Since we only chose one representative syllabus per institution, in an effort to keep the data set manageable, we did not account for variability within institutions, which likely exists at many schools, as we found at our own institution. In other words, the categories and counts we've compiled are likely a simplification of the true degree of variability among these courses. Unlike Dawkins and Karunakaran (2016), we are not necessarily encouraging all researchers interested in proof to take mathematical content into count when analyzing student data, although we do believe doing so adds depth to data analysis. Instead, we encourage researchers to be more specific when describing the ITP population they are drawing from in order to help situate their chosen population relative to the various types of ITP courses that exist. We offer the 15 categories and descriptions provided here as a framework for ITP course categorization for future studies. Our categories serve to provide additional information and may add depth to a highly-studied population in mathematics education. Identifying and categorizing the variability within these courses lays the foundation for further studies, which might include studies within certain categories, or comparisons of students across categories of ITP courses.

The Role of Visual Reasoning in Evaluating Complex Mathematical Statements: A Comparison of Two Advanced Calculus Students

Erika David, Kyeong Hah Roh, Morgan Sellers, Kody D'Amours
Arizona State University

The purpose of this study is to examine the role of visual reasoning while students evaluate complex mathematical statements about real-valued functions. We conducted clinical interviews with nine undergraduate students from mathematics courses at different levels. In the interviews, we asked these students to evaluate several mathematical statements alone and then using various graphs. In this paper, we focus on the cases of two students who had completed Advanced Calculus to highlight the contribution of their visual reasoning about several graphs. We found that student's graphical interpretation of "between" in these statements affected their evaluation of the statements. Even at advanced levels, students' visual cues dominated their reasoning about the statements. Our findings indicate that students' visual reasoning contributes to their evaluation of mathematical statements and helps to account for differences between students' meanings of statements.

Key words: Visual Reasoning, Complex Mathematical Statements, Graphical Interpretations, Undergraduate Students, Intermediate Value Theorem

Introduction

Mathematical statements, including definitions, theorems, and mathematical claims, which may be true or false, are a central part of elementary through postsecondary mathematics curriculum. Mathematics education research has shown that students often struggle with both understanding mathematical statements (Roh, 2010; Selden & Selden, 1995) and evaluating whether mathematical statements are true or false (Bubp, 2014; Dawkins & Roh, 2016; Selden & Selden, 2003). In particular, studies have shown student difficulty with statements involving multiple conditionals such as "if $p \rightarrow q$, then $r \rightarrow s$" (Zandieh, Roh, & Knapp, 2014) or multiple quantifiers such as "$\exists x \forall y\ P(x, y)$" (Dubinsky & Yiparaki, 2000). In this paper we focus on students' understanding of statements involving both conditional structure and multiple quantifiers, which we refer to as *complex mathematical statements*. Although these statements look complicated, statements with such structure are common in Calculus and Real Analysis. For example, the Intermediate Value Theorem (IVT) can be stated as a complex mathematical statement as follows: "Suppose that f is a continuous function on $[a, b]$ with $f(a) \neq f(b)$. Then, for all real numbers N between $f(a)$ and $f(b)$, there exists a real number c in (a, b) such that $f(c)=N$."

In order to help students understand these types of statements, instructors may often provide a graphical illustration to introduce the idea of the statement. Several textbook authors and researchers have cited the benefits of incorporating visual representations of theorems and/or proofs in instruction (Alcock & Simpson, 2004; Arcavi, 2003; Davis, 1993; Guzman, 2002; Hanna & Sidoli, 2007). While research has looked at students' understanding of multiple quantifiers (Dawkins & Roh, 2016; Dubinsky & Yiparaki, 2000; Epp, 2003; Roh & Lee, 2011) and conditional structure (Durand-Guerrier, 2003; Zandieh et al., 2014), few studies have looked at the role of students' reasoning about the graphs or images that correspond to a statement about a real-valued function. Although instructors may consider such explanations clear representations of the statement, we do not know what sense students make from these graphical illustrations. While these visual representations have the potential to be valuable to student understanding, little research has been conducted to examine the role of students' visual reasoning in understanding and evaluating complex mathematical statements. This study addresses the following research question: *How do students' visual reasoning contribute to their evaluations of complex mathematical statements about real-valued functions?*

Theoretical Perspective

Our study is grounded in a constructivist perspective and builds on Moore and Thompson (2015) and Moore (2016)'s theories of students' graphical activity. We adopt von Glasersfeld's (1995) view that students' knowledge consists of a set of action schemes that are viable given their experience, and that we, as researchers, do not have direct access to their knowledge. This perspective implies that we as researchers can only model student thinking based upon their actions. Thus, our analysis reflects our best attempt at creating a hypothetical model of student visual reasoning grounded in evidence found in their words, gestures, and markings on paper.

In this study, we reference Moore and Thompson's (2015) distinction between *static shape-thinking* and *emergent shape-thinking* as well as Moore's (2016) constructs of *figurative* and *operative* thought in the context of graphing as a means of situating our constructs that describe students' visual reasoning we observed. Moore and Thompson (2015) describe *static shape-thinking* as conceiving of a graph as an object in itself, in which mathematical objects and actions are subordinate to visual perception. In contrast, they describe *emergent shape-thinking* as conceiving of a graph as a trace which emerges from the coordination of two varying quantities. To develop this distinction, Moore (2016) aligns static shape-thinking with *figurative thought* and emergent shape-thinking with *operative thought*, consistent with Piaget's (2001) and Steffe's (1991) use of the terms. Moore (ibid) explains that figurative thought is dominated by visual properties of a graph, such as aspects of the shape of the curve which overrides considerations about relationships of the quantities being represented. In contrast, for students engaged in *operative thought*, "figurative elements of their activity are subordinate to that coordination [of covarying quantities]" (Moore, 2016, p. 3). Students engaged in operative thought may still perceive visual properties of a graph, but their thought is guided by the relationships represented in the graph. Furthermore, Moore (ibid) explains that these modes of thought are not exclusive of the other. Students may engage in both, although one may dominate the student's activity, depending on which mode of thought the students' actions are subordinate. While these constructs help to distinguish certain student graphing behavior, they do not account for important nuances of the graphing behavior we observed in this study. Thus, we define the constructs *location-thinking* and *value-thinking* to distinguish between the relevant aspects of the graphing behavior we observed, as explained in the results section.

Methods

For this study, we conducted two-hour clinical interviews with nine undergraduates at three different levels: students who had just completed Calculus, an Introduction to Proof course, and Advanced Calculus, respectively. Due to the complex nature of the interview, we decided to have one researcher serve as the interviewer with the other three researchers as witnesses, two of whom were in the interview room, and the third who watched the interview live-streamed from elsewhere. We recorded the interview with three cameras to capture the entire frame, student work on the table, and to live-stream the interview to the third witness. All four researchers had laptops, whose screens the participant could not see, to communicate their current models of the participant's thinking in real-time via group chat. This set-up allowed all four researchers to offer clarifying questions for the interviewer to pose to the participant to test these models.

In the interview, the participants were asked to evaluate four complex mathematical statements about real-valued functions and provide justification for their evaluation. One of these statements was the Intermediate Value Theorem (IVT), which we presented in the introduction. The remaining three statements were variations on IVT with the re-ordering of the quantifiers (for all, there exists) and/or variables reversed (N, c). For example, another statement read, "Suppose f is a continuous function on $[a, b]$ where $f(a) \neq f(b)$. Then there exists a real number N between $f(a)$ and $f(b)$, such that for all real numbers c in (a, b), $f(c)=N$." This altered statement was made from a reversal of *both* the quantifiers *and* variables in IVT.

Once the participants had evaluated each of the four statements, the interviewer asked them to compare the statements and explain whether any of the statements had the same meaning, in their interpretation. The interviewer later asked students to look at each statement along with six graphs we created, with the chance of changing their evaluation in order to gain insight into the effects of students' reasoning about various graphs on their evaluation. These graphs, which were intended to represent a spectrum of possible functions and relevant counterexamples, included: a constant function, a monotone increasing function, a vertical line, a polynomial with extrema beyond the endpoints of the displayed function, the tangent function, and the sine function. The participants were also asked to explain how they interpreted various aspects of the graph and to label relevant points and values on the graphs where appropriate.

After conducting the interviews, our research team closely analyzed the video data for patterns in student thinking that could explain their statement evaluations. Our data analysis was consistent with Corbin and Strauss's (2014) description of grounded theory, in which categories of student visual reasoning emerged from the data, as we did not begin our study with the specific intent of investigating visual reasoning. Through analyzing the student interviews, students' interpretation of the phrase "between $f(a)$ and $f(b)$" emerged as highly relevant to their reasoning about the graph and subsequent evaluation of the given statement.

Results

In analyzing the interviews, a distinction emerged in students' interpretation of the phrase "between $f(a)$ and $f(b)$," which stemmed from their meaning for $f(a)$ and $f(b)$. As we analyzed student meanings for this phrase, students fell into one of two categories in terms of their interpretation of this phrase, and we labeled each student as a *value-thinker* or *location-thinker,* accordingly. In this categorization, *value-thinkers* interpret "between $f(a)$ and $f(b)$" as referring to output *values* between the *values* of $f(a)$ and $f(b)$. In contrast, *location-thinkers* interpret "between $f(a)$ and $f(b)$" as *locations* between the *locations* of $f(a)$ (at $(a, f(a))$) and $f(b)$ (at $(b, f(b))$). In other words, value-thinkers distinguish between the value of the output of the function and the resulting location of the coordinate point on the graph, whereas location-thinkers do not make this distinction. Students who were labeled as value-thinkers were seen as engaging in operative thought and emergent shape-thinking, as their visual perception of the graph was subordinate to their meanings for output value and they coordinated the values of the varying quantities. Location-thinkers, on the other hand, did not clearly fall into the category figurative thought, and by extension, static shape-thinking. The visual cues from the graph dominated their thinking in some aspects of the graph and informed their interpretation of "between $f(a)$ and $f(b)$." Although location thinkers engaged in figurative thought, they did not conceive of the graph statically. Instead, for these students, a graph emerged from the coordination of input values with locations of the points on the graph. In this way, we consider our constructs of value-thinking and location-thinking as novel in describing students' graphical activity. We summarize the characteristics of each way of thinking in the following table.

Table 1. *Comparison of location-thinking and value-thinking characteristics*

<table>
<tr><th rowspan="2"></th><th colspan="2">Location-Thinker</th><th colspan="2">Value-Thinker</th></tr>

Based on our analysis of the interview data, four students were identified as location-thinkers and five students were classified as value-thinkers. In this paper, we choose to highlight the cases of two students, Jay, a value-thinker, and Nate, a location-thinker, to illustrate the difference in these visual reasoning and their subsequent impact on the student's understanding and evaluation of the given statements. Both Jay and Nate had recently completed Advanced Calculus and earned an A in the course. Additionally, both students showed evidence of having strong meanings for multiple quantifiers and conditional structure. However, their evaluation of the truth values of these statements differed. Jay correctly evaluated each of the four statements and offered justifications that were consistent with the mathematical community. Nate paraphrased one of the statements[1] as, "for every single *c* there is a point on the curve that it maps to," indicating that he correctly interpreted the multiple quantifiers in the statement. While Jay correctly evaluated this statement as false, Nate evaluated it as true. Jay and Nate's evaluations of these statements serve as a contrast due to the significance of visual reasoning in their evaluations of the statements.

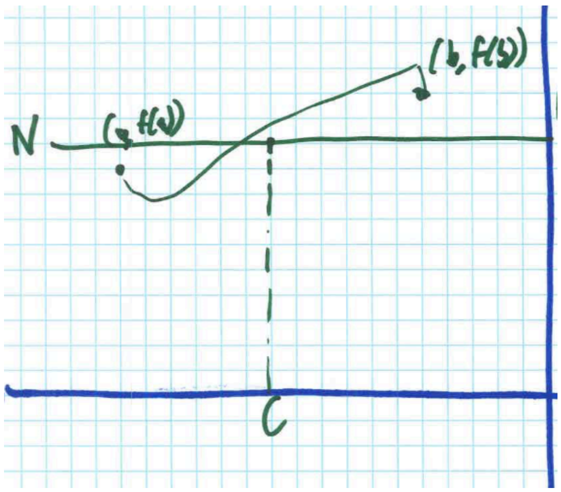
Jay: A value-thinker

The excerpt of Jay's interview below provides evidence for Jay's interpretation of "between" as value-thinking. In this excerpt, Jay has just looked at the IVT and evaluated the statement as true. He used the graph he drew (*Figure 1, left*) to explain why this statement, in his interpretation, is true.

---

[1]Suppose that f is a continuous function on $[a, b]$ such that $f(a)\neq f(b)$. Then, for all real numbers c in (a, b), there exists a real number N between $f(a)$ and $f(b)$ such that $f(c)=N$.

… So this right here is *y* equals *N*, this line is *y* equals *N* (*points to horizontal line which he labeled N*). If *f* crosses this line (*points to horizontal line he just drew*), then there exists a real number c in the open interval such that *f*(*c*) is *N*. Because if I cross these lines... lines say here, this (*marks c on x-axis*) is my value of *c*, right? Because that's where *f*(*c*) is *N*. Okay, so the only way for like this not to be true is if you can draw a continuous graph through it or a continuous graph from *a* to *b* with *f*(*a*) being this (*marks f(a) below the line drawn), f*(*b*) being this (*marks f(b) above the line drawn*), such that you skip *N*.



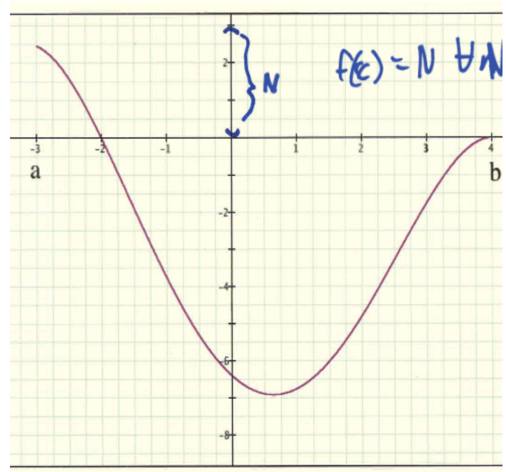


Figure 1. Jay's hand-drawn explanation for why the IVT is true (left) and Jay's possible values of N (right)

Both Jay's graph and his explanation above of why IVT is true reveal how he made sense of the phrase "between *f*(*a*) and *f*(*b*)" in the statement. Jay drew a horizontal line between these output values that intersected the *y*-axis, which indicated that he attended to the *values* of the output, rather than the *location* of the ordered pair point in space. Later, Jay described that the horizontal line he drew in his diagram is arbitrary, indicating that he imagined all of the possible horizontal lines passing between the horizontal line through *f*(*a*) and the horizontal line through *f*(*b*). For Jay, the phrase "between *f*(*a*) and *f*(*b*)" was connected to this image that he shared. Not only did Jay consider the values of *f*(*a*) and *f*(*b*), he visualized the graphical meaning of IVT, which is that a continuous function will always intersect any horizontal line drawn between the output values of *f*(*a*) and *f*(*b*). Further evidence of Jay's visual reasoning for "between" was found later in the interview, when Jay evaluated another statement and provided graph, and marked off the relevant interval for *N* along the *y*-axis (*Figure 1, right*). Jay's interval of possible *N* values between *f*(*a*) and *f*(*b*) in Figure 1 indicates he again considered the *values* between the value of *f*(*a*) and *f*(*b*) rather than the spatial locations of these points.

Nate: A location-thinker

In contrast with Jay's value-thinking, Nate's reasoning was labeled as location-thinking. Evidence for Nate's thinking can be seen in the following excerpt. Nate had already evaluated

Statement 1 (which is false)[2] as true, and below explained why it is true using the same provided graph that Jay used above (which, from our perspective, is a counterexample to Statement 1).

> Nate: So for all these *c*'s (*sweeps pen along x-axis between a and b)* you can see that it mapped to a point on the curve. For every single *c* there is a point on the curve that it maps to…So after that *c, N* would be here (*marks c around 1 on x-axis, N at ordered pair location of (c, f(c))*. So it maps to that. And this *c* would be in here (*marks c around 2 on x-axis*). And this *c* would be like, *N* right here (*marks corresponding N's for each c on graph*).
>
> Interviewer: Okay. Lets say we picked a point over here (*points to a point beyond (a, f(a)), (b, f(b)), rightmost marked point on Figure 2*). Could we say that the output would be between *f*(*a*) and *f*(*b*)?
>
> Nate: I would not say its between *f*(*a*) and *f*(*b*). Even though the, yeah. This is the, the actual numbers 2.5 and 0 (*marks the points 2.5, 0*). This would be… If you are looking at numbers 2.5, 0, this would be in between that interval. But it's in between that number interval. But it's not in between the functional interval in this case. So *f*(*a*). The interval will refer, refers to all these points between *f*(*a*) and *f*(*b*) (*sweeps pen along curve)*. All points of the function. That's what I am interpreting.

In the transcript above, when asked about the far right point the interviewer selected, if the output would be between *f*(*a*) and *f*(*b*), Nate explained, "it's in between that number interval, yeah, but it's not in between that functional interval in this case." The "it" Nate referred to here is the point in question, which he confounded with the output of the function at that point. Nate further clarified that "the interval refers to all the points between *f*(*a*) and *f*(*b*)" and illustrated what points he is talking about by sweeping his pen along the curve between the points *(a, f*(*a*)) and (*b*, *f*(*b*)).

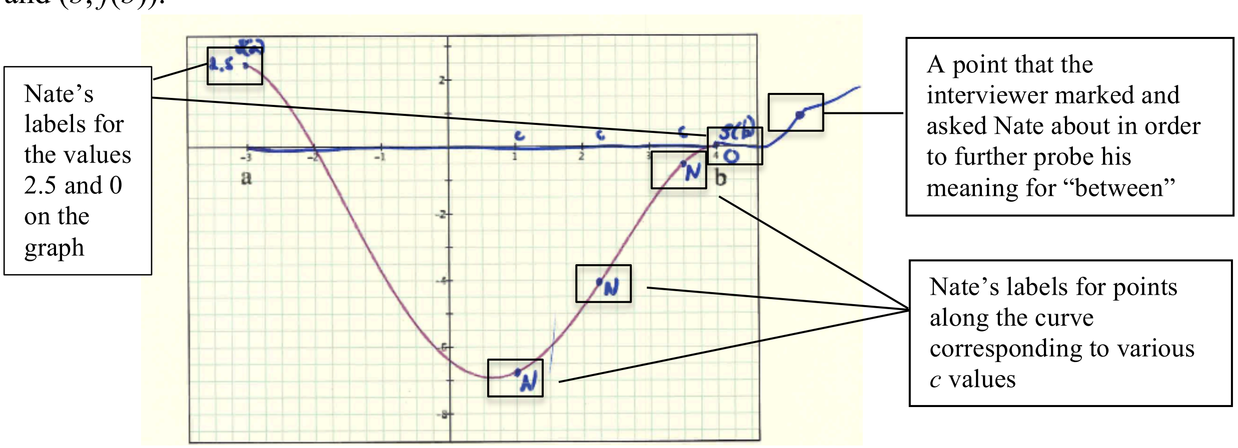

Figure 2. Nate's work on provided graph with his possible N values labeled on the curve, outside the range of values between f(a) and f(b).

Nate's response indicates that his perception of the graph guided his interpretation of and evaluation of Statement 1. Nate labeled *f*(*a*) and *f*(*b*) not on the *y*-axis, but at the location of the point (*a*, *f*(*a*)) and (*b*, *f*(*b*)), which indicates that he conceived of the output of the function as the point itself. These two labeled points became visual boundaries for Nate, between which lay all

[2] Statement 1: Suppose that *f* is a continuous function on [*a*, *b*] such that $f(a) \neq f(b)$. Then, for all real numbers *c* in (*a*, *b*), there exists a real number *N* such that $f(c)=N$.

of the relevant N values. In other words, he interpreted the relevant values of N "between $f(a)$ and $f(b)$" as *all* of the points on the path of the curve between the starting point that he labeled as $f(a)$ and ending at the point in space that he labeled $f(b)$. Nate's response to the question of the curve extending beyond the point $(b, f(b))$, but including values that are numerically between $f(a)$ and $f(b)$, is further evidence that Nate conceived of "between $f(a)$ and $f(b)$" as all of the points along the path between $(a, f(a))$ and $(b, f(b))$. While Nate said the point in question was not between $f(a)$ and $f(b)$, he acknowledged that this point was numerically between 2.5 and 0 (the values of $f(a)$ and $f(b)$). The fact that Nate did not ignore the numerical value of the outputs, and even acknowledged the confusion surrounding this meaning indicates that he recognized multiple possibilities for the meaning of between. Nate's interpretation of "between" in terms of the location of the points, prompted by his visuospatial perception of the graph, reveals the power of his visual perception to override his numerical evaluations.

Together, both Jay's and Nate's meanings for "between" and their subsequent evaluations of the given statements highlight the role of visual reasoning in evaluating such statements. Since both participants understood the quantifiers and conditional structure of Statement 1 the same way, but had different truth-value evaluations, the difference in their visual reasoning became the focus of our analysis. For Jay, the phrase "between $f(a)$ and $f(b)$" was visually connected to horizontal lines between the *values* of $f(a)$ and $f(b)$. Jay interpreted the outputs of the function as *values*, distinct from the coordinate points on the graph and thus was classified as a *value-thinker*. For Nate, "between $f(a)$ and $f(b)$" referred to every point along the path of the graph between the *location* $f(a)$ (at $(a, f(a))$) and the *location* $f(b)$ (at $(b, f(b))$). Since Nate did not distinguish between the outputs of the function and the locations of the coordinate point on the curve, Nate was labeled a *location-thinker*. In summary, Nate and Jay, both successful Advanced Calculus students consistently interpreted "between" differently, which led to their different understandings, and subsequent opposing truth-value evaluations of Statement 1.

