Prior to the interviews, we identified what we believed to be the primary goals that the professors had for student learning and prepared questions about them. There were two primary types of claims that the professors made; the first, described their intended learning goals for the students. For each of the learning goals that a professor stated and the related descriptions of when and how they attempted to convey that content. We aligned those with our instances of coded content. We indicated what type of content was coded for and the mode of presentation. Because we had correctly identified the professor's learning goals from our attendance of the lecture, we were able to ask what motivated their choice of presentation mode for the content. We used open-coding to develop summary codes for decisions, and then summarized them as to whether the reasoning relied on large-scale beliefs about students, or content or structure of the course, or factors specific to the intended content.

## Results

Table 2 presents the number of instances of each category, the percentage of instances that were written on the blackboard or only printed orally, and the percentage of possible instances that these comments appeared in students' notes (for example, there could have been up to 383 total recorded instances of Oral Heuristics collectively in student notes, only 30 instances were recorded).

*Table 2. Summary of content and recording in notes*

| | | Instances in all lectures | Recorded in students' notes |
|---|---|---|---|
| **Definition** | Total: 2 | | |
| | Oral | 0 (0% of all instances) | 0% (0 out of 0) |
| | Written | 2 (2%) | 82 |
| **Rule** | Total: 18 | | |
| | Oral | 9 (%) | 11% (20 out of 180) |
| | Written | 9 (9%) | 24% (45 out of 185) |
| **Example of process** | Total: 23 | | |
| | Oral | 6 (6%) | 0% (0 out of 69) |

| | | | |
|---|---|---|---|
| | Written | 17 (17%) | 80% (219 out of 276) |
| **Informal Rep.** | Total: 14 | | |
| | Oral | 8 (8%) | 10% (17 out of 168) |
| | Written | 6 (6%) | 14% (13 out of 89) |
| **Proof** | Total: 1 | | |
| | Oral | 0 (5%) | 0% (0 out of 0) |
| | Written | 1 (95%) | 64% (9 out of 14) |
| **Graph** | Total: 2 | | |
| | Oral | 0 (0%) | 0% (0 out of 20) |
| | Written | 2 (2%) | 78% (14 out of 18) |
| **Heuristic** | Total: 33 | | |
| | Oral | 7 (7%) | 8% (30 out of 383) |
| | Written | 26 (26%) | 40% (34 out of 85) |
| **Theorem** | Total: 8 | | |
| | Oral | 0 (0%) | 0% (0 out of 20) |
| | Written | 8 (8%) | 83% (105 out of 126) |

These data largely confirm the first two hypotheses that we test in the paper. First, there were 356 instances of mathematicians presenting mathematical methods, conceptual content, modeling mathematical behaviors, and examples across the 11 lectures, or over 32 instances per lecture. This corroborates the growing body of research that mathematicians do not solely focus on formal mathematics in advanced mathematics. Second, for method, informal representation, and modeled mathematical behaviors, most of these comments were made orally and not written on the blackboard. The presentation of examples was an exception. Examples usually were written on the blackboard; we believe that this is because this allowed the mathematics professors to perform formal calculations and derivations with the examples. Third, when professors presented their comments orally, these comments rarely were recorded in students' notes. However, if they wrote their comments on the blackboard, they usually were recorded in students' notes. When the formal content was not written on the blackboard, the students do not record it. This suggests that what students record in their notes is determined primarily by the mode of presentation, rather than the type of content being presented.

## How the Professor Conveyed Content and Why

We illustrate three aspects of instruction; what the professor hoped to convey to students, how it was conveyed and why the professor conveyed it that way, and whether the students recorded it. The most important idea that the professor wanted to convey was, "that the anti-derivative is the same thing as the definite integral … that these two processes are inverses of each other." We interpreted the second statement, "that these two processes are inverses of each other" as relating differentiation and anti-differentiation. Thus, we took the professor's statement to mean that she wanted students to take away that anti-differentiation and the definite integral are the same thing and that differentiation and anti-differentiation are inverse processes.