Discussion

Based on our findings that almost half of the students whom we interviewed were identified as location thinkers, visual reasoning about mathematical statements plays a significant role in students' understanding. These results highlight and explain some important aspects of students' graphical activity that were not previously accounted for by current theories and studies on visual reasoning (Moore & Thompson, 2015; Moore, 2016). Thus, the use of our constructs of value-thinking and location-thinking could progress the depth of analysis in the field of student graphical activity, especially with regard to ideas from Calculus and Analysis. As illustrated through the cases of Nate and Jay, different interpretations for "between," both rooted in visual reasoning, contributed to different evaluations of a complex mathematical statement about real-valued functions. While in our study, value-thinking helped students to understand versions of IVT, in other contexts, such as Geometry, location-thinking may be preferable. Ideally, students should possess the ability to think in both ways, as well as the discernment for when to use each. Overcoming various perceptual cues found in graphs, beyond conceiving of the graph as a static shape, is a nontrivial achievement, even for advanced students. Teachers utilizing such representations should support students in overcoming adherence to visual cues. In the classroom, instructors should be aware of the various ways in which students may interpret information from a visual representation. Further research on this topic may include developing instructional tasks to address this topic, whether in the context of the IVT or other statements commonly associated with graphs, such as the formal limit definition of continuity at a point.

Features of Explanatory Proofs: An Exploratory Study

Eyob Demeke
California State University, Los Angeles

In mathematical research as well as pedagogy, mathematicians rely on proofs to convey mathematical knowledge. Both mathematicians and mathematics educators have argued that a proof is more valuable to students when it explains why a theorem is true. In this contributed report, I discuss attributes of explanatory proofs that eleven doctoral students in mathematics described. Doctoral students in this study interpreted the nature of mathematical explanation in the context of a proof in a wide range of ways. In particular, these participants expressed that they are more likely to consider a proof more explanatory when it succeeds in providing (a) insight into the derivation of certain formulas, (b) intuition as to why the theorem is true, or (c) insight into how the author or the reader could have discovered the proof in practice.

Keywords: Proof, Mathematical explanation, Roles of proofs, Abstract Algebra.

In 1976, two mathematicians—Kenneth Appel and Wolfgang Haken—jointly supplied a computer-assisted proof of the four-color theorem, which roughly states that four colors are sufficient to color the regions of any map so that no two adjacent regions have the same color. Soon after its publication, the proof generated controversy within the mathematics community. The controversy was less about the validity of the proof but more about absence of insight gained from the method the proof employed. For some prominent mathematicians such as Paul Halmos, the proof failed to provide a sense of illumination as to why the theorem is true, since it relied on a computer program verifying thousands of cases (Thurston, 1994). The controversy surrounding the proof of the four-color theorem suggests that for a mathematician a proof is far more than a certificate of truth and that mathematicians have considerable interest in the reasoning used in a proof. Furthermore, we have evidence lending support to the claim that mathematicians do not always need a proof in order to believe a claim or proposition. In a recent survey study of mathematicians, Weber et al. (2014) argued that mathematicians do obtain conviction based on quasi-empirical or heuristic evidence. de Villiers (1990) also noted this when he wrote: "proof is not necessarily a prerequisite for conviction—conviction far more frequently is a prerequisite for proof" (p. 18).

Furthermore, a careful look at the history of mathematical research suggests that mathematicians continue to search for proofs for conjectures that are widely believed to be true. Consider, for instance, the Riemann hypothesis; it is believed that most mathematicians consider it to be true, yet mathematicians continue the search for a proof. This is perhaps because a proof, if found, will be a rich source of insight into why Riemann's conjecture is true. In their book The Mathematical Experience, Davis and Hersh (1983) made the following observation on why mathematicians continue to search for the proof:

> …It is interesting to ask, in a context such as this, why we still feel the need for a proof…It seems clear that we want a proof because…if something is true and we can't deduce it this way, this is a sign of a lack of understanding on our part. We believe, in other words, that a proof would be a way of understanding why the Riemann conjecture is true, which is something more than just knowing from convincing heuristic reason that is true (p. 368).

The quote above underlines the fact that verification of the certainty of a theorem is not the only role a proof plays in mathematical scholarship. Several authors such as de Villiers (1990) have written extensively about the various roles a proof can play in conveying mathematical understanding. This paper aims to explore the explanatory role a proof plays in conveying mathematical understanding. In other words, this study seeks to expand our understanding of what it really means for a proof to explain by collecting and analyzing interview data from doctoral students in mathematics with a wide range of research interests.

Conceptual Framework and Relevant Literature

According to de Villiers (1990), a proof can function as a means of verification, explanation, systematization, discovery, or communication. Hersh (1993) maintains that in mathematical research conviction is an essential aspect of any valid mathematical proof. Hersh (1993), in fact, defines a proof simply as: "a convincing argument, as judged by competent judges" (p. 389).

For a mathematician, a proof—beyond convincing—also could function as an explanation as to why a theorem is true (de Villiers, 1990; Hersh, 1993; Knuth, 2002; Thurston, 1995; Weber, 2002; Weber, 2008). Roughly speaking, a proof serves as an explanatory argument when it can lead one to "acquire an intuitive understanding of the main ideas of the proof" (Fukawa-Connelly, 2013, p.2). Moreover, in mathematics instruction, researchers have suggested that the primary purpose of a proof in a mathematics class should be to provide complete explanations why a given theorem is true (Hersh, 1993; Hanna, 1995; Weber, 2012; Yopp, 2011). Hersh (1993) writes: "proof can make its greatest contribution in the classroom only when the teacher is able to use proofs that convey understanding" (p.7). Harel and Sowder (2007) also noted this when they said: "…mathematics as sense making means that one should not only convince oneself that the particular topic/procedure makes sense, but also that one should be able to convince others through explanation and justification of her or his conclusions" (p. 808-809). Mathematics professors interviewed in Weber's (2012) and Yopp's (2011) study also maintain that they present proofs to students to convey understanding of why theorems are true.

The consensus view from research cited above is that the primary role of a proof—at least in the teaching of mathematics both at the K-12 and undergraduate levels—should be to convey mathematical explanations (Weber, 2012; Hersh, 1993). That is to say, a proof should help students develop understanding of why something (be it a claim, proposition, lemma, theorem, corollary, and so forth) is true. However, the relatively few existing studies on this topic do not provide a full account of what it means for a proof to explain or when a proof explains. To reiterate, one of the goals of this study is to expand our understanding of what it means for a proof to explain.

In addition to verifying that a theorem is true and explaining why it is true, a proof functions as a means of systematization of known results (de Villiers, 1990). According to de Villiers (1990), proofs are our only tool "in the systematization of various known results into deductive system of axioms, definitions, and theorems" (p.20). For example, the proof of the intermediate value theorem for continuous functions; de Villiers (1990) asserts that the primary function of this proof is basically a systematization of continuous functions. Systematization, among other things, provides global perspective, simplifies mathematical theories, and enables us to identify inconsistencies, circular reasoning, and hidden assumptions (de Villiers, 1990).

Finally, proofs can convey established or novel techniques that can later be used to tackle other problems (Thurston, 1994; Weber, 2012; Yopp, 2011; Lew et al., 2015). For example, mathematicians interviewed in Weber's (2010) study stated that when reading a proof, they would hope to learn new techniques that might eventually help them prove conjectures or problems they have been thinking about. Also, mathematicians interviewed in Mejia-Ramos and Weber (2013) said that the main reason they read published proofs is to gain techniques that they can later apply to other problems. The notion that mathematicians use proofs to convey proving methods or techniques is not limited to research publication; indeed, a significant number of mathematicians interviewed in both in Weber's (2012) and Yopp's (2011) study claimed that they presented proofs to students to illustrate proving techniques. A recent study by Lew et al. (2015) also maintains that mathematics professors present proofs to convey new proving methods.

Methods

Participants

The data to address the research questions are obtained from interviewing eleven doctoral students in pure mathematics from a PhD granting public university in the northeastern United States. All participants have passed their PhD qualifying exams. The participants' research interests include, but are not limited to, algebra, category theory, algebraic topology, analysis, and operator algebra. After completing their PhD degree, nearly all participants (nine out of eleven) indicated that they wanted to pursue an academic career in a more teaching focused institution. This attribute of these participants is of particular importance to this study as they are near experts and likely to be teaching undergraduate mathematics courses in the near future. Also, researchers have argued that for mathematics research to advance, we should examine the beliefs and practice of mathematicians (Harel & Sowder, 2007).

Research Procedure

I met each participant individually for a videotaped, semi-structured task-based interview that resulted in about 63 minutes of footage. One of the goals of these interviews was to gain insight into characteristics of proofs that some consider explanatory. During the interview, I gave participants four tasks. Two of the tasks are given in appendixes A and B. In each task, participants were asked to read two different proofs proving the same result. Participants were told that they can write on and/or highlight the text of the proofs. Additionally, they were encouraged to think out loud while reading each proof.

Participants were asked to read each proof for understanding as opposed to validating the proofs, and they were told that these proofs are taken from either an undergraduate textbook or a research journal. The methodological rationale for incorporating two proofs for each result was to elicit the multiple perspectives on the nature of explanatory proofs. For each task, I asked participants to compare and contrast each proof. In particular, after participants read both proofs in each task, I asked them the following questions:

- Does one proof show something different than the other proof? If so, how so?
- Do you prefer one proof to another? If so, why? If not, why not?
- Do you find one proof more explanatory than the other? Why or why not?

Materials: The Tasks

During the interview, rather than simply asking participants if they hope to gain explanation from proofs they read, I opted to elicit some narrative as to how participants view the nature of mathematical explanation in the context of proofs. To that end, I took proofs deemed explanatory in the literature and asked participants questions to probe their views on the method employed in the proofs in tasks A and B. A subset of proofs in tasks A and B has been presented in the proof literature as being conceptually more beneficial to students because these proofs succeed in showing not only that something is true—convincing or verifying that the claim is true—but also, they provide an explanation of why it must be true (cf. Hanna, 1990, Knuth, 2002, Cellouci, 2008). Additionally, participants were asked questions to elicit some narrative about their philosophical disposition about proofs. Of particular interest to this research was whether or not they distinguished proofs that only verify from proofs that, in addition to verification, also establish why a theorem is true.

Data Analysis

Each interview was transcribed fully and imported to a qualitative software, MAXQDA, for analysis. Participants were assigned pseudonyms G1-G11. I then analyzed interview transcripts using thematic qualitative text analysis (Kuckartz, 2002). In the first pass through the data, participants' responses were organized by topic: explanatory role vs. non-explanatory role. I coded participant's response as explanatory role when the response followed a prompted question about whether a participant found a given proof explanatory or not. Furthermore, a participant's response was coded as explanatory role when it suggested any of the following comments:

- A proof establishes a cause or reason for the veracity of the theorem (Yopp, 2011)
- A proof provides an intuitive understanding of the key ideas so that from the proof it is clear why the theorem must be true (de Villiers, 1990; Steiner, 1978; Yopp, 2011; Fukawa-Connelly, 2013)
- A proof provides intuition about mathematical objects or the topic involved in the proof

Furthermore, I wrote analytic memos while carefully reviewing each interview transcript. During this process I documented emerging themes; in particular, those relating to how participants talked about the meaning of explanation in proofs.

Results

Participants described how a proof can explain in a wide range of ways. For example, for G11, a proof is more explanatory when it succeeds in showing why a certain result is true by showing how it can be derived. According to this interpretation of mathematical explanation in proofs, participants such as G11 drew distinction between proofs that only verify from those that, in addition to verification, also provide a reason as to why something is true. When I asked G11 which proof in task B he finds more explanatory, he commented:

> Obviously the first one…because...so we're trying to show that the sum of the first n integer is given by this formula. And uh so it actually shows you where this formula comes from. It exactly shows if you do it this way then it exactly shows where this formula comes from, but now in the second proof you are starting with this statement that let p_n be this number n times n plus one over two so where did

you get this from…

In the excerpt above, note that G11 does think that proof 2 of task B, the induction argument, is valid and does verify that the formula for the sum is correct; however, he pointed out that it does not provide a reason or insight into why $\frac{n^2+n}{2}$ is the formula for the sum of the first n positive integers. In short, proof 1 shows how one could have obtained or derived the formula, whereas proof 2 first assumes the formula and then it shows that it is correct.

Participants stated that while some proofs such as proof 1 in task B do make the distinction between showing something is true—verification—and why it is true more apparent, other proofs are less successful at doing so, as the following excerpt from G1 illustrates:

> Why in mathematics is a tricky thing. Uh so for some of them like the sum of k where k is 1 to n [referring to the first proof of task B], I feel like the why there is the first proof where it's gauss's proof. It's self-evident, it's nice.

Some participants, such as G5 and G7, also spoke about mathematical explanation in proofs in terms of the extent to which a proof displays the author's thought process. That is to say, these participants find a proof that disguises the thinking behind the discovery of the proof less explanatory. And, they consider proofs that enhance one's clarity by providing some sense of understanding as to how the author originally interpreted the theorem to be more explanatory. Consider, as an illustration, the various ways participants described the absence of this phenomena—mathematical explanation—in proofs of task A. G7 said the following:

> Okay so here we say note that 641 has this expression. Okay now 641 has many expressions. Okay and so it seems funny to say note that well I don't know. I guess maybe it's…and it doesn't say like why are we considering the number 641…where does this number come from you know? Did we just try the you know 200 and however many odd numbers or odd numbers before that or I don't know did we try the prime numbers up to 641 and finally that's the one that worked? So you know this is very like opaque to me [emphasis G7's]

Likewise, G7 did not find the second proof of task A any more explanatory than the first, as the following excerpt illustrates:

> Well it's conclusive but it doesn't teach me anything. Okay and this one um so I mean there are two important parts to this proof and one of them is hidden. Okay so one important part of this proof is um we should identify, somehow identify this number 641 with which to attack this the 2 to the 2 to the 5th plus 1. So I mean we're going to attack 2 to the 2 to the 5th using 641. Okay. So some part of this proof is coming up with 641 is the useful number we should apply. Okay and then all right and the rest of the proof is this modular arithmetic argument to get you know to get that it works. You know I sort of lost interest.

In both excerpts above, we observe that for G7, the mysterious appearance of 641 made both proofs less explanatory. Both proofs fail to provide some sense of understanding as to why or how the authors thought of the number 641 to be important in the first place. To put it simply, both proofs were less successful in conveying how the author came up with those factors of the number in question, and as such, G7 found them less explanatory. Another participant, G5, also found proof 1 of task A less explanatory. He commented:

> I mean okay I will say this at least the second proof uses techniques of number theory to convince me that 641 divides this number but it's still kind of coming off like they know 641 is going to divide this number. I mean where's the lead up to knowing that 641 is even going to be a candidate? You know that would be

nice. I mean I look at both of these and I still just go okay uh how would I ever recreate this.

In this excerpt, G5 stated that proof 1 of task A failed to provide an explanation for the sudden appearance of the number 641. He asked, "where's the lead up to knowing that 641 is going to divide this number." According to G5, proof 1 masks the thought process that led to its discovery and the proof would have been more exploratory had it described why the number 641 is crucial or how one could have discovered it initially.

Discussion

Hanna (1995) writes: "in trying to define the true function of proof in mathematics education it is helpful to look at the function of proof in mathematics itself" (p.14). This study contributes to the mathematics education community in several ways. First, it expands our understanding of the roles a proof can play in conveying mathematical understanding; in particular it sheds light on how proofs can convey mathematical explanation.

Much of the scholarship on proof and proving (e.g., Hanna, 1990; Weber, 2012; Yopp, 2011; Hersh, 1993; De Villiers, 1990) has suggested that a proof is pedagogically more valuable when it is used during instruction as explanatory argument, yet the notion of mathematical explanation in proofs—despite being one of the most cherished roles of a proof—is rarely articulated in mathematics education research. Several authors such as Hanna (1990) and de Villiers (1990) discuss the explanatory role of a proof, but neither of these studies present interview or survey data with students or mathematicians; instead, the discussion of explanatory proof in previous studies is merely based on the authors' reflections and hypotheses based on their own experience. Moreover, even though both Weber (2012) and Yopp (2011) present the explanatory role of a proof based on interviews with mathematicians, still the lack of concrete examples in these studies makes the distinction between the verification and explanation role of a proof subtle.

While participants in this study did not display the same interpretation of mathematical explanation in proofs, their responses provided a rich source of perspective on the nature of proofs that are deemed explanatory. Further study, with more participants and a wider range of proofs, is called for so that we can continue clarifying our understanding of what it means for a proof to explain.

The current study also provides data that suggest that certain presentations of a proof have the potential to enhance the proofs' explanatory power. For example, I conjecture that a proof is more likely to be explanatory when it clearly displays to its audience how its key ideas are linked to prove the theorem. In other words, the degree to which a connection between a proof's key ideas are made transparent to the reader has some bearing on the level of mathematical explanation conveyed in the proof; in some cases, this entails including more detail or explanation of assertions within a proof. Sometimes explanation of assertions within a proof can be made using visual aids such as pictures or diagrams. However, the extent to which students can actually extract a mathematical explanation from proofs that incorporate a picture or a diagram is mainly untested. Future research can examine the pedagogical effectiveness of proofs that include pictures, heuristic approaches.

Appendix A: Task A

Note: The following two proofs are borrowed from Avigad (2006).

Claim: $2^{2^5}+1$ is not prime.

Proof 1

A calculation shows that $2^{2^5}+1=(641)(6700417)$. Q.E.D.

Proof 2

First, note that $641=(5)(2^7)+1 \Longrightarrow (5)(2^7)\equiv -1(mod\ 641) \Longrightarrow (5^4)(2^{28})\equiv 1(mod\ 641)$. On thoe other hand, we have that $641=5^4+2^4 \Longrightarrow 5^4\equiv -2^4(mod\ 641)$. Then $(5^4)(2^{28})\equiv -2^{32}(mod\ 641)$. So we have that $1\equiv -2^{32}(mod\ 641)$. Q.E.D.

Appendix B: Task B

Note: The following two proofs are borrowed from Hanna (1990)

Claim: $\sum_{k=1}^{n} k=\frac{n(n+1)}{2}$.

Proof 1

We write out the terms first forward (as in *) and then backward (as in **)

1 + 2 + 3 +… + (n-1) + n …………(*)

n + (n-1) + (n-2) +… + 2 + 1 ………..(**)

The conclusion follows from the fact that the sum of the two terms in each column is (n+1) and we have n columns. Q.E.D.

Proof 2

We will proceed by induction. Let $P(n)$ be a statement that says the sum of the first n natural numbers is $\frac{n(n+1)}{2}$. We will show that $P(n)$ holds for all natural numbers n. The case for $n=1$ is immediate. For the inductive step, assume that for some $k, P(k)$ is true, so $1+2+\cdots+k=\frac{k(k+1)}{2}$. We must show that $P(k+1)$ is also true. Since $1+2+\cdots k+(k+1)=\frac{k(k+1)}{2}+(k+1)=\frac{(k+1)(k+2)}{2}$, we conclude that $P(n)$ is true. Q.E.D.

Undergraduate Students' Holistic Comprehension of a Proof

Eyob Demeke
California State University, Los Angeles

In this paper I explore eleven undergraduate students' comprehension of a proof taken from an undergraduate abstract algebra course. My interpretation of what it means to understand a proof is based on a proof comprehension model developed by Mejia-Ramos, et al. (2012). This study in particular examines the extent to which undergraduate students are able to summarize a proof using the proof's higher-level ideas. Additionally, eleven doctoral students in mathematics were asked to provide a summary of the same proof that the undergraduate students received. Undergraduates' holistic comprehension of the proof was then analyzed in light of summaries that the doctoral students provided. The main finding of the study is that undergraduates' comprehension of the proof was overall inadequate—notably, they demonstrated limited skills in summarizing a proof via the proof's key ideas. Moreover, undergraduates failed to recognize the scope of the method used in the proof.

Key words: Proof, Proof Comprehension, Abstract Algebra.

In advanced undergraduate mathematics courses, students are expected to spend a significant portion of their time reading proofs. Although proof comprehension is a fundamental aspect of undergraduate mathematics education, studies by Conradie and Frith (2000), Rowland (2002) and Weber (2012) suggest that mathematicians rarely measure their students' comprehension of proofs. For example, Weber (2012) reports that mathematicians assess their students' comprehension of proofs by asking students either to reproduce the proof or prove a similar or a trivial consequence of proofs they presented in class. However, Conradie and Frith (2000) suggests that asking students to reproduce a proof may not be a pedagogically useful way of assessing students' understanding of a proof because students can and do correctly reproduce a proof by simply memorizing it word for word, with virtually no understanding at all.

Despite its importance in undergraduate mathematics education, research on undergraduates' comprehension of proofs is limited. In fact, much of the proof literature focuses on students' aptitude to construct or validate proofs and less on their ability to comprehend proofs (Mejia-Ramos et al., 2012; Mejia-Ramos & Inglis, 2009). Mejia-Ramos and his colleagues (2009) systematically investigated a sample of 131 studies on proofs and they found that only three studies focused on proof comprehension. They hypothesize that the scarcity of the literature on proof comprehension is perhaps due to the lack of a model on what it means for an undergraduate student to understand a proof. In this study, I adopt an assessment model for proof comprehension that was developed by Mejia-Ramos, et al. (2012) to explore undergraduates' comprehension of proofs. In particular, this study seeks to address the following research questions.

To what extent do undergraduates comprehend a proof? More specifically, to what extent do undergraduates:

- summarize a proof using its high-level ideas,
- recognize and appreciate the scope of a method used in a proof?

Theory: Assessment Model for Proof Comprehension

Mejia-Ramos, et al. (2012) proposed that one can assess undergraduates' comprehension of a proof along seven facets. These seven facets are organized into two overarching categories: local and holistic. A local understanding of a proof is an understanding that a student can gain "either by studying a specific statement in the proof or how that statement relates to a small number of other statements within the proof" (p.5). Alternatively, undergraduates can develop a *holistic* comprehension of a proof by attending to the main ideas of the proof. Below, I will elaborate on what it means to understand a proof holistically.

Assessing the Holistic Comprehension of a Proof

According to the proof comprehension model, the holistic understanding of a proof consists of being able to: (1) summarize the proof using the proof's main ideas, (2) identify the modular structure of the proof, (3) recognize and extend the method used in the proof, and (4) illustrate the method of the proof using a specific example or diagram. They developed these four facets of holistic comprehension of proofs based on: (a) mathematicians' perspectives on how and why they read and present proofs and what it means for them to understand a proof; (b) the proof literature on the role of proof; and (c) the recommendations by mathematicians and mathematics educators on proof presentations that would presumably improve students' proof comprehension. Below, I elaborate on (1) and (3).

Summarizing a proof via its high-level ideas. Mejia-Ramos, et al. (2012) state that "one way that a proof can be understood is in terms of the overarching approach that is used within a proof" (p.11)." Being able to summarize a proof via its high-level ideas entails understanding the proof's "top-level overview" or "big idea". A good summary of a proof may include what Raman (2003) describes as a proof's *key ideas.* Raman (2003) defines *key ideas* as "heuristic ideas which one can map to a formal proof with appropriate sense of rigor" (p. 323). *Key ideas* provide "a sense of understanding and conviction why a particular claim is true" (Raman, 2003, p. 323). Mathematicians can evaluate their students' understanding of this aspect of a proof in at least two ways. They can, for instance, directly ask students to provide a brief summary of the proof that includes the proof's higher-level ideas. Alternatively, they can provide students with a few summaries of the proof and ask them to choose which summary best captures the main ideas of the proof (Mejia-Ramos et al., 2012). In this study, I asked undergraduates to provide a proof summary using the proof's main ideas.

Transferring the general ideas or methods to another context. Mejia-Ramos, et al. (2012) suggested that identifying the scope of a method or technique used in a proof is an important aspect of proof comprehension. Mathematicians can assess this aspect of proof comprehension by asking students to (a) identify methods or techniques without which the proof would have collapsed, or (b) prove new claims by applying methods similar to those used in the original proof. In this study, undergraduates were asked questions to elicit their understanding of the scope of a method used in a proof.

Review of the Literature

As noted earlier, educational research on proof comprehension in undergraduate mathematics has received little emphasis. Osterholm (2006) was among the first to look into student's comprehension of mathematical texts. He conducted a quantitative study of reading comprehension of abstract algebra students (he compared texts with one including symbols and another one not). He concludes that "mathematics itself is not the most dominant aspect affecting the reading comprehension process, but the use of symbols in the text is a more relevant factor" (p.325). His contention is based on the fact that the group of students who had almost no symbols and notations in their reading assignment outperformed, in a reading comprehension test, those whose reading assignments involved mathematical symbols and notations. Although Osterholm (2006) does point to difficulties student encounter while reading mathematical texts, it should be noted that his study only asked students to read mathematical texts and not proofs specifically.

Research also suggests that undergraduates are not successful in gleaning understanding from the proof they see during lecture (Selden & Selden, 2012; Lew et al, 2015). For example, students interviewed in Lew et al.'s (2015) study fail to comprehend much of the content the instructor desired to convey, including the method used in the proof. Students interviewed in Selden and Selden's (2012) study also failed to understand a proof holistically since they were fixated on verifying each line and put little emphasis in attending to the overarching methods used in the proof. One purpose of this study is to build on the growing body of research on proof comprehension.

Methods

Research Settings

This study took place in a large public university in the northeastern United States. The content of the proof used in this study come from an introductory abstract algebra course. In the chosen research setting the standard textbook used is *Abstract Algebra: An introduction* by Hungerford (2012). The goal of the course (as stated in the syllabus) is to introduce students to the theory of algebraic structures such as rings, fields, and groups in that order.

Participants

Undergraduate student participants. Since the main purpose of this study is to explore undergraduates' comprehension of proofs—in particular, proofs that appear in an introductory abstract algebra course—I personally approached undergraduates who had taken or were enrolled in an introductory abstract algebra course. Eleven undergraduates agreed to participate in this study and were assigned pseudonyms S1-S11. At the time of the study, six of the eleven undergraduate participants (S3, S5, S6, S7, S8, and S9) were enrolled in an introductory abstract algebra course. Seven participants—S1, S2, S3, S5, S6, S7, S8, and S9—were pursuing a major in secondary mathematics education and said they intended to be high school mathematics teacher. The remaining four students were mathematics majors. Furthermore, each participant had taken a minimum of three proof-based courses and all but three (S1, S3, and S6) said they received an A or B in their introduction to proof course. Participants' responses on a background survey suggest that each participant spent at least two hours per week reading proofs outside of class.

Doctoral students. Eleven doctoral students at the aforementioned research site agreed to participate in this study. I used doctoral students to analyze undergraduates' summaries of a proof. At various times, I asked the doctoral students to provide, in writing, a summary of a proof using the proof's key or main ideas. To avoid confusion, in the remainder of this paper I will refer to these doctoral student participants as experts.

Materials and Research Procedures

In this study undergraduates were asked to read a proof that shows that any finite integral domain is a field. This proof is given in appendix 1. I chose this proof because (a) it nicely draws connection between two important topics covered in abstract algebra: integral domains and fields, and (b) it uses a proof technique that I speculated most participants probably have not seen.

The principles I employed to write this pedagogical proof—a proof that is geared toward undergraduates for the purpose of pedagogy—is based on the Lai, Weber, & Mejia-Ramos (2012) study. Lai et al. (2012) report that mathematicians valued pedagogical proofs that (1) made assumptions and conclusions of the proof explicit, (2) centered on important equations to emphasize the main ideas, and (3) did not contain "true but irrelevant statements." (p.94). Also, when writing the proof, I consulted mathematics professors and made appropriate modifications.

Participants were asked to read the proof until they felt they understood it and were encouraged to write and/or highlight on the proof paper as well as to think out loud while reading. Once a participant finished reading the proof, she/he was asked to:

- to provide a good summary of the proof including the proof's main or higher-level ideas
- to indicate assertion(s) in the proof that would fail if R was infinite.

Analysis

Recall that eleven doctoral students in mathematics were asked to write a summary of the proof using what they think are the main ideas of the proof. Doctoral students were also asked to describe the key ideas of each proof. First, I carefully studied doctoral students' summaries of the proof. I then developed a synthesized summary for the proof. This synthesized summary, which will hereafter be referred to as the expert's summary, also incorporated all the key ideas that doctoral students described for each proof. That process resulted in the following summary of the proof.

> The proof shows that any finite integral domain R is a field by showing that any non-zero element of R has a multiplicative inverse. Let a be any non-zero element of R. The absence of zero divisor in R taken together with the fact that R is finite implies that left multiplication by a defines a bijective map from the integral domain to itself (In other words, $f_a: R \to R$ given by $f_a(x) = ax$ is a bijection). Surjectivity of this map guarantees that a has a multiplicative inverse.

The key ideas identified in the expert's summary of the proof:

- overarching method: given an arbitrary non-zero element $a \in R$, one can show that there exists $b \in R$ such that $ab = 1_R$ (R is a finite integral domain)
- define a left multiplication by a non-zero element $a \in R, f_a: R \to R, x \mapsto ax$. Use the kernel of f_a to show that it is injective.
- the finiteness of R coupled with the injectivity of f_a shows that f_a is a surjective map from R to R.

The above expert's summary of the proof was eventually verified by two experienced researchers in mathematics education as to whether or not it indeed incorporated all the *key ideas* of the proof that doctoral students discussed; modifications were then made to the expert's summary, as needed.

Finally, using a rubric, two researchers, both with a master's degree in mathematics, independently conducted a comparative analysis of undergraduates' summaries of the proof against expert's summaries. When disagreement emerged, w engaged in discussion until a consensus was reached.

Results and Discussion

Results on Undergraduates' Summaries of the proof

Recall that undergraduates' summaries of the proof were analyzed in comparison to the expert's using a rubric that is omitted here for a shortage of space. Nearly all participants, nine out of eleven, provided a summary of the proof that suggested a limited proof comprehension. In particular, their responses indicated that they either *poorly* or *very poorly* understood the proof. The results of students' summaries of the proof is given in Table 1. Note, in table 1, that a majority, six undergraduates, provided a *very poor* summary of the proof, which implies that their summary failed to highlight the main ideas of the proof that was described in the expert's summary.

Table 1 Undergraduate students' summaries of the proof

Evaluation	Undergraduate students
Very poor	S3, S5, S6, S8, S9, S11
Poor	S1, S2
Satisfactory	S4, S7, S10
Good	None

In order to give you a sense of a *very poor summary*, I will provide a detailed description of summaries given by S5, S8, and S9. When asked to provide a good summary of the proof including the proof's main ideas, S5 offered the following summary:

> R is an integral domain and field. It is both surjective and injective to the kernel of the function that defines it. There is also $1_R \in R$ that allows it to have multiplicative inverse, thus units. I know a field's non-zero elements all make units, a field.

S5's summary consists of incomplete sentences and phrases that are either mathematically incorrect or appear to have been copied from the proof word for word. For instance, S5 begins by supposing the thing that needs to be shown—that R is a field. Also, there is evidence of a misunderstanding about injectivity and surjectivity of a map. This is evident when he asserts that R, as opposed to f_a, is both surjective and injective. Finally, S5's summary doesn't mention how crucial assumptions in the proof such as the finiteness of R are used in the proof. Thus, S5's summary is deemed to be *very poor*, which means it was considered to be very different from the expert's as it did not highlight main ideas of the proof. S8, likewise, provides a *very poor summary*:

> The proof basically gave a less textbook traditional explanation of a way to prove that all finite integral domains are fields. It used the understandings of kernals [sic], bijections, injection, surjections in order to prove facts about rings, where usually you learn the facts about rings before being introduced to functions

Her summary above makes no mention of the proof's high-level or *key ideas* and thus does not suggest a satisfactory comprehension of the proof. While she enumerates topics that are used in the proof, her summary does not illustrate how they were employed in the proof. S8's summary, for example, indicates that the concept of bijectivity is employed in the proof, but she does not explain how it is used. Along the same lines as S5, and S8, S9 also supplied a summary of the proof that did not suggest a satisfactory comprehension of the proof. For example, S9 provided the following summary:

> Given a finite integral domain, you can prove that it is a field by showing it has a multiplicative inverse, no zero divisors, injective and surjective, kernels, and if there is a multiplicative inverse such that $ax = 1_R$ and $a \neq 0_R$ then R is a field.

S9's summary above says very little beyond restating the claim. S9 essentially repeats phrases that appeared in the proof verbatim. He does not draw any connection between *key ideas* described in the expert's summary of the proof. Also, S9's summary states that R is first shown not to have zero divisors, but this is neither necessary nor true; R is assumed to be an integral domain and therefore it does not have zero divisors. Overall, S9's summary fails to mention the proof's key ideas and consequently shows limited comprehension of the proof.

While the majority, six out of eleven students, provided what is considered to be a *very poor summary* of the proof, S1 and S2 supplied a *poor summary* of the proof. S2, for example, provided the following summary of the proof:

> The aim of the proof is to show that if R is a finite integral domain, then R is a field. It then wants to show that R has a multiplicative inverse, then that the kernel of $f_a: x \to ax$ to be trivial. The prof then shows that $x = 0$ since if $ax = 0$ then a or x is 0 but a is not, thus ker $f_a = \{0\}$ so f_a is injective. Thus, $|R| = |f_a(R)|$, which shows it is surjective. It then proves a has a multiplicative inverse, so R is a field.

S2's summary is incoherent and appears to duplicate some parts of the proof word for word. Moreover, her summary includes way too much unnecessary information; for example, she repeats the argument for the triviality of f_a. While S2's summary does mention some *key ideas* that are noted in the expert's summary, it doesn't make the logical connection between those *ideas*. In fact, S2 appears to have the logic of the proof backward, as she seems to think the existence of multiplicative inverse is what guarantees the triviality of the kernel of f_a.

While no one provided a *good summary* of the proof, three students—S4, S7, and S10—provided a *satisfactory summary* of the proof. S7, for instance, summarized the proof as follows:

> First it is important to show each nonzero element of R has a multiplicative inverse. Then I consider a nonzero element $a \in R$ and the map of f_a. I use the kernel of f_a to prove f_a is injective. Then from the fact that f_a is injective and therefore $|R| = |f_a(R)|$, f_a is also surjective. Finally, I show $f_a(x) = 1_R$ hence a has a multiplicative inverse and therefore R is a field.

Evidently, S7's summary above has significant resemblance to the expert's summary of the proof. In particular, S7 does mention some *key ideas* of the proof. However, she did not indicate the fact that the surjectivity of f_a depends on the finiteness of R, which was a crucial idea that was noted in the expert's proof. Furthermore, the last line of her summary is incorrect in the sense that f_a is not identically equal to the identity 1_R. Also, based on what is stated at the very end of her summary, S7 does not seem to have understood how a (the fixed nonzero element) has a multiplicative inverse. However, S7's summary overall does bear some resemblance to the expert's summary and suggests a satisfactory understanding of the proof. On the whole, while nearly all students provided a *poor* or a *very poor* summary of proof, no one provided a *good summary.* Indeed, only S4, S7, and S10 managed to provide a satisfactory summary of the proof.

Results on Undergraduates' Ability to Recognize or Appreciate the Scope of a Proof's Method

No undergraduate demonstrated why R must be finite for the proof to be valid. When asked why the method of the proof would fail if R was assumed to be infinite, six out of eleven undergraduates offered no response or said "I don't know…" The other five students pointed incorrectly to an assertion that would fail if R is infinite. Table 2 below illustrates the various responses they provided:

Table 2 Reasons undergraduates provided for why R must be finite

Reason why R must be finite	Participants
R would not be commutative (line two)	S1
There wouldn't be exactly be the same number of elements in each	S3
f_a would not be injective (line seven)	S2, S8, S5
No response/I don't know/Not sure	S4, S6, S7, S9, S10, S11

Table 2 shows that participants failed to pinpoint a specific assertion in the proof that would fail—the argument in line eight—if R was infinite. That is to say, if R is infinite, $f_a(R) \subseteq R$ and $|R| = |f_a(R)|$ taken together would not guarantee that $f_a(R) = R$, which would not make f_a surjective.

To summarize, Mejia-Ramos and colleagues (2012) maintain that being able to provide a good summary of a proof is a key indicator of comprehension. However, undergraduates in this study showed a limited comprehension of the proof. In particular, in their proof summary undergraduates failed to highlight the proof's main idea. For a large number of participants, their proof summary was essentially a replica of a few sentences that appeared in the proof. Further research is needed to identify why undergraduates fail to summarize a proof using the proof's main ideas.

Appendix 1

Claim Let R be a finite integral domain. Then R is a field.

Proof. 1. Let R be a finite integral domain whose multiplicative identity is 1_R and whose additive identity is 0_R.

2. Since R is a commutative ring, it suffices to show that every nonzero element in R has a multiplicative inverse.

3. Let a be a fixed nonzero element of R $(a \neq 0_R)$. Consider the map $f_a: R \to R$ defined by $f_a: x \to ax$. I first show that the kernel of f_a is trivial.

4. Note that kernel of $f_a = \{x \in R: f_a(x) = 0_R\} = \{x \in R: ax = 0_R\}$.

5. Since R has no proper zero divisors, $ax = 0_R \Longrightarrow a = 0_R$ or $x = 0_R$. But, $a \neq 0_R$ thus $x = 0_R$.

6. Therefore kernel of $f_a = \{0_R\}$ and so f_a is injective.

7. Next, note that $|R| \geq |f_a(R)|$. Since f_a is injective, it follows that $|R| = |f_a(R)|$.

8. Because $f_a(R) \subseteq R$ and $|R| = |f_a(R)|$, I have that f_a is surjective.

9. Finally, since $1_R \in R$, I have that $\exists x \in R$ such that $f_a(x) = ax = 1_R$. So a has a multiplicative inverse. Therefore, R is a field.

Generalising Univalence from Single to Multivariable Settings: The Case of Kyle

Allison Dorko
Oregon State University

A function is defined as a mapping from one nonempty set (the domain) to another nonempty set (the co-domain or range) such that each element of the domain maps to exactly one element of the range. Algebra curricula typically include classification tasks in which students determine if a relation violates the univalence criterion – the condition that each element in the domain corresponds to exactly one element of the range. This paper provides a longitudinal case study of how one student generalised the univalence criterion from single- to multivariable functions. For f(x), Kyle primarily thought of univalence in terms of the vertical line test and the variables x and y. He generalised univalence for the multivariable function f(x,y) by thinking about input, output, independence, and dependence. Kyle's story provides an example of how a student might generalise facets of the function concept in normatively correct ways.

Key words: multivariable functions, generalisation, univalence

Introduction

Functions are fundamental to mathematics. Introduced in algebra, functions appear throughout calculus, real and complex analysis, transformational geometry, and many other areas of mathematics. It follows that understanding function is critical for student success in mathematics. While high school curricula have traditionally focused on functions of one variable, the Mathematical Association of America has proposed adding multivariable topics as a way to increase mathematical competence for all students (Ganter & Haver, 2011; Shaughnessy, 2011). Supporting this, research findings indicate that seventh graders can accurately model real-life situations of two variables (Yerushalmy, 1997). However, at the undergraduate level, we know students struggle with multivariable calculus topics (Dorko & Weber, 2014; Jones & Dorko, 2015; Kabael, 2011; Trigueros, & Martínez-Planell, 2010). Hence research about how students come to understand multivariable functions can help inform instruction for a broad band of students.

Understanding how students think about multivariable functions necessarily includes how they determine what is and is not a function. This involves evaluating whether or not a relation violates the univalence criterion, and students tend to use the vertical line test in such evaluations (Leinhardt, Zaslavsky, & Stein, 1990). However, we do not know how students think about what is and is not a function, and how they generalise univalence, in the multivariable case. Hence this paper focuses on the following research question: *How do students generalise univalence?* I investigated this via a longitudinal study of five students who completed a series of interviews throughout their differential, integral, and multivariable calculus sequence. In this paper, I present a case study of a single student who successfully generalised univalence.

Background

Univalence is the condition that each element in a function's domain is mapped to exactly one element of the range. For a single-variable function f: R $\rightarrow$ R such that $y = f(x)$, univalence means that each x maps to exactly one y. Beginning algebra instruction typically includes 'classification' tasks in which students are given a relation and asked if it represents a function (Leinhardt, Zaslavsky, & Stein, 1990). For a graphical representation, students typically evaluate univalence with the vertical line test. A graph is univalent, and hence a function, if any line $x = c$ for some constant c and x in the domain will intersect the graph exactly once. For a multivariable function g: R x R → R such that $z = g(x,y)$, the univalence condition means that each (x,y) maps to exactly one z. The vertical line test generalises such that any vertical line through a point (x,y) in the domain will intersect the graph of $z = g(x,y)$ exactly once.

Student understanding of univalence for single-variable functions

Researchers have documented that students commonly solve graph classification tasks with the vertical line test (Clement, 2001; Thomas, 2003) and that some students will convert a non-graphical representation to a graph so they can use the vertical line test (Kabael, 2011; Thomas, 2003). Other students solve classification tasks by looking for *x*'s and *y*'s (Thomas, 2003). For example, Thomas (2003) observed students say the set of points $(x, 2x)$ for $x \in \mathbb{R}$ was not a function because there were no *y*'s. Finally, students may solve classification tasks by comparing graphs to prototypical examples such as $x = y^2$ (Clement, 2001).

Students commonly conflate univalence with other properties, such as one-to-one-ness (Bakar & Tall, 1991; Clement, 2001; Even, 1993; Markovits, Eylon, & Bruckheimer, 1986; Vinner & Dreyfus, 1989). Students may not include the univalence criterion when defining function, or they may state it backward, saying each element in the range is paired with exactly one element in the domain (Even, 1993; Kabael, 2011). Similarly, Thomas (2003) found that some students used a horizontal line test instead of a vertical line test on graphical classification tasks.

Student understanding of multivariable functions

Kabael (2011) found after instruction about multivariable functions, 21 of 23 students solved graphical classification tasks by converting the graphs to algebraic formulae. In a test at the end of the multivariable calculus course, 13 of the 23 solved graphical classification tasks with the vertical line test. On classification tasks in which the students were given algebraic formulae, 5 of the students drew a graph and used the vertical line test. Four students evaluated univalence by determining algebraic formulae for all classification tasks on both tests. These findings suggest by the end of the course, some but not all students had generalised univalence across representations (Kabael, 2011).

Researchers have found that thinking of functions in terms of inputs and outputs allows students to generalise in normatively correct ways (Dorko & Weber, 2014; Kabael, 2011). In contrast, focusing on specific variables leads some students to believe that the domain of a function $f(x,y)$ is the set of all possible x values and the range is the set of all possible y values, as is often true for the $f(x)$ case (Dorko & Weber, 2014). Kabael (2011) also observed that students struggled with domain and range, giving a particular (x, y, z)-tuple as an example of an element of the domain or an element of the range. Difficulty with domain and range may play a role in students' ability to generalise univalence, as testing for univalence requires identifying an element of the domain and checking that it is paired with exactly one element of the range.

Theoretical Perspective

I interpret students' thoughts and generalisations from an actor-oriented perspective (Lobato, 2003; Ellis, 2007). This perspective focuses on what connections students identify across situations, even if their perceived similarities are not normatively correct. In the actor-oriented perspective, generalisation is defined as "the influence of a learner's prior activities on his or her activity in novel situations" (Ellis, 2007, p. 225). Students may make connections across situations by identifying similarities, or by "discerning differences and modifying situations" (Ellis, 2007, p. 225). Hence in exploring how students generalised univalence in graphical and tabular contexts, I looked for similarities and differences in how they handled the single- and multivariable tasks.

The actor-oriented approach is an alternative to traditional transfer (e.g., Gick & Holyoke, 1980; Judd, 1908), in which research questions tend to focus on whether or not participants identify pre-determined similarities. By attending to only what is normatively correct, such a perspective often fails to capture the sense participants make of situations. One reason the actor-oriented perspective is appropriate for the design of this study is that in the multivariable pre-interview (see below), students were looking at a novel context (R^3) with significant differences from the original (R^2) context. Hence the actor-oriented perspective allowed us to capture what students saw as similar, what they saw as different, and what adaptations they made between the two contexts.