To convey that differentiation and anti-differentiation are inverse processes, the professor described them that way orally once, without recording it on the board. She also described anti-differentiation as "going backwards" to the original function four separate times, always orally. The professor also referred to "undoing" a process another 4 times, in describing differentiation. None of the students recorded any of the orally-stated claims. More, she twice drew illustrations of the relationship in general form. One such instance was after presenting the FTC Part 1 (see *Figure 1*). She added a line noting, “that is, integration is identical to anti-differentiation.”

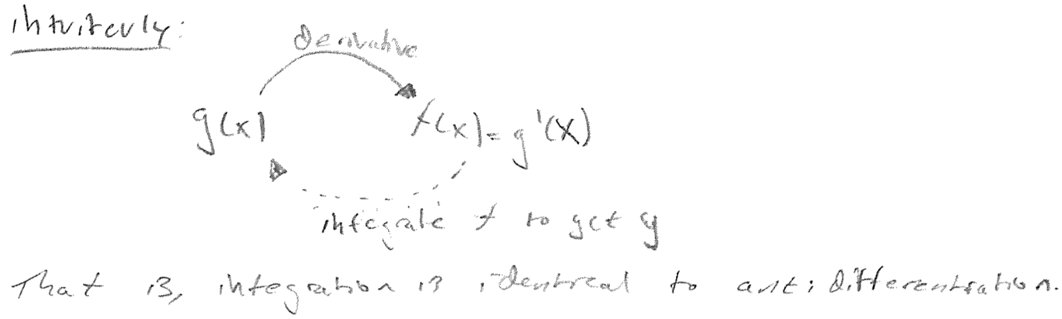

*Figure 1. Diagram after the FTC Part 1*

This diagram carried both of her intended claims and 7 of 9 students recorded the diagram while one student recorded the sentence without the diagram. The professor also drew a third illustration of the relationship for a specific pair of functions within the context of an example of a process. While 6 of the 9 students in the class recorded the example in their notes, none of them drew the diagrammatic representation included in the example. Thus, 7 of 9 students made any recording that captured the second of the two primary ideas that the professor attempted to convey out of 13 possible times that she expressed the idea, and 8 of 9 captured at least one instance of the first primary idea she wanted to convey. This was the only time she stated the first primary idea informally.

The professor gave a general explanation of her thinking related to writing content on the board. She said:

> The students who tend to be at the top of the class, I can take care of their questions by just saying it without writing it down. And then students who tend to get overwhelmed by the details and maybe perform a little bit lesser on different quizzes and things, the more I ... I have to be careful about what I write down because if I write down too much information that tends to overwhelm them and they're not able to separate the forest from the trees. Does that make sense?

We interpreted the professor here as making a collection of claims; first that the best students in her class would acquire the ideas even if they are only ever stated orally. Second, that the weaker students need something different than the strong students as “too much information tends to overwhelm them.” The idea of “separating the forest from the trees” we interpreted as giving priority to certain types of mathematical proficiencies. In particular, because the professor always wrote algebraic examples of procedures on the board as well as formal mathematical statements, she appears to be claiming that these examples and formal statements are the “forest” that the students must apprehend while the informal ideas are the “trees”—which she claims “might overwhelm them.” That is, we interpreted her as claiming that it is not necessary that the weaker students come to understand the more informal ideas.

## Discussion

Our findings offer support for the generality and validity of the following claims:

1. When lecturing about calculus instructors regularly discuss informal aspects of mathematics. Specifically, these lecturers represent mathematical concepts using informal

representations, discuss heuristics that can be useful for completing mathematical tasks, give informal explanations of concepts and processes.

2. When lectures make these comments orally, students usually do not record these comments in their notes.

We did not support the third claim. Instead, instructors recorded 26 out of 33 heuristics on the board. A corrected version of the claim is that:

- Lecturers recorded all definitions, theorems and proofs that were included in the class on the board. They also recorded 74% of examples and 79% of heuristics. Most content recorded on the board (43 of 71 instances, 61%) consisted of examples and heuristics.

Yet even though heuristics were generally recorded on the board, they were not often included in student's notes. We note that examples were recorded in student's notes at an 80% rate. As a result, we suggest two, related, concerns; first, that we have potentially mis-cast examples as informal content. As the calculus class focuses on procedural fluency, examples of processes represent an important category of content that may deserve a different categorization. Another possibility is that the notion of formal and informal is inappropriate for a calculus class; rather, the focus should be on content that describes, illustrates, and justifies procedures. When such content is presented in 'entirely mathematical' text (e.g., text for which a standard mathematics definition/meaning exists) this should be considered the 'formal' corpus of the calculus course. This data suggests that students are differentiating between the types of content that they chose to record in their notes. More investigation is needed to explore their decision to record or not record content in their notes, and, what, if any mathematical or presentation cues they use.

Finally, we have investigated why professors chose to present content in the way that they do. Our investigation reveals that instructors are thoughtful about even this level of detail in their lectures. In particular, we showed an instructor who had considered the range of students in the class and the relative importance, for the students, of the different types of content. The professor we showed here indicated two different main ideas that she wanted the students to take-away from the class, both stated using informal language. She repeatedly stated one them during the class, including drawing three diagrams that illustrated the relationship. She only presented the second 'main' idea one time, but did so in writing. We note that none of her conversation here was specific to the content presented, instead, focusing on the nothing that some students would understand the orally presented content and some needed a written presentation that focused on the "forest," which we understood to be the most important ideas. This appears to be slightly at odds with her claim that these were the most important ideas that she wanted to convey. More investigation is warranted into the decision-making, but, we caution that attempting to force instructors to specify conditions specific to particular pieces of content might lead to post-hoc justifications when the decision was not made consciously, perhaps being habit or culture.

*Several researchers have noted that it is important for students and teachers to be able to differentiate between what is mathematically critical to a concept or representation and what is a convention maintained for the purposes of communication. In this report, we describe two studies examining the extent to which pre-service and in-service teachers (PSTs and ISTs) understand graphing conventions either as conventions or as rules that must be unquestionably maintained. We highlight the extent to which conventions are pervasive in both PSTs' and ISTs' meanings for graphs and related ideas (i.e., function and rate of change) and describe why such meanings are problematic.*

Keywords: Conventions, Graphs, Preservice Teacher Education, In-service Teacher Education

Hewitt (1999, 2001) distinguished between arbitrary and necessary information in mathematics curriculum and learning. He described arbitrary information as that which students need to be informed about by an external source (e.g., the name of an object or representational conventions), whereas necessary information students can deduce for themselves. In addressing graphs and coordinate systems, Hewitt (1999) described aspects of coordinate systems that are necessary (e.g., the need for a starting point or origin and orienting vectors or quantities) and noted:

> These are some aspects of where mathematics lies within the topic of co-ordinates, rather than with the practising of conventions. I am not saying that the acceptance and adoption of conventions is not important within mathematics classrooms, but that it needs to be realised that this is not where mathematics lies. So I am left wondering about the amount of classroom time given over to the arbitrary compared with where the mathematics actually lies. (p. 5)

Whereas mathematicians and mathematics educators are likely to agree with Hewitt's distinction, the extent to which students and teachers maintain understandings consistent with his description is an open question. Hence, in this report, we present the findings from two studies, one with pre-service teachers (PSTs) and one with in-service teachers (ISTs), intended to address the question, "In what ways do pre-service and in-service teachers understand graphing conventions?" In this report, we highlight the extent to which conventions are pervasive in both PSTs' and ISTs' meanings for graphs and related ideas (i.e., function and rate of change).

## Theoretical Perspective

Of relevance to this report, when discussing students' use of notation and representational systems with respect to conventions, Thompson (1992) described two ways in which an individual can use a convention: (a) using a convention unthinkingly and possibly unknowingly and (b) using a convention with an awareness that she is conforming to a convention (i.e., convention *qua* convention). Thompson (1992) elaborated, "To understand a convention *qua* convention, one must understand that approaches other than the one adopted could be taken with equal validity. It is this understanding that separates convention from ritual" (pp. 125). We leverage Thompson's distinction in the context of teachers' graphing activity, arguing a teacher's use of graphs entails a *convention qua convention* if the teacher maintains a convention with the *awareness* of maintaining a convention (i.e., understands the convention as one way to represent some idea among other equally valid choices). We claim a teacher's use of graphs entails the *habitual use of "convention"* if the "convention" is a necessary or inherent aspect of a teacher's meanings for graphs and associated topics. In this case, what we as researchers perceive to be a convention is not a convention qua convention with respect to that teacher's meanings; hence, we intentionally use quotations to indicate this difference in perception. As we illustrate in the results section, what an observer understands to be a convention can instead be habitual to a PST's or IST's use of graphs to the extent that the teacher unknowingly assimilates situations in ways that entail the "convention". Alternatively, the teacher might consider using graphs in some different way, but the teacher does not conceive such a way equally valid due to her or his system of meanings necessitating that the "convention" be maintained.