Research Design

Data Collection

I conducted task-based clinical interviews (Hunting, 1997) with each of five students at three separate instances over the span of their differential, integral, and multivariable calculus courses. This paper focuses on a subset of tasks from the interview in which students were given graphs and tables and asked which represented functions. The interviews were recorded with audio, video, and Livescribe technology, and I subsequently transcribed them for analysis.

The first interview, conducted at the beginning of students' single-variable calculus course, contained R^2 graphs and tables (Figures 1). The second interview, conducted during integral calculus, contained R^3 graphs (Figure 2). Asking students about graphs in R^3 before instruction about multivariable functions allowed me to capture students' initial sense-making about multivariable functions and how the univalence criterion might generalise. Before starting the tasks I presented students with a picture of R^3 axes, pointed out the axis labels, and explained that the *xy* axis made a flat plane like a tabletop and the *z* axis was vertical and orthogonal/perpendicular to the *xy* plane. I demonstrated this using the corner of a table and a pen held orthogonal to it. Some of the students had plotted points on R^3 axes in high school algebra, but that was the extent of their experience with multivariable topics.

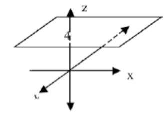

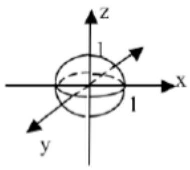

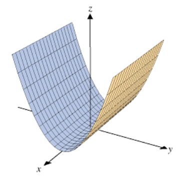

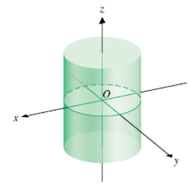

Figure 3. Interview 3 classification tasks, listed in the order they appeared to students. Tasks c2 and A2 from Kabael (2011)

The phrasing "do the following represent functions?" in the Interview 2 and 3 tasks was purposefully ambiguous. Since findings from research indicate that some students generalise domain and range by thinking about inputs and outputs and/or independence and dependence (Dorko & Weber, 2014; Kabael, 2011), I wanted to see how students would determine which variables were the input(s), output, independent, and dependent variables.

The third interview, conducted at the end of students' multivariable calculus course, contained both graphs and tables in R^2 and R^3 (Figures 3). I explained how to read the tables and gave the example 'in Table I, when x is 0 and y is -1, z is 0.' These post-instruction tasks captured the sense students made of normative ideas and how they connected those ideas to prior knowledge. In short, the longitudinal nature provided unique insight into the generalisation phenomenon.

Data Analysis

I used a constant comparative analysis (Strauss & Corbin, 1998) to code students' reasoning. Findings from literature influenced my coding in that I looked for x, y, input, output, independent, and dependent, as these are common ways students think about multivariable functions (Dorko & Weber, 2014; Kabael, 2011). However, I was careful to include other phrases not within that list. After coding students' responses for particular phrases, I compared the students' reasoning from interview 1 to 2 to 3. Because of the longitudinal nature of the study, this allowed me to compare how students thought about what a function is pre- and post- instruction, and to identify ideas that stood out to them. In particular, I looked for ways of thinking that were the same across interviews, and ways of thinking that were different. This allowed me to address the question of how students generalised from the single- to multivariable case.

Results

In thinking about the questions, students used words like x and y, input, output, independence, dependence, no dependence, repeated x values, pattern, and vertical line test. When answering the multivariable questions, many first stated the definition of univalence for a single-variable function. They then applied this criterion directly to the multivariable setting (example below), and/or worked on how to adjust it for R^3.

Kyle was the only student who answered all of the questions correctly. I present some of his thinking as an example of how a student successfully generalised univalence.

Single-variable tables and R^2 graphs

Kyle answered all of the single-variable table and single-variable graph questions correctly. He searched for *x* values paired with multiple *y* values in both contexts and used the vertical line test for the graphs (Excerpts 1 and 2).

Excerpt 1. SV Interview, SV Tables i, ii, and iii

Kyle: Okay, so for every *x* there is only one *y*. Well this one is not a function, so *i*, *i* is not a function… Because there are two values for *x* of 3 that have different *y* values. The *y* is 4 and this one, 5 on this one.… *ii* is a function. And *iii* is a function… I determined that because … in *ii*, for every *x* value, it has a *y* value. It has one *y* value, not multiple *y* values. And same with *iii*. There's no repeated *x* values that have different *y* values.

Kyle's work with the single-variable tables revealed that he understood that each element in the domain must map to something in the range ("for every *x* value, it has a *y* value"). I take the statements "for every *x* there is only one *y*" and his example of $x = 3$ mapping to $y = 4$ and $y = 5$ as evidence that Kyle understood the univalence criterion. His responses to the R^2 graph tasks provided further evidence that he understood a function must be univalent (Excerpt 2).

Excerpt 2. SV Interview, SV Graphs b and c

Kyle: So *b* is a function of *x*, and this is also, *c* is also a function of *x*. So you determine whether a graph represents a function if for every *x* value there's only one *y* value that is present. And so for both these graphs, that's the only, that's the case. There's, there's like a test you could do where you make lines going straight down and if the line only goes through one point in the curve…then it's a function.

Here, Kyle described the vertical line test and restated his criterion of each *x* mapping to one *y*. One point of note is that while Kyle stated the letters *x* and *y*, he did not use any other descriptors (e.g., input, output, independence, dependence). This may be an artifact of the tasks, which were all posed with *x*'s and *y*'s.

Multivariable graphs (pre-instruction)

In classifying MV graphs A, B, C, D, E and F, Kyle sought to generalise the vertical line test and his notion that each *x* has exactly one *y*. In doing so, he appeared to draw on the particular symbols, coordinate points, and the notion of an output.

Symbols and coordinate points

Kyle reasoned with symbols and the form of coordinate points for graph A and graph C (Excerpt 3 and 4).

Excerpt 3. MV Pre-interview, MV Graph A

Kyle: [Graph A]…it's a function, I think…for every *x* there's a *y*, for every, for every *x* there could be multiple *y*'s, so it's not a function…

Excerpt 4. MV Pre-interview, MV Graph C

Kyle: [Graph C] I mean I guess it can be a function, because it could have a different… at every, maybe…for 3D if it's a value of *x*, it has to have a different *y* and *z* [writes *(x,y,z)*] instead of just for every value of *x* there's a *y*, as long as something's different in the *y* or the *z*, then it's okay… for some value of *x* there has to be a value of *y* and a value of *z*.

Kyle's first attempt at generalising seemed to be to evaluate the R^3 graph with the same criterion he used for R^2 graphs. That is, his first statement was that the graph was not a function because "for every *x* there could be multiple *y*'s", which was his evaluation criteria for graphs in R^2 (Excerpts 1 and 2). In further thinking, Kyle sought to change the way he evaluated the R^3 graph. For instance, he considered that maybe a multivariable function would have 'something different' in the *y* or the *z*.

I interpret Kyle's statement "for some value of *x* there has to be a value of *y* and a value of *z*" as a generalisation of his statement in the single-variable tables "for every *x* value, it has a y value." That is, he seemed to try to generalise the idea of each element in the domain mapping to an element of the range. I take as evidence the phrases "for every x" (single variable) and "for some value of x" (multivariable), suggesting that Kyle was attempting to pair x with something in each case. He generalised x having "a y" (single-variable) to x having "a value of y and a value of z" (multivariable). In these statements, Kyle seemed primarily focused on the particular symbols themselves rather than what they might represent.

As Kyle thought about this, he wrote the three-tuple (x, y, z). This seems salient for two reasons. First, it is further evidence of Kyle's attention to symbols. Second, he appeared to use it as a tool to help him generalise. The evidence for this is how he alternated between talking about the single variable case to the multivariable case (Table 1).

Table 1. Using the coordinate point structure as a tool for generalisation

Statement	SV or MV
"maybe…for 3D if it's a value of x, it has to have a different y and z"	Multivariable
[Writes (x, y, z)]	Multivariable
"instead of just for every value of x there's a y,	Single variable
as long as something's different in the y or the z, then it's okay."	Multivariable

In short, the coordinate point seemed to help him generalise the 'mapping' idea from single- to multivariable. Kyle then wrote $f(x, y, z)$. The interviewer explained that for a function in R^3, the notation is "f(x,y) equals something." This helped Kyle discern that z was an output (Excerpt 5).

Excerpt 5. MV Pre-Interview, Graph C

Kyle: Right, that equals something, and that equals the z value. [writes $f(x,y) = z$] then z would be what we're, the output of it… $f(x) = y$. For every x value there's only one y value. So my thought now is that every x and y value there's only one z value for it to be a function.

Kyle appeared to see the $f(x) = y$ and $f(x,y) = z$ forms as similar, allowing him to realise that z was the output. He then correctly stated the univalence criterion for $f(x,y)$. I infer that seeing z as the output afforded this generalisation.

Vertical line test

Kyle's approach to the sphere task included generalising the vertical line test. Like the coordinate points, he alternated between talking about the single- and multivariable cases (Excerpt 6).

Excerpt 6. MV Pre-interview, MV Graph A

Kyle: [Graph A]…there's parts that don't pass the vertical line test, then it's not a function… So for something to be a function, for every x value there can only be one y value…. And you can test that with the vertical line test because what it's doing is it's, it's keeping x the same but…if there's more than one value of y, then it, then it doesn't pass… But I think that, I think that works for not just, if it's x and y, like this, then that's the vertical line test [draws R^2 example]. But if it's x, y, and z, it could be, it could either be the vertical line test for z [gestures to indicate lines parallel to the z axis], or the I guess the same principle applies if it's going that way [draws lines on the xy plane, parallel to the y axis].

I take Kyle's statement "I think that works for not *just*, if it's x and y" [emphasis mine] as Kyle generalising the vertical line test to R^3. Specifically, I infer that the word 'just' as meaning Kyle thought the vertical line test would work *not only* for x and y, *but also* for x, y, and z. However, although he thought the vertical line test generalised to R^3, he was unsure which direction the lines should go, as evidenced by his drawings of lines both parallel to the z axis and parallel to the y axis. He stated later he thought lines parallel to z would be correct.

Multivariable tables and graphs (post-instruction)

Kyle answered all the multivariable table tasks correctly. In contrast to his focus on *x*'s and *y*'s in the first interview, here he thought about inputs, outputs, and having one *z* value "for each pair of independent variables" (Excerpt 7).

Excerpt 7. MV Post-interview, Table 1 and Graph G

Kyle: [Table 1] So my definition is like for each pair of independent variables, there can only be one *z*…it is a function… like for a point *x* is 0, *y* is 0, *z* is, there's one value for that.

Kyle: [Graph G] So if it's *f*(x,y) equals *z*, yeah, the output would be *z*. For every *f*(x,y) there could only be one *z*. And this is a function because, because yeah there's only one *z* value for every *x* and *y*.

I infer that Kyle leveraged the ideas of independence and output to aid generalisation. He stated that "the output would be *z*", then returned to variable-based language to state his generalisation "there's only one *z* value for every *x* and *y*." Like the second interview, he appeared to draw on the symbols *f*(x,y) = *z* to conceptualise *z* as an output, which afforded generalising univalence.

Discussion

In the first interview, Kyle spoke only about *x* and *y*. This may have been an artifact of the task design. He continued to reason primarily with symbols, and it is notable that all of his statements of univalence were in terms of variables (e.g., "there's only one *z* value for every *x* and *y*"). This does not mean that Kyle had a weak conception of function. On the contrary, he talked about independence and dependence, and outputs, and in particular these ideas helped him generalise. However, symbols served as tools as Kyle generalised. one of his first attempts at generalising included thinking about the coordinate point *(x, y, z)* and what such a set of points would have to look like to make something a function. He seemed to attend to the similar forms form $f(x) = y$ and $f(x,y) = z$ to think about which variable represented the output. Others have documented relating objects as a way students generalise (Dorko & Weber, 2014; Ellis, 2007).

One answer the research question *How do students generalise univalence?* is students generalise univalence by thinking about inputs, outputs, independence, dependence, specific coordinate points, using examples and counterexamples, and attending to symbols. Another way is that students often first seek to apply their criterion from R^2 directly to R^3. For example, Kyle's first attempt at generalisation was to say the sphere was not a function because there existed multiple *y'*s for a single *x*. He also considered that the vertical line test in R^3 might use a line parallel to the *y* axis. After applying these R^2 ideas, Kyle seemed to try to adapt them for R^3.

Suggestions for Instruction and Future Research

My findings support others' that function machines, input-output, and independence-dependence provide powerful ways for students to think about and generalise functions (Dorko & Weber, 2014; Kabael, 2011). Hence I suggest that we continue to emphasise these ways of thinking in instruction. One way to do this is to decrease our use of *x* and *y*, asking questions like

m	-4	9	0	0	3
n	1	4	-6	8	2

Could *m* be a function of *n*? Could *n* be a function of *m*?

$r = q^2$

Could *r* be a function of *q*?
Could *q* be a function of *r*?

There is still much work to be done regarding how students generalise multivariable topics. One question concerns the cognitive mechanisms underlying such generalistion. For instance, how can we explain students' tendency to apply an idea from R^2, and then alter it? Such work can contribute toward developing theory about generalisation and transfer.

SCNI: A Robust Technique to Investigate Small-Group Learning at College

Fady El Chidiac
University of California, Berkeley

The Stimulated Construction of Narratives about Interactions (SCNI) technique for data collection, introduced in this paper, enables robust investigations of small-group learning at college. The SCNI technique consists of promptly soliciting participants' perspectives on their recent joint activity using video records thereof. Thus the SCNI technique creates a space to network the narrative discourses that shape how participants understand their world, and the pragmatic forces that shape participants' interactions in a practice. Data reported in this paper are collected from a number theory class comprised of ethnically diverse students. In this paper, I will report three cases to illustrate the advantages of SCNI data over data collected by video records and unmediated interviews in elucidating, nuancing, and expounding what matters for group work. Through these cases, I will use three different analyses appropriate for SCNI data. Limitations and recommendations for efficient conduct of SCNI are discussed as well.

Key words: Small-Group Learning, Narrative Identity, Interaction Analysis, Discourse Analysis.

Since the 1970s, qualitative and quantitative research have been constantly emphasizing and confirming the positive effect of small-group work on students' learning and achievements (Astin, 1977, 1993; Cockrell, Caplow, & Donaldson, 2000; Laursen, Hassi, Kogan, Hunter, & Weston, 2011; Springer, Stanne, & Donovan, 1999; Tinto, 1997). Simultaneously, an ever growing body of scholarship has been reporting debilitating processes in group work, such as lack of social skills (Barnes & Todd, 1977), poor mathematical knowledge (Webb, Ing, Kersting, & Nemer, 2006), weak coordination (Barron, 2003), undue influence (Engle, Langer-Osuna, & McKinney de Royston, 2014), communication problems (Sfard & Kieran, 2001; van de Sande & Greeno, 2012), problematic identities (Heyd-Metzuyanim & Sfard, 2012; Langer-Osuna, 2011) and others (see a review by Webb, 2013). To investigate the differential processes taking place in group work, researchers have been investing less in achievement studies and more in the study of social interactions in small-group learning, as noted by Cohen (1994).

Additionally, recent research (Esmonde, 2009a, 2009b; Esmonde & Langer-Osuna, 2013; Gresalfi, 2009; Langer-Osuna & Esmonde, In Press) has emphasized the need to study learning ecologies constructed through ongoing interactions with an emphasis on how socio-emotional and power relationships play out in the moment-by-moment of group work. Such a research program, I claim, requires new techniques for data collection. To this date, video records and/or unmediated interviews have been the most common data sources used to investigate small-group learning. Socio-emotional and power forces at play through ongoing interactions do not sufficiently manifest through videos or unmediated interviews for the following reasons:

- During ongoing interactions, participants often act without manifesting the forces underpinning or motivating their actions.
- In unmediated interviews about interactions, participants often sustain a handful of strong impressions from group work and become oblivious of fleeting but otherwise significant ones.
- Although data from unmediated interviews can elicit participants' individualized discourses by which they narrate self, others and the world, it cannot help determine which discursive forces are at play in situ.

This paper will show how video records of group work and interviews of participants are not sufficiently robust to investigate socio-emotional and power relationships in small-group learning. The *Stimulated Construction of Narratives about Interactions* (SCNI) technique for data collection, to be introduced and explicated in this paper, attempts to address the aforementioned challenges to an ecological study of small-group learning. The SCNI technique consists of promptly soliciting participants' perspectives on their recent joint activity as they watch a video of the group work.

In this paper, I will first lay out the conduct of SCNI interviews, then explicate the underpinning theoretical frame of this technique. Second, I will present three cases of SCNI data, which will illustrate how SCNI data complement data from video records. I will also use different analytical methods to treat the SCNI data as illustration of the diverse appropriate analyses that can be used with these data. The underpinning belief of this paper is that combined data from SCNI and video records afford robust understanding of processes that shape small-group learning.

The SCNI Technique

The SCNI technique consists of probing participants to construct narratives about (comment on) their social interactions by watching a video of the activity in which they participated within 24 hours prior to the SCNI interview. The SCNI technique builds on the cognitive technique commonly known as Stimulated Recall (Gass & Mackey, 2000) and video viewing practiced by interactional analysts (Jordan & Henderson, 1995). Contrary to the heavily cognitive SR technique, the SCNI technique aims at eliciting not only cognitive but also fleeting and enduring social processes individualized by participants. While SR and video viewing interviews seek to understand what happens in the studied group work, SCNI interviews are also interested in knowing who participants are and what frameworks they have individualized to make sense of their world. This distinction will become evident as I explicate the theoretical grounding of the SCNI technique.

Conduct of SCNI Interviews

An SCNI session consists of (i) the preparation of the *medium* (i.e., the video of actual activity); (ii) a low-probing video viewing section; and (iii) a proactive open interview section. I started recording the SCNI sessions with an audio recorder but soon came to realize that they are best recorded as videos to facilitate future analyses.

During the classroom activities, stable and unmonitored video cameras (wirelessly connected to microphones placed in the middle of the group table) captured the entire interactional space of each group. The resulting videos are used to mediate the following two interview styles.

The SCNI sessions, conducted individually in this study, take place within 24 hours of the end of the videotaped group activities. The interviewer launches the interview with this probe: "In my study I try to understand the interactions between people. Today, I would like you to help me see through your eyes to understand what happened in your recent group session. You will watch a video of it to help you recall what happened. You can pause the video at any time you recall your significant mathematical reasoning and your feelings about yourself or your groupmates at the moment of the interactions. Try your best not to confuse your current thoughts and emotions with those you experienced when you were working in group."

The interviewee and interviewer sit facing a screen placed in front of the interviewee and streaming the recently videotaped group session. This seating foregrounds the video and backgrounds the interviewer to the informant. During this phase, the interviewer may use gentle probes, such as pausing the video and asking whether the informant can recall what s/he was thinking or feeling at that time, or if s/he understood a groupmate's explanation. If informants drift away from talking about the moment of interactions, the interviewer may gently orient him/her back to the task by asking, "Is this what you were thinking/feeling at the moment?" The interviewer must also note the time stamps when the video is paused for commenting.

At the end of the session, the interviewer follows up on the participant's significant comments by rewinding the video to those moments and asking open questions such as, "What did you mean when you said you were frustrated here?"; "Is it common that you feel/think like this in such circumstances?"; or "At time *t*, you said Fred is smart. Why is that?"

People tend to tailor their talks to their perception of their interlocutors' knowledge. Hence, to trigger talks about the mathematics involved in the group work, the interviewer must be knowledgeable in the subject matter and exhibit his relevant mathematical knowledge to interviewees. In my data collection in an upper-division course, I introduced myself as someone who had earned a Master degree in mathematics and assisted students during group work and tutoring sessions.

Theoretical Grounding of SCNI

The SCNI technique creates a space to network the narrative discourses and the pragmatics that govern participants' interactions in a practice (Figure 1). As participants in SCNI talk about their interactions in a recent activity, their comments will be constrained and enabled by two forces: on the one hand, the narrative discourses that construct and regulate their subjectivities (Kramsch, 2010) and, on the other, the pragmatic forces that have just regulated their interactions. Hence, in SCNI sessions, interviewees are positioned in a space negotiating two realms: (1) their individualized discourses that shape the narrations of self, others, and activities and (2) the pragmatic forces that shaped the recent interactions they watched in a video.

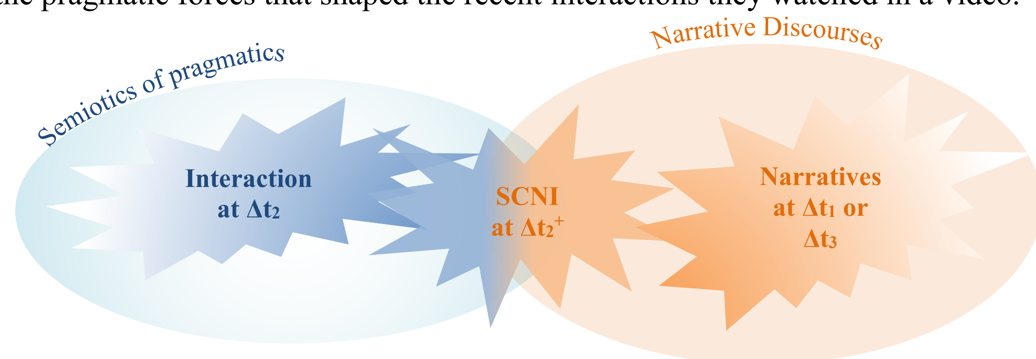

Figure 1. The SCNI conducted at time Δt_2^+ on social interactions at time Δt_2 produces data shaped by (a) the semiotics of pragmatics that govern social interactions at time Δt_2 and (b) discourses that frame unmediated narratives -at time $\Delta t_1 < \Delta t_2$ and $\Delta t_3 > \Delta t_2$.