## Relevant Literature

Understanding a convention *qua* convention involves an individual being aware of a variety of equally viable representational choices while understanding that a particular choice is customary to a group of individuals. Speaking on various conventions practiced in U.S. and international school mathematics, Zazkis and Mamolo (Mamolo & Zazkis, 2012; Zazkis, 2008) hypothesized that students are hindered in making such distinctions when they only have experiences in which educators maintain particular conventions. Mamolo and Zazkis argued that a potential outcome of educators unquestionably maintaining conventions is that students are not afforded opportunities to develop understandings suitable for novel (e.g., alternative coordinate systems) and unconventional situations.

International and U.S. education researchers (Akkoc & Tall, 2005; Breidenbach et al., 1992; Even, 1993; Montiel, Vidakovic, & Kabael, 2008; Oehrtman, Carlson, & Thompson, 2008) have documented that students often associate function in graphical situations with little more than a ritual application of the vertical line test, a common procedure taught in U.S. school mathematics. As an example, Montiel et al. (2008) identified that students were inclined to apply the vertical line test when investigating relationships in the polar coordinate system. Because some students' meanings entailed carrying out an action tied to the Cartesian coordinate system and a particular axes orientation, those students claimed that relationships such as $r = 2$ do not define a function. In this and other examples (e.g., Breidenbach et al., 1992), the researchers posed graphs that they understood to be representative of functions, yet the students' meanings for functions and their graphs did not afford such understandings.

Our purpose is not to rehash the well-documented claim that students often understand function in unsophisticated ways (see Leinhardt, Zaslavsky, and Stein (1990), Oehrtman et al. (2008), and Thompson and Carlson (2017) for extensive reviews). Rather, our purpose is to draw attention to a particular feature of students' meanings that is more deeply-rooted and problematic than researchers have previously reported. Namely, we infer that the students in these studies drew upon meanings in which what we perceive to be conventions of a particular coordinate system had become features inherent or intrinsic to those students' meanings. For instance, what we perceive to be the convention of representing a function's input along the Cartesian horizontal axis was something the students used habitually (i.e., "convention").

## Methods

In order to explore and better understand PSTs' and ISTs' understandings of conventions, we conducted two studies that used similar tasks (see Task Design). In the first study, we designed and conducted 90-120 minute semi-structured clinical interviews (Ginsburg, 1997) with 31 PSTs enrolled at a large state university in the U.S. The PSTs were entering their first semester in a four-semester preparation program for secondary mathematics teachers. Each PST began the program during her or his junior year (in credits), and each PST had completed at least two mathematics courses past Calculus II. We chose participants from the volunteer pool whose schedules aligned with the researchers' schedules.

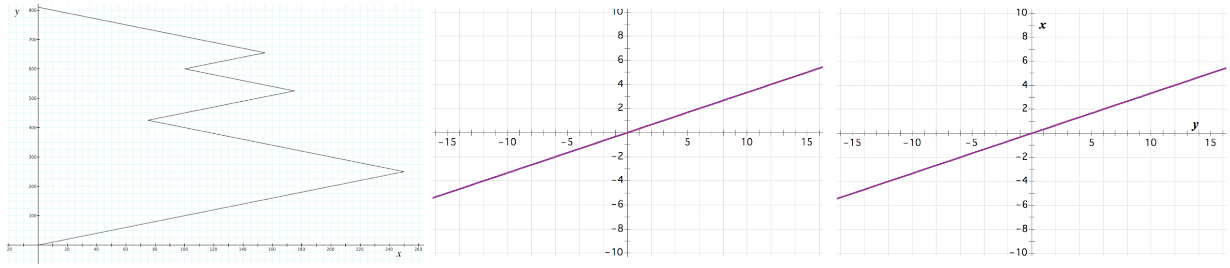
We videotaped the clinical interviews and digitized all written work. We analyzed the data using selective open and axial analysis approaches (Strauss & Corbin, 1998) and conceptual analysis (Thompson, 2008). We identified instances of PST's activity that offered insights into his or her meanings. We used these instances to develop hypothesized models of the student's meanings and we compared a PST's activity across instances and tasks in order to test and improve our interpretations of her or his activity, including identifying themes across instances and tasks. Lastly, we compared across students in order to identify compatible and contrasting meanings. The research team met throughout the data analysis phase in order to refine models of students' meanings and clarify themes in the students' meanings and uses of graphs.

In the follow-up study, we adapted our original tasks for an on-line survey completed by 45 ISTs. The ISTs were geographically distributed across the U.S. and were enrolled in a fully online graduate mathematics course designed specifically for ISTs. We coded the ISTs' responses using open and axial approaches (Strauss & Corbin, 1998) and thematic analysis (Braun & Clarke, 2006). Members of the research team analyzed a subset of the ISTs' responses and we met to discuss our observations, identify commonalities across responses, and adapt or create new codes to capture more ISTs' responses. We iterated this process four times as we refined our codes to capture all ISTs' responses; after obtaining final codes, a second researcher recoded approximately 65% of the data to check for inter-rater reliability. We obtained Cohen Kappa values of 0.78 and 0.85 for the two tasks described, indicating a high level of agreement.

## Task design

We designed each task to include what we perceive to be an unconventional feature with respect to the use of graphs in U.S. school mathematics. Because we did not expect the PSTs or ISTs to spontaneously interpret the displayed graphs as entailing unconventional aspects, we designed tasks to include specific claims with respect to features that we intended to be unconventional, often through hypothetical student responses. By including hypothetical responses focused on aspects we considered unconventional, we were able to infer the extent that something was an inherent or habitual aspect of the PSTs' and ISTs' uses of graphs.

To illustrate, we provided the graph in Figure 1a and posed a variant of, "What about a student who claims that this graph represents $x$ is a function of $y$?" With respect to ***Figure 1***b, we presented the graph as the work of a hypothetical student who graphed the relationship $y = 3x$. We asked the participants to describe how the hypothetical student might have been thinking when creating the graph. The follow-up prompt included a graph with the axes labeled (***Figure 1***c), and we explained that a hypothetical student clarified his graph of $y = 3x$ by labeling the axes as given in the second graph (i.e. $x$ on the vertical axis and $y$ on the horizontal axis). Both tasks illustrate our intent on designing graphs that can be conceived as mathematically viable (albeit unconventional) as presented with respect to the given prompts and claims.



(a) (b) (c)

*Figure 1.* (a) Is $x$ a function of $y$? (b) and (c) A hypothetical student's work to graphing $y = 3x$.

## Results

We structure the results section by first presenting the PSTs' responses to each task. We then synthesize the ISTs' responses to both tasks. We conclude by comparing the PSTs' and ISTs' responses.

### PSTs Responses

Table 1 summarizes the PSTs' responses to the claim, "$x$ is a function of $y$." Ten of the 25 ('Not true' and 'Unsure') PSTs maintained that the graph does not represent a function due to the graph not passing the vertical line test, because there exist $x$-values for which there is not a unique associated $y$-value, or a combination of both. For these 10 PSTs, "function" immediately drew to mind an action that entailed treating (implicitly or explicitly) $x$ or the quantity represented along the horizontal axis as the input quantity (i.e., "convention" as habit). For the seven PSTs who maintained that the statement is true on the condition that the graph is rotated 90-degrees counterclockwise, they understood the phrase "$x$ is a function of $y$" to necessitate a particular axes orientation—an orientation in which the defined input values are represented horizontally—they required (i.e., habitual use of "convention") that the graph be rotated before considering the validity of the claim with respect to properties of the $x$-$y$ pairing.