Following interaction analysis methods (Jordan & Henderson, 1995), the SCNI technique provides participants' perspectives, that is, the pragmatic frames that participants activate to make sense of interactions *during ongoing activity*. Are the narratives produced by interviewees in SCNI sessions pure recall of what really happened in recent activity? Certainly not. But neither are they pure constructions disconnected from the reality of recent activity. Narratives of past events are partly faithful and partly unfaithful to actual events. By placing interviews, like in

SCNI sessions, soon enough to the focal activity and constraining narratives by strong stimuli like videos of activity, we increase the reliability of recruited data.

Informants' responses in SCNI sessions ought to be treated as narratives. Like all narratives, they draw on *remembered* impressions that are *narrated* employing internalized genres and styles (Baynham, 2014; Dervin & Risager, 2014). The discontinuity of SCNI data with actual interactions does not threaten its reliability. On the contrary, the internalized narratives by which informants narrate their recent interactions regulate their enduring identities (Kramsch, 2010). To put it in a way pertaining to small-group learning, by talking about their recent group work in SCNI sessions, participants implicitly or explicitly give off signs of their entrenched understanding of themselves, their groupmates, mathematics, and group work activity. Whether in group work or in SCNI sessions, participants act by the same *habitus* (Bourdieu, 2003; Bourdieu & Thompson, 1991) that gives each one of them an enduring existence through different contexts and activities.

As noted in the introduction of this paper, researchers of small-group learning must invest in robust studies of ongoing interactions in group work and all that they involve (hidden social norms, emotions, and power). Yet ongoing interactions are fleeting. Traditionally they are accessed through either records thereof, such as videos, audios and fieldnotes, or perpetrators of actions. Researchers have attempted to capture ongoing interactions through video records and thus made them objects of analyses. Although video analysis is a powerful tool to investigate ongoing interactions, it presents limitations and biases, such as the orientation of the camera (transforming the 3-D reality into 2-D video), and the limitation of capturing good sound quality in a noisy environment (see Erickson, 2006; Hall, 2000). In some way, videos are one narrative about reality. In addition to videos, past interactions can be accessed through participants who engaged in them. The uniqueness of SCNI technique resides in investigating ongoing interactions by revealing the subjectivities/habitus/identities of participants in relation to the studied interactions.

The SCNI technique has its own limitations. First, interviewees must have agility in talking about interactions and verbalizing their emotions and experiences. Although the SCNI technique resulted in rich data for all participants in my research (youngest age is 19 years old), it may not be equally informative with elementary and middle school students. Second, crucial for rich SCNI data, the interviewer and interviewee must construct a safe environment as much as possible, allowing the interviewee to speak his/her mind and say what s/he conceals in her/his ongoing interactions with groupmates because of face-saving and politeness processes (Goffman, 1967; Pearson, Kreuz, Zwaan, & Graesser, 1995).

Results

Data reported is collected from a number theory class at a Northern California college. The course was solely based on small-group work throughout the semester. Students (10 females and 13 males) composed their groups at their will. There were 5 groups of 4 or 5 students each. Four groups (G1, G2, G3 & G4) consented to be videotaped (all their group sessions were videotaped) and 15 students of these groups participated in individual interviews (early and late unmediated interviews + SCNI). Groupmates participated in SCNI interviews on the same day and every other week. I conducted 45 SCNI interviews in total.

Case 1: Friends, yet not alike

Izabelle, Nawal, Leila, and Gaia wanted to be in the same group, G1, because they had been friends for at least a year. On September 22nd (henceforth 9/22) the instructor Hoffmann started the class by explaining the definition of primitive roots for about 10 minutes then set the groups to work. The group G1 was still in the middle of a worksheet that they could not finish during the last session. While groupmates were opening their notebooks and getting ready to work together, Gaia called the instructor. We observe in the video of this group session that Leila was surprised (evidence: eyes wide open, head turns swiftly, then she frowns) when she looked up and found the instructor at the group table. The video does not show significant reactions from Izabelle and Nawal. In the individual SCNI interviews that followed this group session, Izabelle did not comment on Gaia's behavior, but Leila and Nawal did.

Leila: [*pauses the video at the moment when Gaia calls the instructor*] I was a little annoyed by what happened there ... haha because we were all like kind of like trying to get like going and then Gaia she's been like really on top of stuff but I just felt like as a group like ... we should have ... kind of like went over stuff together and then she just like jumped in and like asked Hoffmann when we like I or at least I didn't feel like I was ready to like kind of ... ask the questions about that yet. Because I hadn't even really had the chance to look at it so like as far as like working as a group I was like a little like ... frustrated like I hadn't even had the chance to look at it and we were already going [*cough*s] going for it.

Nawal: [*pauses the video slightly before the moment when Gaia calls the instructor*] I felt kind of annoyed with Gaia when she did what was coming up. Cuz she called over the professor right away instead of like asking us the question she had and I thought it was kind of like not very like group like because I feel like if you have a question and you're sitting with your group you should like ask the rest of your group members first because like maybe someone gets it too or maybe they have the same question. So I remember feeling kind of like annoyed and I thought it was kinda rude how she like called him [Professor] over and asked him directly instead of like talking to us about it first.

While Izabelle seemed to not be affected by Gaia's calling the instructor, Nawal and Leila found Gaia's act annoying. However, Nawal and Leila narrated their frustrations differently. Leila was frustrated because she "hadn't even had the chance to look at" the problem and thus not yet ready to follow any conversation about it. Nawal felt insulted ("it was kinda rude") that Gaia did not consider her groupmates capable of answering her question, because Gaia "called and asked [Hoffmann] directly instead of like talking to [them] about it first." Three women who had associated with each other in the past two years and shared a Hispanic background had different reactions and understandings of the same act. The diversity of individualized discourses employed to make sense of group interactions would not have been revealed without SCNI interviews. Video analysis is not enough to study group interactions.

Case 2: My personal space

For the purposes of this paper, I will merely sketch the argument for cases 2 & 3 (the full set of data will be included in the extended paper, if the proposal is accepted). In the early unmediated interview (general questions about students' experiences with mathematics classrooms and small-group work), Leila (on 9/12) said that she needed her "personal space" and became irritated when groupmates, particularly Gaia, started writing on her notebook and got physically close to her. Indeed, on the group session of 9/22, Leila gave Izabelle, who moved her body close to Leila, a look from the side of her eyes and immediately Izabelle backed off and smiled. In her SCNI on 9/22, Izabelle commented, “Leila likes her own space.” Nonetheless, on 9/22 Gaia stood twice (for about 1 minute 30 seconds each time) over Leila’s shoulders and wrote on her notebook. Surprisingly Leila did not seem irritated by Gaia in the video.

In her SCNI interview on 9/22, Leila repeatedly commented that she was struggling to make sense of the mathematical conversation of the instructor with her group. She also mentioned that she was masking her lack of understanding by nodding every time the instructor looked at her. When the instructor left the group, Leila was totally confused about the task and what they were supposed to prove and how. But her groupmates started working on the problem without noticing her struggle, for which reason she was even more irritated. She ended up asking her groupmates a couple of questions, and it was Gaia who immediately volunteered to explain matters to Leila by standing over her shoulder and writing on Leila’s notebook. In her SCNI interview, she commented on this moment of group session.

Excerpt SCNI-Leila on 9/22. [*Leila pauses the video of group session at 28:10 when Gaia is standing behind Leila and explaining to her*].

Leila: […] at this point I was like understanding like when Gaia explained to me [*clears throat*] how you get from like our what we're trying to show like how you would factor out one part or whatever [*sniffs*] and then like basically like how we got to like what our conclusions were supposed to be and then this is where it clicked for me, I was like, Oh that makes sense now … So I was feeling good about myself. [*laughs*] for once.

[*The video is running at 28:50. Events in the video: Izabelle remarks that the difference is reversed; Gaia moves close to Izabelle to explain to her that* $if\ a-b\ \equiv 0\ then\ b-a\equiv 0$]

Leila: Yeah see Gaia is so teachery [*laughs*]

Facilitator: Ok, umm, why are you saying this?

Leila: Gaia is like very teachery like sometimes it's good like I like like in cases like this I like it but sometimes it's a little too much for me ... like it's a little sometimes I feel like it's a little overbearing. But like in this situation like the way that she like approached helping me and showing me like, Oh I was really appreciative of it because she like really helped me and explained it really well.

Leila did not seem irritated by Gaia’s invasion of her personal space as she was explaining the exercise to her in this group session (9/22). She backgrounded her sensitivity about her personal space because other contextual issues were more pressing at that moment. Leila was desperate to understand the mathematics discussed and to catch up with her groupmates’ work. Because Gaia’s explanation was helpful to Leila and thus responding to a contextual pressing need, the latter could tolerate Gaia’s intrusion into her personal space. This case cautions us about using data from unmediated interviews to explain ongoing interactions, which are subject to contextual forces that can qualify or compromise what people think about themselves and others in absolute terms.

Case 3: Two types of passive engagement

Boutros, a member of group G3, and Tito, a member of group G2, were only passively engaged in group-work for several sessions. Both of them sat in their group silently, listened to what groupmates were discussing, took notes, sometimes detached themselves from the group to do individual work, and almost never shared their mathematical thoughts with the group. They would engage sometimes in off-topic conversations with groupmates.

In their first SCNI interviews (Tito on 9/24 and Boutros on 10/15), Tito and Boutros commented on their respective group sessions in two distinct ways. Tito exhibited evidence that he was following the group discussion, even when he was not actively participating. He accurately commented on group activity using "we" (31 times) instead of "they" (5 times), despite his rarely participating in the group activity. On the contrary, Boutros spoke little about group activity, which he could rarely identify, using the pronouns "they" (7 times) and "we" (4 times). While Tito identified himself with the collective activity (e.g., "we solved the problem"), Boutros narrated a gap between his and his groupmates' actions. Following are two samples of Tito's and Boutros's comments.

Tito: Um, clearing it up. Cause we already finished it <u>we</u> were um, <u>we</u> concluded that Tom's part was right, so <u>we</u> just so everyone's writing it down.

Boutros: Uh, yeah I was looking at the problems on the worksheet and tryna figure out what they were working on. Yeah like I think I was listening to them a little bit, so I knew what problem <u>they</u> were doing […] It was the second one? So <u>they</u> finished the first one and then <u>they</u> started working on the second which, which was, which was can't remember right now. [*underlines are mine*]

I also coded the subjectifications and objectifications (as presented in Heyd-Metzuyanim & Sfard, 2012) in Tito's and Boutros's styles of narrations. Each one of them produced 100 subjectifying units, i.e., attributing social and socio-mathematical actions to agents. Note that for Tito, 31% of subjectifying units were attributed to the collectivity ("we"), compared to only 4% for Boutros. Boutros produced 20, as opposed to Tito having produced only 4, objectifying units.

According to the sfardian learning theory (Sfard & Prusak, 2005), Boutros is more prone to maximize his learning gain than Tito, because he is aware of a gap between his and his groupmates' actual actions. Although working in small-group, Tito may have fallen into the same illusion of students attending lectures, who misperceive the neat proofs laid out on the whiteboard by the instructor as representations of their own state of understanding and thus remain heedless of their actual state of knowledge. Future work will investigate this prediction and conjecture.

Conclusion

When working in small-groups, students draw on their social and socio-mathematical habits, which they internalize through their prior experiences in other or outside classrooms, to act and interpret groupmates' acts. As the field of small-group learning is moving toward investigating interactions and their underpinning power and socio-emotional forces, the SCNI technique is well suited to the task. Data from unmediated interviews may not be reliable for contextual analysis (case 2) and video analysis of group sessions may not be sufficiently informative (case1). The SCNI technique affords nuanced data in rapport to ongoing interactions, mainly due to participants' perspective *in situ*, and opens up the possibility for new analytical methods (for example, case 3) to enhance our understanding of small-group learning.

Infinitesimals-based registers for reasoning with definite integrals

Rob Ely
University of Idaho

Abstract: Two representation registers are described that support student reasoning with definite integral notation: adding up pieces (AUP) and multiplicatively-based summation (MBS). These registers were developed in a Calculus I class that used an informal infinitesimals approach, through which differentials like dx directly represent infinitesimal quantities rather than serving as notational finesses or vestiges. Student reasoning reveals how the AUP register supports modeling with integral notation and how the MBS register supports sense-making with and evaluation of integrals.

Keywords: calculus, integral, register, semiotics, infinitesimal, differential

My goal is to examine and illustrate two registers for interpreting and working with definite integral notation, registers that are particularly useful for supporting student modeling and sense-making with integrals. These registers—adding-up-pieces (AUP) and multiplicatively-based summation (MBS)—are situated in a Calculus I course that uses an "informal infinitesimal" approach to calculus. I briefly summarize this general approach to calculus before describing these registers and how students reason with them.

Informal Infinitesimals Approach to Calculus

For nearly two centuries, Calculus was "the infinitesimal calculus." For its inventors, G. W. Leibniz and Isaac Newton, it was a set of techniques for systematically comparing infinitesimal quantities in order to determine relationships between the finite quantities that they comprised (and vice versa). In the 19th century, calculus was reformulated in terms of limits rather than infinitesimals, and 20th century calculus textbooks have followed suit. Yet calculus textbooks and courses still use Leibniz' notation, dx and $\int$, but without the meanings Leibniz assigned to these: dx is an infinitesimal increment and the big S is a sum ("summa"). The notations are now vestiges, and in particular, differentials no longer directly represent quantities that students can manipulate and reason with.

The guiding principle of the informal infinitesimals approach is to restore this direct referential meaning to calculus notation. The approach is supported by the work in nonstandard analysis in the 1960s showing that calculus can be founded upon infinitesimals with equal rigor and power, but it uses the informality of Leibniz' reasoning rather than the formal development of the hyperreal numbers (e.g. Keisler, 1986). For instance, the derivative at a point dy/dx really *is* a ratio of two infinitesimal quantities, not code language for $\lim_{h\to 0}\frac{f(x+h)-f(x)}{h}$. The chain rule is canceling fractions. And an integral really is a sum of infinitesimal bits, each of which in MBS is given by the product $f(x)\cdot$dx. By taking differentials seriously, students can develop formulas for volumes of rotation, arclength, work, and many other ideas, formulas, and applications in first-year calculus (Dray & Manogue, 2010), and in vector calculus and physics (Dray & Manogue, 2003).

Registers and Signs

For Duval (2006), a representation *register* is a collection of signs and a set of transformations by which some of these signs can be substituted for others. Transformations within the same register are *treatments*; transformations of signs from one register to another are *conversions*. Barthes defines a *sign* as a combination of a signifier and a signified (1957/1972). For instance, a bunch of roses (signifier), together with the concept of passion it is representing (signified), comprise a sign. In our case, when a mathematical representation (e.g., "dx") signifies a concept (e.g., an infinitesimal increment), the combination of the representation "dx" (signifier) and infinitesimal increment (signified) is a sign. An interpretation is thus a signified concept. So if a representation stays the same but its interpretation changes, it becomes a different sign, since it signifies a different thing or concept. This points to a conversion to a different register, because within a given register interpretation should remain relatively stable. Such a conversion is often accompanied by a new lexicon of signs, interpretations, and treatments that which might support the new purpose or apply to the new context.

Consider the following example: We can use infinitesimals to develop the formula for the arclength of a curve in the plane between $x = 0$ and 1. We imagine a curve to be comprised of infinitesimal segments, each of which is the hypotenuse of a right triangle with legs dx and dy. Then the arclength of the curve would be the sum of these hypotenuse lengths: $\int_{x=0}^{1} \sqrt{dx^2 + dy^2}$. So far we have performed a modeling step, treating the dx and dy as quantities representing magnitudes, and have used the adding up pieces (AUP) register (which I detail soon). But this is no form to be evaluated for any particular curve, however. To be evaluated, the integral must first be *converted* by imagining all the dx's as uniform in size and then being factored from the integrand, to get $\int_{x=0}^{1} \sqrt{1 + (\frac{dy}{dx})^2}\, dx$ (if y is a function of x, say $g(x)$). Now the integral is of the form $\int_{x=0}^{1} f(x)\, dx$ (where $f(x)$ is $\sqrt{1 + g'(x)^2}$). So the integral can be evaluated by $F(1) - F(0)$, for some F as an antiderivative of f. Thus using algebraic manipulations we have converted to a new register that is suited for evaluating integrals. The $\sqrt{[\,]^2 + [\,]^2}$ structure lost significance and the $\int_a^b f(x)\, dx$ structure gained salience, and it became important for the original curve to be seen with y as a function of x.

The Adding Up Pieces (AUP) and Multiplicatively-Based Summation (MBS) Registers

The elements of the AUP and MBS registers are based on the work of Jones (2013, 2015a, 2015b). The interpretations involved in both registers are summarized in Figures 1 and 2, and the strange numbering on these (I2, etc.) draws from the learning progression in my class through which they emerge, which I reference elsewhere in detail (Ely, in review). The interpretations in the AUP register (Figure 1) entail the idea that a definite integral measures how much of some quantity A is accumulated over an interval of a domain, say from $t = a$ to b. This domain is partitioned into infinitely many infinitesimal increments of uniform size dt. For each infinitesimal increment dt there corresponds an infinitesimal increment of A, dA. The integral $\int_a^b$ adds all of these up to give the total accumulation of A over the interval from $t = a$ to b. In order for this to make sense, one must appeal to conception C5: The sum of infinitely many infinitesimal bits is a finite accumulation of A.

The AUP register allows one to transparently represent a general bit of the sought quantity and of the whole quantity as an accumulation of these bits. The treatments in the register include (a) writing a symbolic expression for a generic bit d*A* and (b) rewriting this expression for d*A* in terms of other infinitesimal quantities that specify the expression for the domain at hand, usually in terms of its corresponding domain increment d*t*. These treatments require viewing infinitesimals as legitimate quantities that behave normally under algebraic operations (including possibly some additional Leibnizian rules for operating with infinitesimal quantities). The treatments also rely on two other grounding conceptions: (1) equivalent expressions can be substituted for the same quantity (conception C6), and (2) a foundational understanding of covariation, which in turn relies on the basic understanding that variables vary (Thompson & Carlson, in press). The student must be able to coordinate changes of *A* with changes of *t* in order to reason that for each increment d*t* there is a corresponding increment d*A*.

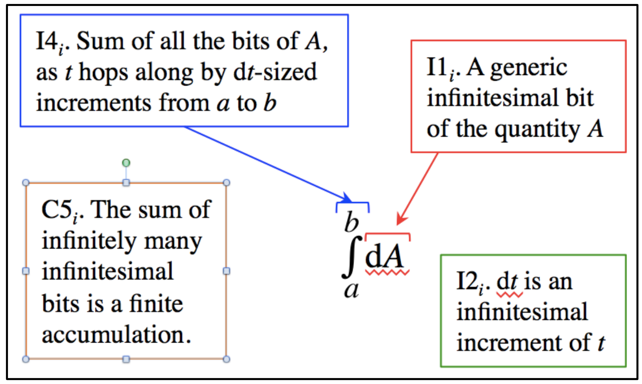

Figure 1 – Interpretive elements of integral notation in the adding up pieces (AUP) register

The MBS register includes many of the same notational interpretations as AUP, but it also adds to these the expression of each piece d*A* as a product $r(t)\cdot \mathrm{d}t$. This introduces the integrand, which is necessary for the Fundamental Theorem of Calculus (FTC) to apply. We follow Thompson, Byerley, & Hatfield's (2013) approach to treat the integrand $r(t)$ as a rate at which *A* accumulates over the increment d*t*. This ultimately allows us to recognize and use that an accumulation function *f* for *A* will have $r(t)$ as its rate-of-change function. Thus, one supporting conception in this interpretation of the product $r(t)\cdot \mathrm{d}t$ is the idea that *A* accumulates at a constant rate $r(t)$ over the d*t* increment, and that this constant rate is determined by the value of *t* closest to that d*t* increment. This relies on conception C4: A concept image for rate of change at a moment (Thompson, Ashbrook, & Musgrave, 2015). This momentary rate of change can vary constantly as *t* varies. The second supporting conception is the multiplicative structure associated with rate, expressed in conception $C1_i$ (see Figure 2). The

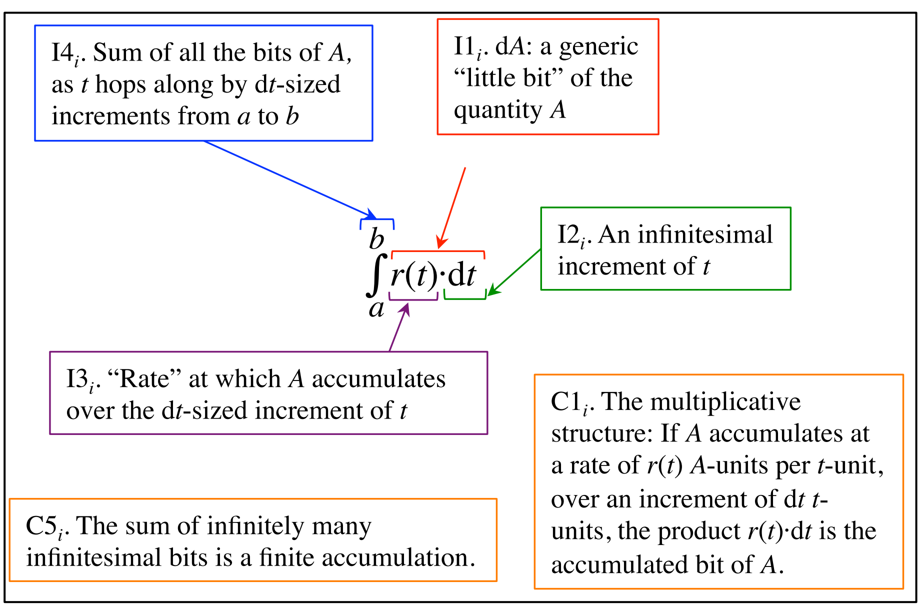

Figure 2 – Interpretive elements of integral notation in the multiplicatively-based summation (MBS) register

word “rate” is used here broadly. It does not necessarily mean that $r(t)$ is measured in a compound unit like miles-per-hour. Rather it means that as t changes, A changes by a proportional amount, and $r(t)$ provides that rate of proportionality (Lobato & Ellis, 2010). Most broadly, $r(t)$ serves as a factor allowing conversion from an increment of t to an increment of A, by $dA = r(t) \cdot dt$. Reasoning with quantities, rather than bare numbers or symbols, is crucial to this interpretation.