Finally, we interpreted seven of the 25 PSTs' actions to suggest they did not require $x$ or the horizontal axis to represent input values. Yet, five of the seven students hesitated with the claim "$x$ is a function of $y$" and described that they had a tendency to imagine the graph oriented so that the values defined as the function's input were represented along the horizontal axis. Some students first rotated the graph to determine that the statement is true and then paused when we asked if the statement was also true when considering the graph as given. Ultimately, each of the seven students understood the graph *as given* to be representative of $x$ as a function of $y$.

*Table 1. Codes, counts, and sample PSTs' responses to the statement, "x is a function of y."*

| Code (value) | # | Sample Responses |
|---|---|---|
| True (1) | 7 | Yeah I guess if you do it this way [*writes* '$x(y)$' *on paper*]…for every $y$ there is exactly one $x$. And for every $y$ [*puts marker on vertical axis on graph and moves it horizontally to a point where it hits the curve*] yeah, there's exactly one $x$…I've never thought about it that way but yeah, he's right…awesome way of thinking about that. |
| True, if graph is rotated counter-clockwise 90-degrees (2) | 8 | So she said $x$ is a function of $y$. That'd be, that'd be looking at it this way [*turning the paper 90-degrees counterclockwise*] and saying look there's no [*motioning hand over the graph as if doing the vertical line test*], there's no crossing…So, I mean that's true, but you'd have to flip the whole graph…[*redraws graph in rotated orientation, labeling the horizontal axis as y and the vertical axis as x*] That'd be $y$ and that'd be $x$. So $x$ is a function of $y$. And that's a function…[*Interviewer returns PST's attention to the graph as given*] No, because $x$ isn't a |

| | | |
|---|---|---|
| | | function of $y$. This [*motioning to her sketch*] is the graph of $y$ as a function of $x$. |
| Not true or unsure (3) | 10 | Okay. Um [*pause*] $x$ is a function of $y$. [*long pause*]…Well you know something's not a function if [*placing her marker in a vertical line over the graph*]… if two different inputs can give you the same output… Which you have here obviously that, you know, these one two three four five six $x$-values give you different $y$-values [*using her marker to mark points on the graph in a vertical line*]. I mean these, the same $x$-value can give you six different $y$-values. |

Table 2 presents a summary of the PSTs' responses to the hypothetical student who graphed $y = 3x$ as shown in Figure 1c. We interpreted each of the 20 PSTs (Table 2, the last two categories) who deemed Figure 1c as incorrect or who expressed uncertainty about the hypothetical solution to hold meanings which entailed the habitual use of "convention." These "conventions" included assigning $x$-values to the horizontal axis, maintaining particular axes directions for positive and negative values (which arose after rotating the graph), using the horizontal axis as an input quantity (and inferring from the given equation that $x$ represents input values), or a combination of these. Only 11 PSTs maintained that the graph as given in Figure 1c unquestionably represents $y = 3x$. These PSTs identified the graph's departure from convention, and specifically its departure from a customary axes orientation. They also claimed that the departure does not influence the correctness of the represented relationship between $x$ and $y$.

*Table 2. Codes, counts, and sample PSTs' responses to the prompt and graph associated with Figure 1c.*

| Code (value) | # | Sample Responses |
|---|---|---|
| Hypothetical student unquestionably constructed a correct graph (1) | 11 | He graphed it completely right. That's $y$ equals three $x$…he's not wrong. He just has a different perspective than the traditional $x$-$y$…that's just counter to tradition and normal classroom settings. But I think it's smart of him to understand that it's [the convention] not glued. |
| Hypothetical student constructed a graph that is both correct and incorrect (2) | 11 | It's wrong with like how we normally write graphs…So he should lose points because he wrote the graph in like really incorrectly to what, how the graph should be written. Like the horizontal axis should always be $x$ and the vertical axis should always be $y$. But if you're looking at it based on did he understand that, when $y$ equals three, $x$ equals one, like he understood that, um, relationship between $x$ and $y$. |
| Hypothetical student did not construct a correct graph or uncertain if the hypothetical student constructed a correct graph (3) | 9 | They messed up the placement of $x$ and $y$…They are looking at it like this right now [*rotating graph 90-degress counterclockwise*]…If you are looking at it this way, it's a negative slope [*tracing graph downward left-to-right*] and it should be a positive slope [*tracing imagined graph upward left-to-right*]…slope is wrong. |

## ISTs' Responses

For brevity's sake, we do not present the ISTs' responses to each task, as they are compatible with the PSTs' responses. Instead, Table 3 provides the codes we created to capture the ISTs' responses to the hypothetical student work for both tasks, sample responses to the task associated with the graph in Figure 1a, and counts of the number of IST responses coded within each category for each task. We note that only 12 and 25 IST responses for the tasks associated with Figure 1a and Figure 1c respectively indicate they understood conventions qua conventions for these particular tasks. The remaining 33 and 20 ISTs respectively maintained understandings that entailed a habitual use of "convention".