The MBS register promotes reasoning with the FTC: if we can find any accumulation function $f(t)$ whose rate-of-change function (i.e. derivative) is this $r(t)$, we can use it to recover the accumulated amount A, by determining $f(b) - f(a)$. The treatments within the MBS register include the same kinds of algebraic operations with summand and integrand as in the AUP register, and also include evaluating the integral $f(b) - f(a)$ by means of an antiderivative f.

Other Modes of Student Reasoning with Definite Integrals

Although we focus on AUP and MBS, these modes of reasoning are relatively rare among students in traditional calculus courses. For instance, Jones (2016) surveyed 150 undergraduate students who had completed first-semester calculus, using Prompts 1 and 2 on the next page. Only 22% of students made even a passing reference to summation of any kind on either prompt, and on each prompt less than 7% appealed to reasoning consistent with AUP or MBS. On the other hand, 87.3% of students appealed to an “area” interpretation on Prompt 1, and 76% used an “anti-derivative” interpretation on Prompt 2.

These two interpretations have also been described, and found prevalent, by other researchers. The *area* interpretation is that the definite integral represents an area “under” a curve in the coordinate plane, with the “d[]” denoting the variable on the horizontal axis, which forms the bottom of the shape. “The shape is taken as a fixed, undivided whole that is not partitioned into smaller pieces” (Jones, 2015b, p. 156). The *anti-derivative* interpretation is that the integrand came from some other other “original function” through differentiation; now the integral symbol represents an instruction to find this original function. The d[] dictates the independent variable “with respect to” which the derivative had been taken, and the limits of integration are the values that one must plug into the original function to get the numerical answer (Jones, 2015). Fisher et al. (2016) found that the majority of students in a standard calculus class used only the area interpretation when describing the meaning of a definite integral, and Grundmeier, Hansen, & Sousa (2006) found that only 10% of students mentioned an infinite sum when asked to define a definite integral.

Various studies claim that sum-based interpretations of the definite integral are much more productive in general for supporting student reasoning than are area and anti-derivative interpretations (e.g., Sealey, 2006, 2014; Sealey & Oehrtman, 2005, 2007; Thompson & Silverman, 2008, Jones 2013, 2015a, 2015b; Jones & Dorko 2015; Wagner 2016). For modeling in particular, the area and anti-derivative interpretations have serious limitations. The area interpretation is problematic when modeling in the myriad situations when the sought quantity is difficult to imagine as the area of a region (e.g., work, velocity, force, volume, arclength) (Thompson et al, 2013; Jones 2015a). The anti-derivative interpretation provides even less support for modeling, since it gives only a technique for evaluating a definite integral, not for creating one (Jones 2015a). These interpretations produce significant obstacles for students modeling with integrals in physics applications (e.g., Nguyen & Rebello, 2011).

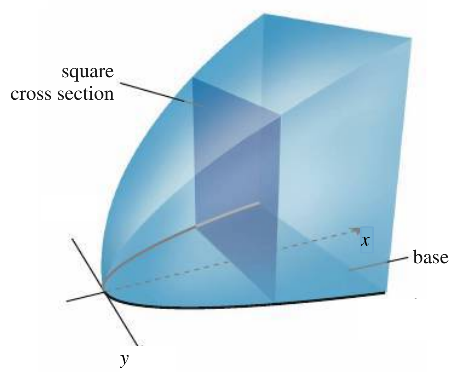
Along with AUP and MBS, there are other sum-based interpretations of integral notation, notably the Riemann sum (limit of sums). Nearly all calculus books define the definite integral using Riemann sums, but this fact seems to contribute little to building sum-based reasoning for the students who use these books. When investigating this apparent pedagogical disconnect, Jones, Lim, and Chandler (2016) found that instructors' teaching moves lead students to perceive the limit of Riemann sums not as a conceptual basis for understanding the definite integral, but merely as a calculational procedure that allows an integral to be estimated accurately. Another way that the limit process involved in the Riemann sum interpretation can form a conceptual obstacle for students is through the problematic collapse metaphor, through which students imagine the pieces losing a dimension in the limit, so the d[] loses its quantitative meaning (Oehrtman, 2009).

Data Collection

I taught an experimental Calculus I class using the informal infinitesimals approach, for science, engineering, and math majors at a large public university in the northwestern U.S. I conducted semi-structured interviews and analyzed student written work. I focus here on two prompts I used in the interviews: Prompt 1, which is verbatim from Jones (2013, 2016), and Prompt 3, a novel modeling context of a kind very different from what the students seen before (although they had done a few volume-of-rotation problems in class and on homework).

Prompt 1: Explain in detail what $\int_a^b f(x)dx$ means. If you think of more than one way to describe it, please describe it in multiple ways. Please use words, or draw pictures, or write formulas, or anything else you want to explain what it means.

Prompt 3: Set up an integral that represents the volume of this solid, whose base is the region bounded by the curves $y=\sqrt{x}$ and $y=-\sqrt{x}$, and whose cross sections perpendicular to the base and perpendicular to the x-axis are squares.



Results

I analyze here the reasoning displayed in the responses of two students, Dmitri and Galena.

Reasoning in the AUP Register

In response to Prompt 3, Dmitri's initial answer of ($\int_{x=0}^{1}(2y \cdot dx)^3$) was incorrect, but after reflecting for a minute he corrected it to $\int_{x=0}^{1}(2y)^2 \cdot dx$. He notes that if the slice was $(2y\mathrm{d}x)^3$, it would make a perfect cube, which can't be right. It should instead look like what is in Figure 4. He narrates as he draws and labels the slice: "This [indicates the width] is going to be dx. This will be the same thing as the other one: this one [indicates the slice's height dimension] is still 2y. This one's still 2y [indicates the slice's depth dimension]. But the width is still dx. So to find the volume of that, we'd have 2y squared times dx. And that is all. And that solves my problem." He then describes how the slices are aggregated, each time "you'd go up an infinitely small amount and then you'd do the same thing for that one, and you'd do that for all numbers between 0 and 1." Then he notes that the collection of all these pieces is the volume of the whole figure.

In this sequence of reasoning, Dmitri appeals to all the elements of AUP. He has imagined a domain partitioned into increments of infinitesimal size dx (I2), described a representative slice of the figure's total volume as the thing being summed (I1), and described the integral as the sum of all such pieces across the appropriate domain (I4). He notes that these have infinitesimal volume but that when you sum them all you get the whole region, which indicates he is using C5.

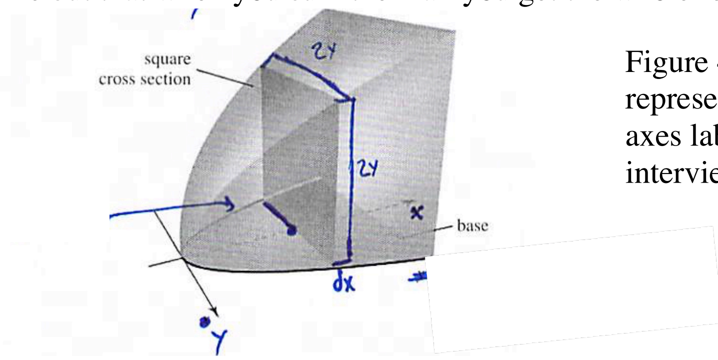


Figure 4 -- Dmitri's modeling of a representative piece of volume. The axes labels were written by the interviewer.

Dmitri checks his answer by appealing to dimensional quantities and units: even if dx is a "really small amount of meters, it's still meters – so meters squared times meters equals meters cubed, and that's the unit of volume." Dmitri uses AUP, not MBS; he never seems to need the summand to be in the form "$f(x)\cdot$dx." His initial answer is not at all in that form, and his final answer still does not have the integrand written as a function of x. Additionally, he appeals to multiplicative structure when he talks about the summand, he does not describe or treat the area part, the integrand, as a "rate" at which the figure's volume grows with each infinitesimal increment of the domain.

Reasoning in the MBS Register

In response to Prompt 1, to explain what $\int_a^b f(x)dx$ means, both Galena and Dmitri express notational interpretations I1-I4 and conceptions $C1_i$ and $C5_i$. Galena's succinct response is shown here, and I indicate how it displays I1-I4. There is no textbook with MBS in it yet, but if there was, Galena's account would be the "textbook" description of MBS:

: Okay, so, I'll just separate this into chunks:

So the dx is gonna be a small increment in time, like ideally it would be infinitely small. Um, so this [gestures to the "dx"] is a chunk of time, or whatever is on your x-axis. It doesn't necessarily have to be time; it could be meters if you were doing it in length. But it's a small increment of whatever x is. $I2_i$

Then $f(x)$ is the rate at which that grows over this [points to the dx] chunk of time, per se. And then, so this is a rate [points to the $f(x)$]. So it would be like meters per second, or whatever this x value is per whatever is the y value [she says these reversed but writes them correctly]. $I3_i$

Uh, and this [points to the entire integral] is making this a summation of these chunks. So this [points to $f(x)$dx] is going to be a chunk. ~~And this is~~ $I1_i$ the summation from a to b of those tiny chunks that you're adding up along the way. $I4_i$

Dmitri's responses to Prompt 1 also illustrate his reasoning using I1-I4, C1 and C5, and he explicitly refers to $f(x)$ as a "rate of change function; … let's say it's meters per second, then dx could be a really small increment, an infinitesimally small increment, of seconds."

Converting From the AUP Register to the MBS Register

An example of Galena's written work illustrates the process of converting between the two registers. The problem asks her to first set up, then evaluate, an integral representing the volume of the figure created by rotating around the x-axis the region enclosed by the curves $y = x + 6$ and $y = x^2$. Galena makes a couple of small mistakes in her work, but the switch between registers is clear. Her modeling work, to set up the integral, is shown in Figure 5.

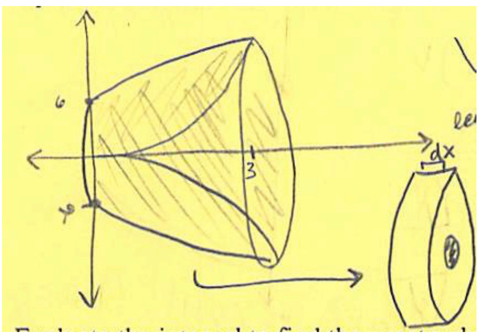

Figure 5—Galena's modeling in the AUP register

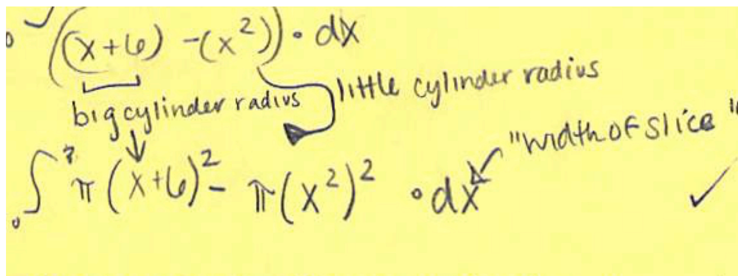

To evaluate the integral, Galena converts to interpreting the integrand $[\pi(x+6)^2 - \pi(x^2)^2]$ not as two dimensions of a slice but as a "rate of change," (she writes this). She then seeks to evaluate by finding an "accumulation function" evaluated at the starting and ending values of 0 and 3. The interpretation of the integrand has changed with the register shift, so she no longer refers to elements of the figure.

Discussion

These are a few illustrative examples of how students in an informal infinitesimals calculus course used the AUP register to model with definite integrals and the MBS register to reason with and evaluate definite integrals, and how there is an explicit change of interpretation marking the conversion between the registers. Since the two registers support these distinct purposes, it may support student learning for the instructor to teach the registers independently and to be explicit about the interpretations and affordances in each register. By explicitly teaching students the signs (notations and interpretations), treatments, and purposes of the two registers, we may help them develop meta-level awareness of the significance and affordance of their actions in the registers. An informal infinitesimals approach to calculus can help students develop these two registers, which are more powerful tools for reasoning with definite integral notation than the prevalent antiderivative and area interpretations.

Students' Attitudes Toward Listing and Subsequent Behavior Solving Counting Problems

Sarah A. Erickson
Oregon State University

Counting problems provide rich mathematical content and a variety of applications for students, motivating investigation into the difficulties students face while counting. In particular, an important result supported by previous quantitative and qualitative evidence is that listing may be an effective strategy for combating some student struggles in counting, particularly since it draws explicit attention to outcome structure. However, anecdotal experience has shown that students can resist listing and feel that it is tedious and not worth the effort. To investigate whether these negative mindsets exist outside these anecdotes, task-based interviews were conducted targeting student attitudes toward listing and their success in using listing to solve counting problems. Contrary to the anecdotal evidence, the students in the study expressed that they felt listing is a worthwhile activity, but their work on counting problems suggest that they would benefit from more explicit support relating to listing in their discrete mathematics classes.

Key Words: Combinatorics, Discrete Mathematics, Counting Problems, Mathematics Education

Introduction

Counting, or combinatorial enumeration, is an important part of students' mathematical curricula for a variety of reasons. Counting problems admit relevant applications in multiple fields, provide opportunities for students to engage in meaningful mathematical practices, and give contexts to help students understand difficult mathematical topics (Kapur, 1970). However, it has been shown that students at a variety of levels struggle to solve counting problems (Melusova & Vidermanova, 2015; Eizenberg & Zaslavsky, 2004; Batanero, et. al., 1997). While student difficulties persist, recent studies have found promise in a strategy known as listing: explicitly writing down one or more of the things you are trying to count while solving a counting problem (Lockwood & Gibson, 2016).

However, despite the quantitative and qualitative results providing evidence for the usefulness of listing, anecdotally it has been found that some students feel that listing is tedious and not worth the effort, preferring instead to look for key words in problem statements and determine an appropriate formula. Students in discrete mathematics classes where they were explicitly encouraged to list have been overheard saying things such as, "But there are so many!" and "I feel like I'm not learning when I list all of the outcomes. I learn better when I'm given the theorems to use, not doing something tedious." Seeing student resistance to listing despite evidence for its utility prompted investigation into the following research questions:

1. *What are undergraduate students' attitudes towards listing as a strategy for solving counting problems?*
2. *How willing are undergraduate students to use listing as a strategy to solve counting problems, and how successful are they are?*

Literature Review and Theoretical Perspectives

Previous research has shown substantial need to better understand how to help students overcome difficulties they face solving counting problems. Specific struggles that earlier studies have found include that student errors can persist even when given combinatorial instruction (Batanero et. al., 1997); intuition on how to approach problems can be misleading (Fischbein & Grossman, 1997, p. 35); students lack efficient verification strategies (Eisenberg & Zaslavsky, 2004); and students get confused on the types of objects being counted (Batanero et. al., 1997).

To help students overcome difficulties while counting, Lockwood (2013, 2014) argues that attention to outcomes—the objects which are enumerated when solving a counting problem—should play a significant role in teaching students to count. Listing therefore can be a useful tool, as it provides students with a concrete way of attending to the outcomes of a counting problem and tying them explicitly to the counting process used to solve the problem. Indeed, Lockwood and Gibson (2016) found quantitative evidence for listing as a potentially useful strategy for students. They also discovered the following features of student lists that seemed most helpful while counting: useful notation and appropriate modeling of outcomes, organized strategy, and evident structure. Useful notation and appropriate modeling of outcomes refer to the way the student encodes each outcome, and whether the encoding correctly articulates what constitutes a desirable outcome. Organized strategy pertains to the order in which these outcomes are written down by the student, which could include the Odometer Strategy (English, p. 458-61, 1991) in contrast to random outcome generation. Finally a student list is said to contain evident structure if its organization reflects the counting process that the student uses. Lists with evident structure make it easier for a student to justify that a particular process counts every outcome once and only once.

In this study, I follow Lockwood (2013, 2014) in viewing outcomes as an intrinsic part of combinatorial enumeration. Since attention to outcomes has been supported by theoretical perspectives (Lockwood, 2013; Lockwood, 2014) and shown to be useful from quantitative and qualitative evidence (Lockwood & Gibson, 2016), finding out how students might feel about listing is an important addition to existing combinatorics education literature. I frame the data analysis and results using Lockwood and Gibson's (2016) features of productive listing.

Methods

To study student attitudes toward listing and success in using it to solve counting problems, individual task-based interviews were conducted and video-recorded with 9 discrete mathematics students at a large university in the western United States. Each student solved 6 counting problems, which were aimed at eliciting listing since their outcome sets have small cardinality or contain outcomes that are easily encoded:

1. *Chocolate Truffles. A chocolate store sells five varieties of chocolate truffles: raspberry, sea-salt caramel, mocha fudge, dark chocolate, and white chocolate. How many ways are there to select two truffles (of possibly the same variety) to buy?*
2. *Committee. A department committee consists of four people. If there are seven senior faculty members, how many committees are there if Bob (one of the senior faculty members) must be on the committee?*
3. *Letter Arrangements. How many ways are there to arrange the letters A, B, C, D, Z, Z, if the two Z's must be together at the beginning or end of the arrangement?*
4. *Binary Strings. How many strings of 1's and 0's are there of length 8?*
5. *Door. How many ways are there to arrange the letters in the word DOOR?*
6. *Olympic Swimming. There are 10 swimmers in the women's 200-m fly final race at the Rio Olympics. How many ways are there to award the gold, silver, and bronze medals?*

While the sample size of this study is small, the interview design allowed for more insight into student attitudes about listing, since I had the opportunity to follow up and question students about their solutions. After the students solved the counting problems, they were given 15 Likert-response statements (responses could range from 1-strongly disagree to 5-strongly agree) which measured constructs related to their attitudes toward listing as a strategy for counting.

After data collection, each solution was coded as being correct or incorrect and whether a listing strategy was used or not. In addition, each list was coded as being *productive* or *unproductive*, where a productive list is one where the student arrived at the correct answer and was able to articulate a relationship between their answer and their list. This is a modification of Lockwood and Gibson's (2016) definition of productive listing. In addition, lists were examined to see if they contained the three features of productive listing found by Lockwood and Gibson (2016). Finally, descriptive statistics for each Likert statement were calculated.

Results

Responses to Likert statements

The Likert statements were aimed at answering several related questions about student attitudes toward listing. For brevity, I will focus on the following questions since they are most relevant to the research questions above: 1) do students think listing is a useful strategy in general, 2) do they find listing to be a worthwhile activity, and 3) what did they report about their teachers' listing activity. Questions 1) and 2) express slightly different constructs in that 1) looks into how students think about listing in general, while 2) gets at whether students report that they themselves find listing to be valuable. This allowed for the possibility that some students might think listing is a useful strategy for other or less-experienced counters, but not for themselves personally.

To investigate question 1), I looked at student responses to the following Likert items: item 1, "When solving counting problems, it is often useful to write down some outcomes;" item 6, "Before solving a counting problem, it's important to articulate explicitly what you're trying to count;" and item 14, "Creating a list of outcomes is not necessary for solving counting problems." In contrast to the anecdote previously mentioned, the students in the study actually expressed broad agreement with statements 1 and 6, which had means of 4.11 and 4.66, respectively. The mean response to statement 14 was lower at 3.44, but most of those responding clarified that they felt listing is useful; they just did not feel it was always necessary for solving every counting problem.

Similarly, student responses indicated that they also viewed listing as a strategy they personally thought was worthwhile. The statements which measured this attitude were Likert item 7, "I dislike writing outcomes when solving a counting problem, because I usually know the right formula to solve the problem right away;" item 10, "Creating a list of what I'm trying to count is tedious and not worth the effort;" and item 11, "Writing outcomes is a useful activity for me when solving counting problems." Items 7 and 10 expressed a negative attitude about listing being personally worthwhile, and so I expected students would agree with them. However, the means of these responses were 2.44 and 2.67, respectively, indicating that students largely disagreed with these particular statements. Likewise, statement 11 had a mean response of 3.67, indicating that students at least did not disagree with the notion that writing down outcomes is useful for them personally.

Overall, the answers to all six of the Likert items above went contrary to expectations. Despite the resistance to listing that I had observed anecdotally from students in the classroom, the results from the Likert-response items indicated that there may be more to their resistance than simply finding listing to be useless and unnecessary. Thus, I needed to look further to see what else besides negative attitudes might contribute to resistance to listing.

A partial answer to this was found in the responses that students gave to Likert item 5, which reads, "My teacher mentioned outcomes but never encouraged us to list." The mean of the responses to this question was 2.78, indicating that students largely neither agreed nor disagreed with this statement. A limitation of this statement as a stand-alone Likert item was that it is a compound statement, meaning that by only looking at the mean response it is difficult to determine which part of the item they agreed or disagreed with. However, students could clarify their answers in the interview as they went through the Likert items, and some of the student utterances indicated that they felt more support could be given to them in terms of productive listing.

For example, Student 1 gave this statement a 2, which meant that he disagreed, but his explanation showed that he disagreed in particular with the idea that his teacher mentioned outcomes while teaching him to count. He said, "[My teachers] encourage formulas, rather than listing, I guess." Student 8 expressed a similar sentiment when he gave the statement a 4. He said,

> *Student 8: "Yep, [my teacher] really doesn't. Like, maybe for the digit problem [my teacher will] list it out, but for all the others, [my teacher will] just use a formula, which is bad, I think, because most people if they don't--if they haven't touched like possibilities and that kind of stuff they don't know which one to use. They'll often get confused."*

In this context when he said, "possibilities," he was referring to outcomes, meaning that he felt it could be more helpful to him and his peers to see his teacher write down outcomes more often so that they would know which formula to use while solving counting problems.

Noting the small sample size of this study, I acknowledge that I cannot make any broad claims or generalizations from these students' responses. However, it was surprising and is worthwhile to know that these students overall seemed to have positive attitudes about listing, and some of their responses to Likert item 5 support the idea that some students might resist listing because they lack instructional support to know how to list productively. The results from the Likert items thus provide some insight into the first research question, which targets students' attitudes toward listing.

Work on Counting Problems

The students in each interview also answered a sequence of 6 counting problems, all of which were written to hopefully elicit listing as a strategy. Indeed, out of the 53 total solutions obtained, 28 of them included listing as a strategy. Since this is over half of the solutions, their work provides further evidence that the students in the study felt that listing is a worthwhile strategy. Interestingly though, when I looked at these students' listing behavior, I saw that their ability to list did not necessarily reflect the positive outlook they had on listing. Out of those 28 lists that the students used, only 17 of them were productive (which, again, meant the students were able to reach the correct answer and relate the list to the solution obtained). In addition, the percentage of correct solutions found using any strategy (69.81%) was slightly higher than the percentage of correct solutions when the domain (of all student solutions) is restricted only to those found using a listing strategy (67.74%). As noted in the literature above, Lockwood and Gibson (2016) had previously found a positive correlation between listing and solving counting problems correctly, so this prompted me to investigate why the students in my study seemed not to be as successful on problems in which they listed.

Looking at instances where listing was productive for students, a characteristic example of their work is Student 2's solution to the Committee Problem. Her list can be seen in Figure 1. Using her exhaustive list, she was able to obtain a correct solution of 10+6+3+1=20. Examining her list, I see that it exhibited all three characteristics of productive listing found by Lockwood and Gibson (2016). She had useful notation and appropriate modeling of outcomes, encoding the outcomes using the items 1, 2, 3, 4, 5, and 6 and writing unordered groups of three of these numbers. Her strategy for writing down outcomes was organized, making use of the Odometer

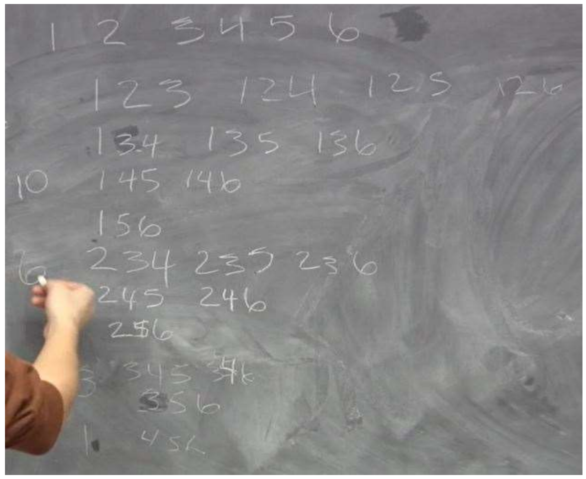

Figure 1. Student 2’s work on the Committee Problem.

Strategy (English, 1991), and her list also had evident structure, in that she was able to draw a clear connection between the list she obtained and the solution 10+6+3+1. In addition, while her productive list was exhaustive, I note that there were several productive lists in the study that were only partial lists of outcomes as well.

However, 11 of the 28 lists that students made in this study were unproductive, either leading students to incorrect solutions or, in one case, failing to contribute to a correct solution. For example, four out of the nine students made an incomplete list while solving the Chocolate Truffles Problem, which led them to the incorrect solution of 5^2=25. A characteristic example is Student 1’s list, which can be seen in Figure 2. In making this list, I see that he listed all of the outcomes in which a raspberry truffle is selected, and then extrapolated an observed pattern he saw in the outcomes: that there are 5 outcomes when one truffle type is fixed. He then reasoned that there are 5 total truffle types, so the solution must be 5×5=25. In this example, I see that he inappropriately modeled the outcomes of this problem using ordered pairs rather than unordered selections of truffles. While it is certainly possible that he would have reached this incorrect solution without the list he made, having a partial list of ordered pairs reflecting the multiplication 5×5 certainly didn’t help as he solved the problem.

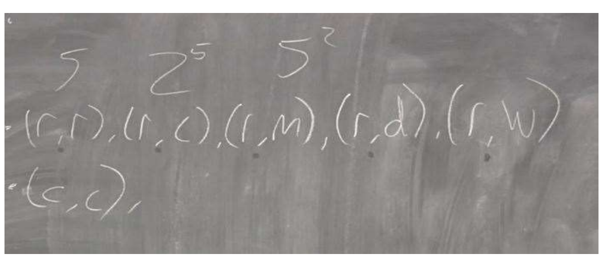

Figure 2. Student 1’s work on the Chocolate Truffles Problem.

While inappropriate modeling of outcomes was present in student work, other features of productive listing identified by Lockwood and Gibson (2016) were missing in the students’ unproductive lists as well. For instance, Student 4 used an unproductive list while solving the

Letter Arrangements problem. While making his list, he tried to write down all of the outcomes beginning with two Z’s and an A, appearing to be trying to use the Odometer strategy (English, 1991). However, he arranged the letters B, C, and D at random and was only able to come up with four outcomes beginning with ZZA, concluding from his partial list that the solution was 2×4×4=32 total arrangements. While, again, it is possible he would have obtained this solution without making a list, the disorganized strategy stands in contrast with the kind of listing shown to be productive in Lockwood and Gibson (2016).

Since the students’ unproductive lists in this study were often missing one or more of Lockwood and Gibson’s (2016) features of productive listing, this suggests that perhaps instructors could provide more support for students learning to solve counting problems by discussing how to create lists with the three features. It appears from these results that even if students are willing and able to list, they will not always be successful in generating productive lists.

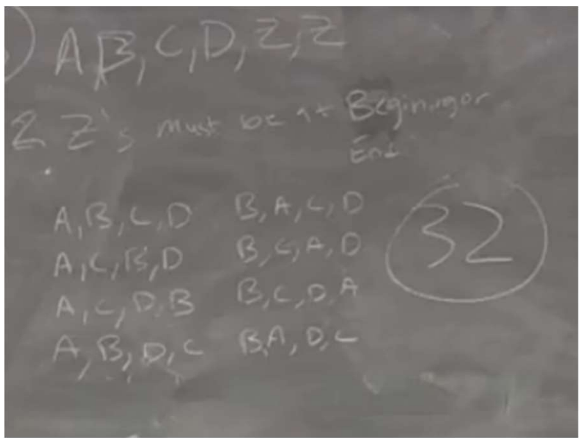

Figure 3. Student 4’s work on the Letter Arrangements Problem.

A second interesting observation about the students’ unproductive listing behavior occurred when the lists were examined by problem. Three of the problems in this study (the Letter Arrangements Problem, Binary Strings Problem, and Olympic Swimming Problem) can be solved by simply applying the Multiplication Principle, while the other three problems are likely to be

Table 1
Descriptive Statistics on Solution Accuracy with and without Listing for Each Problem.

Problem	Percentage accuracy of solutions using any strategy	Percentage accuracy of solutions using a listing strategy
Chocolate Truffles	33.33	42.86
Committee	37.50	40.00
Letter Arrangements	88.89	75.00
Binary Strings	88.89	80.00
Door	66.67	85.71
Olympic Swimming	100.00	100.00

more challenging or novel to students. The Chocolate Truffles Problem requires a multi-choose or a sum to solve it; the Committee Problem can be solved using an unordered selection; and the Door Problem can be solved using division. I found that while overall listing had no correlation with obtaining a correct solution, a closer look showed that listing appeared to have no effect or was a hindrance mostly on the problems requiring just the Multiplication Principle. For the three more challenging problems, the percentage of correct solutions when a listing strategy was used was higher than the percentage of correct solutions where any strategy was used. While there still were several unproductive lists for these three problems, and the percentage of accurate solutions for these more challenging problems was still low, these results support the conclusion that perhaps listing could be more beneficial for students solving more novel or challenging problems. These results are summarized in Table 1. While I cannot read too much into these numbers because of the small sample size, the findings at least suggest that there may be some effect of problem type on students' listing behavior and the extent to which listing is useful for students.

Overall for the students in this study, listing appeared to be most helpful on problems that were more novel or challenging, rather than simply requiring use of the Multiplication Principle. This may be in alignment with findings from Lockwood and Gibson (2016), in which the students were novices and were faced with some more challenging problems than were the students in my study. However, even on these more challenging problems, listing was not always helpful, and the students' willingness to list was not reflected in a need they may have had for more support in knowing how to list productively.

Conclusion

The aim of the study was to investigate students' attitudes toward listing, and to see if my findings would corroborate anecdotal evidence of student resistance to listing. Contrary to anecdotal experience, the evidence from this small-scale study suggests that students may agree that listing is useful and worthwhile, and that some instances of student resistance to listing actually may stem from not knowing how to list productively. Data from the Likert responses suggest that some students wish their teachers modeled productive listing and taught them explicitly how to list. I saw also from their activity while solving counting problems that they personally were willing to use listing as a strategy, but their positive attitude about listing was not reflected in the high percentage of unproductive lists that were created. I additionally observed that effectiveness of listing as a strategy may depend to some extent on the problem type and its degree of novelty.

Since student resistance to listing may result in part from a lack of instructional support rather than simply negative attitudes, a natural direction moving forward would be investigating how instructors can help model and teach productive listing for students in their discrete mathematics classes. In addition, a larger-scale study should be conducted to determine if the positive attitudes about listing I encountered persist when examining a larger sample. Finally, future studies should seek a more sophisticated understanding of the relationship between the utility of listing and problem type.

Tinker Bell's Pixie Dust: Exploring the Differentiations Necessary to Engage in Emergent Shape Thinking

Kristin M. Frank
Arizona State University

Researchers have described the importance of seeing a graph as an emergent trace of how two quantities' values vary simultaneously. Researchers have also identified the many difficulties students face when constructing this conceptualization of graphs. In this paper I explore the role of two didactic objects on a student's conceptualization of graphs. In particular, I examine how a student's interactions with these didactic objects supported her in making key differentiations that enabled her to conceptualize a graph as emerging from simultaneously tracking two quantities' varying values. My findings revealed that a student must differentiate a place on a function's graph from the value of the function's output. Also, the student must distinguish tracking a point in the plane from creating the point by simultaneously attending to the variation of two quantities.

Keywords: Covariational Reasoning, Emergent Shape Thinking, Graphing

Students' conceptualizations of graphs remains a prominent area of study in both mathematics and science education. Researchers have documented how students' impoverished conceptualizations of graphs inhibit them from constructing productive meanings of function and rate of change (e.g., Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Johnson, 2015; McDermott, Rosenquist, & van Zee, 1987; Oehrtman, Carlson, & Thompson, 2008). While researchers have highlighted ways of thinking that either support or inhibit students from developing propitious conceptualizations of graphs (e.g., Moore, Paoletti, Stevens, & Hobson, 2016; Whitmire, 2014), they have not documented how to support students who conceptualize graphs as static shapes in shifting to see them as emergent representations of the simultaneous variation of two quantities' values. In this paper I characterize the constructions and differentiations necessary to see a graph as representing the simultaneous variation of two quantities' values.

Background

Moore and Thompson (2015) describe two ways of thinking students hold for graphs: *static shape thinking* and *emergent shape thinking*. A student engages in *static shape thinking* when he conceptualizes graphs as objects in and of themselves. This student is likely to reason about a graph based on his perception of the shape. For example, a student who engages in static shape thinking might understand slope as the property of the line that determines whether the line falls or rises as it goes from left to right. This way of thinking is consistent with Bell and Janvier (1981) and Carlson's (1998) findings that students often reason about graphs based on their perception of the shape of the curve and confound pictorial attributes of a situation with the shape of the graph.

An alternative way of thinking about graphs is what Moore and Thompson (2015) called *emergent shape thinking*. They explained,

> "Emergent shape thinking involves understanding a graph *simultaneously* as what is made (a trace) and how it is made (covariation). As opposed to assimilating a graph as a static object,

emergent shape thinking entails assimilating a graph as a trace in progress (or envisioning an already produced graph in terms of replaying its emergence), with the trace being a record of the relationship between covarying quantities" (p. 4).

Moore and Thompson explained that students who think about graphs emergently are positioned to reflect on their reasoning and thus have the opportunity to form abstractions and generalizations from their reasoning. As a result, relationships students construct from these generalizations are not tied to particular shapes, labels, and orientations.

As Saldanha and Thompson (1998) explained, "understanding graphs as representing a continuum of states of covarying quantities is nontrivial and should not be taken for granted" (p. 303). To engage in emergent shape thinking the student must first conceptualize two attributes, call them x and y, and imagine representing the varying measures of these attributes along the horizontal and vertical axes, respectively. Then she needs to imagine projecting these measures into the plane and conceptualize the intersection of these projections, the correspondence point, as a way to unite the measures of x and y (Figure 1). When one constructs an object that unites two attributes and the relation between these attributes she has constructed what Saldanha and Thompson (1998) call a multiplicative object. Conceptualizing a point in the Cartesian plane as a multiplicative object that unites values of x and y is essential when engaging in emergent shape thinking because, as Saldanha and Thompson explained, by constructing a multiplicative object, when one tracks the value of x (or y) she is constantly aware that the other quantity also has a value. As a result, as the student tracks the correspondence point, he is simultaneously attending to both the value of x and the value of y.

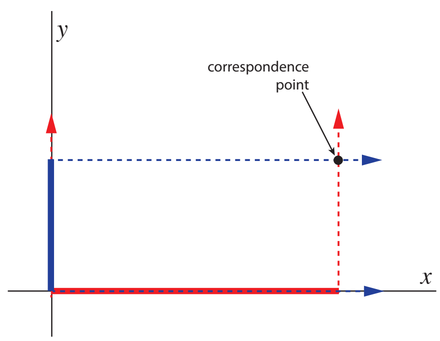

Figure 1: Conceptualizing a point in the Cartesian plane as a projection of two quantities' values, which are represented on the axes.

Methodology

I conducted one-on-one teaching experiments (Steffe & Thompson, 2000) with three university precalculus students (1 male STEM major, 1 female STEM major, 1 female liberal arts major). These students were selected to participate in the teaching experiments because they demonstrated different ways of engaging in covariational reasoning in a recruitment interview. My primary teaching goal was to support students in engaging in emergent shape thinking when constructing and making meaning of graphs. After I completed the interview process I engaged in retrospective analysis by identifying instances that provided insights into the students' conceptualizations of quantities, points in the Cartesian coordinate system, and covariation of quantities' values. I used these instances to generate tentative models of each student's schemes for graphing and covariational reasoning. I tested these models by searching for instances that confirmed or contradicted my model and repeatedly refined my model until it accounted for the student's mathematical activity.

Of the three students who participated in my study, only one student, Ali, came to consistently engage in emergent shape thinking. At the time of the teaching experiment Ali had just completed her freshman year at a large public university and had earned a B in her precalculus course. As a liberal arts major, this precalculus course satisfied Ali's math requirement and she did not intend to take calculus. In the follow sections I describe my initial model of Ali's schemes for graphing and covariational reasoning. Then I describe two didactic objects the research team used to support Ali in engaging in emergent shape thinking. I conclude by hypothesizing why these interventions supported Ali in constructing new meanings for points and graphs in the Cartesian coordinate system.

Results

In the second of four one-on-one teaching sessions it was apparent that Ali was not conceptualizing a point in the Cartesian coordinate system as a multiplicative object and thus was not engaging in emergent shape thinking. She was working on a task adapted from an instrument used to assess secondary teachers' mathematical meanings (Thompson, 2016). This animated item was originally designed to support researchers in better understanding in-service secondary mathematics teachers' schemes for covariational reasoning (Thompson & Carlson, in press). For the purpose of my study, I used this task to help me understand the nature of the multiplicative object Ali constructed when engaged in covariational reasoning.

I showed Ali a video that depicted a red bar along the horizontal axis and a blue bar along the vertical axis. As the video played, the lengths of the bars varied simultaneously in such a way that each bar had one end fixed at the origin. (See Figure 2 for selected screenshots from the video). The horizontal (red) bar's unfixed end varied at a steady pace from left to right while the vertical (blue) bar's unfixed end varied unsystematically. I explained to Ali that the length of the red bar represented the varying value of *u* and the length of the blue bar represented the varying value of *v*. I presented Ali with a printout that included the animation's initial screen depicting a set of axes and the initial placement and lengths of the red and blue bars. I asked Ali to sketch a graph of the value of *v* relative to the value of *u.* I anticipated Ali would be successful if she could imagine placing a point in the plane as a way to simultaneously represent the lengths of the red and blue bars. The video played repeatedly until Ali completed the task.

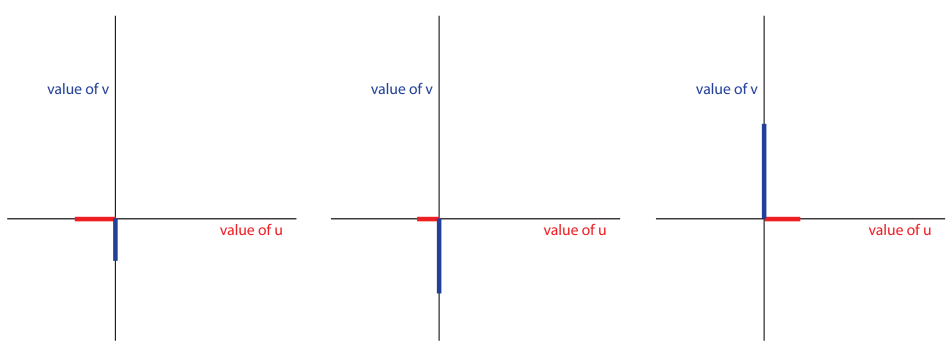

Figure 2: Three screenshots from the animated task.

After watching the video play through two times Ali began making dots within the plane and then connected those dots with a curved line (see Figure 3a). She explained that she figured out the graph by “looking at the motion of how the blue line is increasing and decreasing” and made a dot each time “the blue line kinda stopped and the line kinda dipped down.” When I asked her about the red line she said, “since the whole time this red line is increasing it (the graph) is going to the right.” While Ali was able to produce a correctly shaped graph by tracking the motion of the blue bar with respect to experiential time, her focus on the blue bar suggested that she was not coordinating the varying lengths of the red and blue bars and thus had a non-multiplicative conception of her graph. In the following paragraphs I provide evidence to support this claim.

First, consider Ali’s initial point (see Figure 3a). Since Ali sketched her graph on axes that displayed the initial lengths of the red and blue bars, Ali’s initial point should have been placed at the intersection of the projections of these bars (see Figure 3b). However, her initial point is only aligned with the projection of the blue bar. When I asked Ali to explain how she decided where to place her initial point she said, “I based it off of this blue line (*points to blue line on vertical axis*).” Notice that Ali does not mention the red line when discussing how she placed her initial point. Since Ali only attended to one of the bars when constructing the starting place for her graph, she was not conceptualizing her mark in the plane as a multiplicative object – as a way to unite two attributes simultaneously.

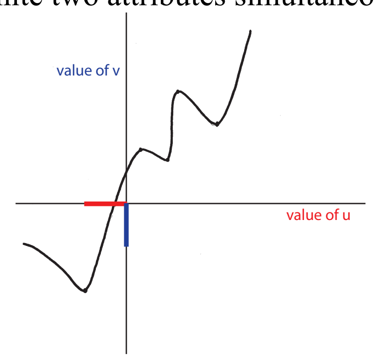

Figure 3a: Ali’s graph generally correct shape but incorrect initial point.

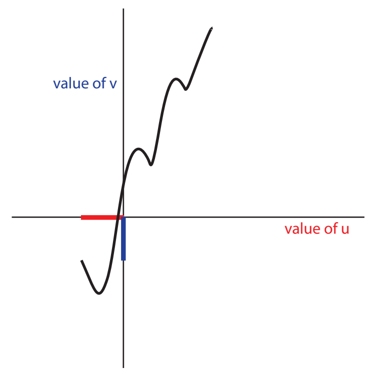

Figure 3b: Accurate graph for animated item in Figure 2.

Ali’s focus on the blue line extended beyond her placement of the initial point. When Ali described what her graph represented she said, “As the red is increasing (*traces hand left to right on horizontal axis*) it (the graph) is showing the motion or like the path of the blue line (*traces along curve from left to right*).” Ali’s conception of the curve was based in the motion of the blue line, not the coordination of the red and blue line. As a result, when Ali described the motion of the blue line she gestured along the curve. This suggests Ali confounded the variation of the length of the blue bar with the path of the curve and thus confounded the length of the blue bar with a place in the plane. Since the motion of the blue line and the curve were synonymous in Ali’s thinking, she had no need to attend to the red line when describing her graph.

This task was not designed to support Ali in making new constructions. Instead, it was designed to assess the role of multiplicative thinking in her covariational reasoning. Since her activity provided evidence that Ali was not thinking multiplicatively the research team used two didactic objects in the third teaching session to support Ali in engaging in emergent shape thinking. As Thompson (2002) explained, a didactic object is “‘a thing to talk about’ that is designed with the intention of supporting reflective mathematical discourse” (p. 198). The first didactic object was designed to support Ali in conceptualizing a correspondence point that simultaneously represented *two* attributes. The second didactic object was intended to support Ali in conceptualizing a curve as a locus of points.

Didactic Object I: Conceptualizing Correspondence Points

To support Ali in conceptualizing a point as a multiplicative object, I introduced the notion of a correspondence point as a way to represent the value of u and the value of v simultaneously. I modified the animation described in Figure 2 so that at any moment I could pause the animation and display the correspondence point as depicted in Figure 1. Following the recommendation of Thompson et al. (under review), I engaged Ali in an activity where I let the animation play, paused the animation, and asked Ali to use the pointer to show where the correspondence point would be. Each time I asked Ali to justify why the correspondence point would be in that specific location. Finally, I displayed the correspondence point to confirm Ali's conceptualization. I repeated this four times to ensure that Ali could construct the location of the correspondence point given the lengths of the red and blue lines and to ensure that she coordinated her conception of the correspondence point with both the red *and* blue lines.

After Ali repeatedly described the correspondence point with the animation paused, I asked her to imagine tracking the correspondence point as the animation played and to try to remember everywhere it had been. Ali watched the animation play through once, tracked the correspondence point with the mouse pointer, and then sketched a graph from her memory of where the correspondence point had been. While Ali's graph now had the correct shape and correct initial point, her image of her graph did not include points. She conveyed that her graph was made of imaginary points that had no coordinates.

This description suggests that although Ali could visually unite attributes to create her graph, she was not viewing her constructed graph in terms of the attributes she used to create the graph. One possible explanation is that to create the graph Ali needed to engage in two actions: first she needed to imagine uniting the length of the red bar and the length of the red bar through a correspondence point and then imagine tracking this point. After constructing the graph she was able to track the motion of a point, but did not retrospectively conceptualize the point as a representation of the simultaneous the lengths of the red and blue bars they varied together. As a result, her explanation of her graph was no different than before; she explained, "As v is increasing and decreasing u is just going to the right." Her conception of the completed graph was still non-multiplicative.

Didactic Object II: Tinker Bell's Pixie Dust

The researchers hypothesized that Ali was not conceptualizing the curve as a collection of points that emerged from simultaneously tracking two quantities' measures. The witness to the teaching experiment intervened to support Ali in conceptualizing her graph as being made by Tinker Bell, the fairy from Peter Pan's Neverland, flying along the path of the curve so that she left a trail of pixie dust marking everywhere she had been. As Thompson (2002) explained, supporting students in conceptualizing graphs being made of pixie dust supports them in coming to imagine lines and curves as being composed of points - pieces of pixie dust - where each piece of pixie dust simultaneously represents the measures of two quantities.

To ensure that Ali was familiar with Tinker Bell and her pixie dust, the witness asked Ali to describe what she knew about Tinker Bell. Ali explained that Tinker Bell is special because she can fly and has pixie dust so as she flies you "see where she has been in the pixie dust". The witness then asked Ali to think about her pen as Tinker Bell and everything she drew (the curve) as pixie dust. When he asked if there was any pixie dust on her graph Ali explained that each particle of pixie dust looked like an imaginary point. Additionally she said the pixie dust represented where Tinker Bell had been and Tinker Bell knew where to fly by "noticing where the value of *u* and the value of *v* were". This is significant because Ali included both the value of *u* and the value of *v* in her conceptualization of placing a piece of pixie dust. I hypothesize that thinking about how Tinker Bell knew where to fly gave Ali a way to differentiate between the two actions she used to construct the graph, coordinating two measures through a point (how Tinker Bell knew where to fly), and then tracking that point (where Tinker Bell flew).

After I introduced the idea of Tinker Bell's pixie dust there were two noticeable differences in Ali's actions. First, when Ali described the value of *v* she would point to the vertical axis as opposed to the curve. This suggests that introducing the notion of a piece of pixie dust enabled Ali to differentiate between the magnitude of an attribute and a place on the curve. As a result, Ali no longer explained a place on the curve, a piece of pixie dust, by attending to just *v*, the length of the blue bar. Instead, she thought about both the *u* and *v* when describing the pixie dust. The second difference in Ali's actions were in her description of how *u* and *v* changed together. Up until this point Ali always described how *u* changed, it increased, and how *v* changed, it increased, then decreased, then increased again. After introducing the notion of pixie dust Ali gave her first explanation of how *u* and *v* changed together that, from my perspective, revealed that she was coordinating two attributes.

> Ali: So as the value of *u* keeps on going towards the right the value of *v* um dips down. So *v* gets a bit closer to the value of *u* and then it dips down. Then as the value of *u* keeps going towards the right the value of *v* increases significantly (*moves pen up vertical axis*) then at a certain point where the value of *u* is about here (*points on horizontal axis*), the value of *v* decreases and then when the value of *u* is about here (*points on horizontal axis*), up until the value of *u* is around here the value of *v* increases and then dips down again (*moves finger up vertical axis*). Then again when the value of *u* is around here (*points on horizontal axis*) then the value of *v* increases again.

This reveals that when Ali attended to the meaning conveyed by her graph she maintained a multiplicative conception of a point and imagined the line coming from simultaneously tracking both the length of the red bar and the length of the blue bar.

Introducing the notion of pixie dust was critical because it gave Ali something real to think about on the graph. As a result, it enabled Ali to differentiate between the value of *v* and the point on the graph. Thus, she came to a reflective conceptualization of a point in the plane where she could imagine constructing a point by attending to the measure of *u* and *v* but also, she could conceptualize a placed point as a representation of both the value of *u* and the value of *v*. Additionally, thinking about where Tinker Bell flew versus how she knew where to fly enabled Ali to differentiate between the actions of placing a point and then tracking that point.

Discussion

At the beginning of the teaching experiment Ali was limited to static shape thinking. She constructed graphs by tracking one quantity with respect to experiential time. This led her to confound the measure of the output quantity with the location of a point in the plane. As a result she conceptualized the variation of the output quantity as the trace of the curve. While this suggests a dynamic conceptualization of graphs, with this way of thinking she did not conceptualize - and had no need to conceptualize - uniting two attributes to make her graph.

Introducing the notion of Tinker Bell's pixie dust supported Ali in making two key differentiations. First, conceptualizing the pixie dust gave Ali a new cognitive object to operate on. Additionally, Ali imagined this pixie dust to be different than the blue bar. Conceptualizing these two objects enabled Ali to differentiate between the value of the output, the length of the blue bar, and the point in the plane, the piece of pixie dust. More importantly, since Ali saw the pixie dust as different from the blue bar, Ali necessitated a way of thinking about placing the piece of pixie dust that involved more than blue bar. She responded to this intellectual need by coordinating her conception of the red and blue bar in order to think about the location of the pixie dust; Ali constructed the pixie dust as a multiplicative object.

The most robust form of emergent shape thinking involves more than constructing graphs by imagining tracking a correspondence point. One must also be able to reverse this way of thinking so that she imagines a curve having been produced by tracking a correspondence point. Constructing this reversible way of thinking is non-trivial as it involves reflecting upon the actions one engaged in when constructing the graph. As Moore and Thompson (2015) explained, "Emergent shape thinking involves understanding a graph *simultaneously* as what is made (a trace) and how it is made (covariation)" (p. 4). This implies that engaging in emergent shape thinking requires two actions: tracing the correspondence point and uniting two varying attributes through a correspondence point. Thinking about where Tinker Bell flew and how Tinker Bell knew where to fly enabled Ali to differentiate these actions so that each was available for reflection. As a result Ali was able to explain her constructed graph in terms of the actions she used to produce it: simultaneously attending to the red and blue bar as they varied.

This study provides insights into the understandings necessary to engage in emergent shape thinking and didactic objects instructors can use to support students in constructing these understandings. Perhaps most importantly, these results provide evidence that educators can support students in shifting from static to emergent shape thinking. This is essential as we call upon pre-service teachers, who often engage in static shape thinking (Moore et al., 2016), to support our students in conceptualizing and representing simultaneous variation in two quantities' measures. Future studies should explore the way in which these shifts might occur in classroom instruction.

I want to address a limitation of this work: the task described is not situated in a context. As a result, I caution interpreting Ali utterances of values of u and v as evidence of having quantified a situation and enacted a measurement process. Instead, it is likely that Ali's meaning for value of u and value of v were tied to the pictorial features of the representation in the Cartesian coordinate system. This claim is supported by Ali's ability to engage in emergent shape thinking in other novel graphing contexts, such as the City A and City B task (see Saldanha & Thompson, 1998), but her inability to construct multiplicative objects in an algebraic contexts. This suggests a limitation to studies situated entirely in the graphing world and motivates future studies that explore the ways in which students construct multiplicative objects in non-graphing contexts. Such studies have the potential to understand how students generalize their schemes for covariational reasoning.

Gender and Discipline Specific Differences in Mathematical Self-Efficacy of Incoming Students at a Large Public University

Ulrike Genschel, Hien X. Nguyen
Iowa State University

*This study investigates differences in mathematical self-efficacy and outcome expectations of 3107 incoming students enrolled in introductory level mathematics or statistics courses at a land grant university in the Midwest. Students were grouped by discipline (STEM (**S**cience, **T**echnology, **E**ngineering and **M**athematics), Social Sciences and Arts & Humanities) and by gender within each discipline. All students enrolled in an introductory mathematics or statistics course during their first semester at the institution were surveyed about their perceived mathematical self-efficacy and outcome expectations at the beginning of that semester. Our results suggest that discipline specific differences are dependent on the definition of STEM majors, namely distinguishing between math intensive and non-math intensive STEM majors. After accounting for this distinction gender differences in mathematical self-efficacy and outcome expectations disappear.*

Key words: Mathematics, Self-Efficacy, Gender, Social Sciences, and STEM

Introduction

The gender gap in the STEM sciences continues to afflict the U.S.'s economic and social prosperity. For the U.S., as a nation, to remain innovative, competitive and at the forefront economically and technologically, the country needs to continue growing the number of baccalaureates in the STEM sciences and provide diverse opportunities for individuals to pursue STEM related career paths. The National Science Board (NSB-2015-10) published in a recent, up to date, report that "policymakers, scholars, and employers have come to recognize that science, technology, engineering, and mathematics (STEM) knowledge and skills are critical to an extensive portion of the entire U.S. workforce and that a broad range of STEM-capable workers contribute to economic competitiveness and innovation."

In addition to unrecognized pathways, one of the recognized reasons for the existing shortage is the systematic exclusion of parts of the population due to the underrepresentation of women and minorities pursuing STEM or STEM-related degrees, a trend that has been challenging to reverse or to even slow down. Although much research has been devoted to understanding reasons for the shortage of women and other minorities in the STEM sciences (e.g., Betz & Hacket, 1983; Blickenstaff, 2005; Eccles et al., 1983; Else-Quest, Hyde, & Linn, 2010; Gainor & Lent, 1998; Hacket et al., 1992; Lent, Lopez & Bieschke, 1991, 1993; Lent, Brown, & Larkin, 1984, 1986; Wigfield & Eccles, 1992;) it is still not fully understood why these groups choose STEM careers at significantly lower rates than non-minority men. Contributing factors include gender differences in STEM science self-efficacy (Eccles et al., 1993; Jacobs, Davis-Kean, Bleeker, Eccles, & Malanchuk, 2005), lack of role models (Betz & Fitzgerald, 1987; Blickenstaff, 2005) or societal norms and expectations Eccles, 1987, Raty et al., 2002). Additionally, the complexity of the associations among these factors adds another layer of complicatedness to the phenomenon. For a more recent and complete review of the literature we refer to Wang & Degol (2013).

The primary focus of this research is on introductory mathematics and statistics classes taken at the beginning of college motivated by the fact that the mathematical and statistical sciences are seen as gate keepers (Gainen, 1995) to the STEM sciences. Without successful completion of calculus or differential equations continuing in many STEM science majors is difficult if not impossible. While research has explored gender differences in mathematical self-efficacy at the middle and high school level or at the college level within specific STEM disciplines, less is known about the critical transition period from high school to college. For students enrolling into STEM majors or interested in pursuing a STEM major introductory mathematics and statistics classes are commonly among the classes taken during their first semester at college. This motivates the question whether students' experiences in these classes contribute or are related to the gender gap. To provide at least partial insight into this question we investigate the levels of mathematical (and statistical) self-efficacy of incoming students at a large public state university.

Theoretical Framework

The theoretical framework builds on the construct of social cognitive career theory (SCCT; Lent, Brown & Hackett, 1994, 2000). SCCT is based on Bandura's social cognitive theory (Bandura, 1986, 1989, Bussey & Bandura, 1999). At the center of SCCT lies an individual's self-efficacy. Self-efficacy is defined according to Bandura (1986) as 'people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performance' (p. 391). Thus when an individual contemplates a particular career path, the conviction the individual has about his or her ability as well as past, successful experiences plays an important role. With specific regard to a STEM field, if a person perceives that ultimately, he or she is not likely to be successful and has had what can be thought of as less than successful experiences, the likelihood that this person will choose that particular career path decreases. Self-efficacy is only one of three components of SCCT. The other two components are outcome expectations and personal goals. Outcome expectations refer to the belief about what outcomes are possible based upon specific courses of actions or experiences. An individual considers the question about what will happen if a course of action is completed. Environmental factors are often perceived as controllable and influential on the outcome, more than the individual's own behavior (Gro, 2008). Self-Efficacy and Outcome Expectations as the two primary pillars of SCCT are important when considering success of underrepresented groups, in particular females, in STEM career choices.

Research Questions and Research Hypotheses

The main research question of interest focuses on the levels of mathematical (and statistical) self-efficacy and outcome expectations of incoming students at a large public university such as Iowa State University. In order to obtain information related to gender gap issues in the STEM sciences, we group incoming students according to gender and discipline of declared major. We categorized declared major into STEM majors (distinguishing between math-intensive STEM and non math-intensive STEM majors), social sciences and arts and humanities. A student was considered as pursuing a STEM degree if the first or second declared major was in a STEM field.

Research Question

What is the level of mathematical or statistical self-efficacy and of outcome expectations of students entering a large public university, such as Iowa State University?

In order to obtain information related to the gender gap in the STEM sciences, incoming students will be grouped according to

(1) gender

(2) declared discipline, i.e. STEM, social sciences, arts and humanities.

Thus, our research question is aimed at baseline information, summarizing academic self-efficacy in mathematics and statistics courses.

Hypotheses

H1.1 *Self-efficacy, mathematical self-confidence and outcome expectations of incoming students are, on average, significantly higher in students with STEM majors compared to students with a social science or an arts and humanities major.*

H1.2 *Within each of the three groups, self-efficacy, and mathematical self-confidence and outcome expectations is comparable for women and men.*

Data and Statistical Analyses

Data for this study stem from a larger parent study, which collected data on 15,960 students enrolled into an introductory mathematics or statistics course during the semesters of Spring and Fall 2012 and Spring 2013. Of these students, 3107 students were described as *an incoming student*, for which we also had complete background data on ACT scores, high school credits in mathematics and natural sciences, as well as high school rank and GPA. Incoming students are defined, as students who entered the university directly from high school, were actively degree seeking, had U.S. residence status and enrolled into an introductory level mathematics or statistics course during their first college semester. Of the 3107 students 1868 completed a pre-survey on mathematical or statistical self-efficacy during week three of the semester. The survey instrument is based on an existing 36-item instrument called the "Survey on Attitudes Toward Statistics" (SATS-36) (Schau et al., 1995 and Schau, 2003). Schau's SATS-36 survey consists of six subscales measuring *Affect*, *Interest*, *Difficulty*, *Cognitive Competence*, *Effort* and *Value*, respectively. Although the survey is well known among statistics educators and has been utilized extensively since its introduction in the literature, the authors were not able to confirm the six dimensional structure but rather that items measuring Affect, Cognitive Competence and Difficulty loaded onto a single factor. This single factor reflects what is generally defined as perceived mathematical/statistical self-efficacy. Our finding is supported by VanHoof, S., et al. (2011). Some items not loading onto any factor motivated additional changes to individual items. These changes, most of them minor, and adapting the survey to mathematics students were made in consultation with a survey expert from the Center of Survey Statistics and Methodology (CSSM) at Iowa State University. In accordance with Lent's Social Cognitive Career Theory (Lent, Brown & Hackett, 1994, 2000) we further added six questions to measure outcome expectations, as outcome expectations are the second pillar in the SCCT framework in addition to self-efficacy.

We used exploratory factor analysis to estimate the latent factor structure (self-efficacy, value, effort, interest and outcome expectations) and evaluated each factor calculating Cronbach's alpha. The levels of Cronbach's alpha (standardized) are 0.87 (self-efficacy), 0.90 (value), 0.76 (effort), 0.61 (interest) and 0.87 (outcome expectations). Subsequently, we obtained the corresponding factor scores for each student and calculated numerical summaries of the factor scores and conducted corresponding two-sample t-tests according to the groupings defined in the Research Question.

Results

We will summarize the results in tabular form for each hypothesis. We begin with H1.1: Although the primary focus is on mathematical self-efficacy and outcome expectations we also include the results for students' perceived value and interest in mathematics. H1.1 hypothesizes that mathematical self-efficacy and outcome expectations of incoming students are, on average, significantly higher in students with STEM majors compared to students with a social science or an arts and humanities major.

Contrary to hypothesis H1.1 we were not able to identify significant discipline specific differences among the incoming student that participated in our study (see Tables 1 and 2).

Table 1
STEM Sciences versus Social Sciences (Soc. Science)

Dimension	Mean STEM	Mean Soc. Science	t-statistic	df	p-value	95% Confidence Interval for difference in means
Self-Efficacy	0.154	-0.084	2.049	72.3	0.0441	(0.006, 0.472)
Value	**0.352**	**-0.371**	**5.80**	**70.5**	**<0.0001**	**(0.475, 0.972)**
Interest	0.028	0.044	-0.139	72	0.8898	(-0.240, 0.209)
Outcome Expectations	0.075	-0.135	2.070	76	0.0419	(0.008, 0.412)

Table 2
STEM Sciences versus Arts & Humanities (Arts & Hum)

Dimension	Mean STEM	Mean Arts & Hum	t-statistic	df	p-value	95% Confidence Interval for difference in means
Self-Efficacy	0.154	-0.126	2.103	56.8	0.0399	(0.013, 0.547)
Value	**0.352**	**-0.550**	**6.402**	**55.8**	**<0.0001**	**(0.620, 1.185)**
Interest	0.028	-0.052	0.713	57.8	0.4789	(-0.145, 0.306)
Outcome Expectations	0.075	-0.117	0.858	60	0.3944	(-0.124, 0.309)

Both, mathematical self-efficacy and outcome expectations are comparable although based on the observed p-values less than 0.05 one may suggest a week tendency[1]. The same result holds for interest suggestion no significant differences between the disciplines. Highly significant, however, is the difference in how students in different disciplines value mathematics. A possible explanation based on the items belonging to the interest dimension is that students in STEM majors directly experience and appreciate the need for foundational mathematics knowledge in order to succeed in their downstream courses while for many social science and arts and humanities majors degree requirements often consist of no more than one class. Regarding the somewhat unexpected results for self-efficacy and outcome expectations we theorize that a possible explanation for this result lies in the definition itself of what majors are considered STEM majors. In recent years several majors such as economics, psychology or food sciences,

[1] Because of the large number of hypotheses tests, we do not use the usual cut-off value of 0.05 for the level of significance but in an effort to adjust for the multiple testing procedures consider p-values of 0.001 or less as statistically significant.

for example, have been grouped more frequently with the STEM sciences in an effort to provide a more inclusive definition of STEM and because many of these majors frequently include STEM related tasks or knowledge. Different majors within STEM, nevertheless have substantially different mathematical prerequisites, which prompted us follow up our analysis by distinguishing between so-called math intensive STEM majors and those that are not math intensive. For a major to be considered math intensive the major's degree requirement had to include science/engineering Calculus I, or equivalent. Table 6 provides the updated results displaying differences in mathematical self-efficacy and outcome expectations for students when distinguishing between math intensive and non-math intensive STEM majors. All four factors show a significant difference between both groups with students in math intensive STEM majors exhibiting higher levels of self-efficacy, value, interest, and outcome expectations. The same distinction further explains gender differences in mathematical self-efficacy and value originally observed in Table 3 for students in the STEM sciences. When accounting for the type of STEM major (math intensive or not) Tables 7 and 8 show that gender differences within each group disappear and can likely be attributed to random variation. Tables 4 and 5 support our second hypothesis H1.2 showing no gender differences in the social sciences and the arts and humanities.

Table 3
Gender Differences in the STEM Sciences

Dimension	Mean Female	Mean Male	t-statistic	df	p-value	95% Confidence Interval for difference in means
Self-Efficacy	**0.032**	**0.201**	**-2.921**	**572.1**	**0.0036**	**(-0.282, 0.055)**

Outcome Expectations	-0.107	-0.185	0.549	188.7	0.5839	(-0.204, 0.362)

Discussion and Conclusions

Although we did not test for significant differences between math intensive STEM majors and the social sciences and arts and humanities, respectively it is possible to conclude that the statistically significant differences found between math intensive and non-math intensive STEM majors will extend to statistically significant differences between math intensive STEM majors and the social sciences and arts and humanities as the sample means for math intensive STEM majors only increased from those of all STEM majors combined. Under the theoretical framework of Social Cognitive Career Theory with self-efficacy and outcome expectations as its two cornerstones the existing differences imply that the shortage of a strong STEM workforce as well as limitations on the number of pathways leading to a workforce will continue rather than beginning to embrace the STEM sciences. Our results were encouraging, however, in the sense that within each of the disciplines gender differences have subsided or continue to no longer present.

Exploring a Pre-Service Teacher's Conceptions of Area and Area Units

Sayonita Ghosh Hajra
Hamline University

Betsy McNeal
Ohio State University

This paper highlights the data from a one-semester course with pre-service teachers in an ongoing study of their conceptions of area at a public university in the western United States. Their meanings of area and area units, both standard and non-standard, were explored throughout the semester. Analysis of our interviews with these pre-service teachers about their responses to area tasks allowed us to uncover three cognitive conflicts in conceptualizing area, namely: 1) how can non-square units be square(d)?, 2) how can we find the area of a shape when the area unit is neither square nor polygonal?, 3) how can we use square or polygonal area units to measure the area of a shape with curved boundaries? The work of one representative case study is reported here. This work will help educators develop tasks to initiate these cognitive conflicts for improved conceptualizations of area.

Keywords: area, area units, geometry, pre-service teachers

Area is a fundamental construct of geometry and is usually introduced in 2nd or 3rd grade. In the Common Core State Standards (CCSSM, 2010), *area* appears in 3rd grade under the Measurement and Data standards. In this grade, area measurement is discussed as covering a planar figure, or fitting squares (the area unit) into a planar figure, without any gaps or overlaps, and then counting the squares (CCSSM, 2010). In general, a 1-unit by 1-unit square is the standard unit that is used to measure area.