*Table 3. Codes description, counts, and sample responses of ISTs pre survey.*

| Code (value) | Sample Responses to the task in Figure 1a | Fig 1a | Fig 1c |
|---|---|---|---|
| The student's mathematical statement is correct despite breaking from conventions. (1) | That's great! I am so glad you were able to apply the "vertical line test" in a horizontal orientation and realize that you would have a function. You are correct in saying that $x$ is a function of $y$. | 12 | 25 |
| The student's mathematical statement is true but the student is incorrect because he/she broke from conventions. (2) | I think the student is understanding that $x$ can be a function of $y$ but they are not displaying it correctly through the graph. | 9 | 7 |
| The student's mathematical statement is incorrect or the IST did not address the student's mathematical statement. (3) | It was not a good explanation and $x$ is not a function of $y$, $y$ is a function of $x$. The value of $y$ depends on $x$. They also did not describe what would make it a function. | 24 | 13 |

## Comparing PSTs' and ISTs' Responses

In order to compare the PSTs' and ISTs' responses, we assigned numerical values to each of the three categories within each coding scheme (shown in parentheses in each table). Table 4 provides the average scores for PSTs and ISTs across both tasks. Although these values appear similar, we used a two-tailed Mann-Whitney U-test to examine if there was evidence that the PSTs' and ISTs' responses indicated that they were from different populations. There was not a statistically significant difference between the populations for either task.

*Table 4. Average scores of PSTs and ISTs and p-values obtained from a Mann-Whitney U-test.*

| | Figure 1a | Figure 1c |
|---|---|---|
| PSTs | 2.12 | 1.94 |
| ISTs | 2.27 | 1.73 |
| *p*-value | 0.4777 | 0.2937 |

## Discussion and Concluding Remarks

At the most fundamental level, our findings are significant in that PSTs and ISTs who have completed advanced mathematics courses have developed mathematical understandings that, at best, limit their ability to engage effectively with these topics in situations that we designed to be unconventional. The fact that the ISTs' and PSTs' responses were similar indicates that teaching experience may not have an influence on creating shifts in teachers' meanings with regards to graphing conventions. This finding underscores the importance of giving both populations opportunities to develop more sophisticated meanings for various ideas that are not constrained by, what to us as researchers, are conventional choices. Even more significant is that so many of these teachers (or soon-to-be teachers) held meanings that led to claims and actions that, although often internally viable to them, were contradictory from our perspective and suggested their habitual use of "convention." We do not have the data to comment on the effects of an interaction in which a teacher makes these comments to an actual student who claimed $x$ to be a function of $y$ or who produced an unconventional graph of $y = 3x$, but it is not hard to imagine that the student would be left wondering what he or she did wrong and possibly conclude that axes-variable label pairs and orientations are critical features of a mathematical idea or established rules that must be followed rather than arbitrary conventions (i.e. Hewitt 1999, 2001).

We hypothesize that the PSTs' and ISTs' meanings 'worked' for them throughout their schooling. Due to the pervasive role of conventions in school curricula and instruction, they were likely able to repeatedly assimilate their experiences to these meanings with little or no perturbation. Slope or rate of change associations based on a direction of a line are likely to 'work' in situations that maintain the "conventions" upon which those associations were constructed; function meanings that inherently or tacitly entail the vertical and horizontal axes as representing a function's output and input, respectively, 'work' in situations that maintain those "conventions." Second, due to the PSTs and ISTs repeatedly having the opportunity to construct and re-construct meanings that 'work' without perturbation, they developed a system of meanings that are internally rational and consistent. Such meanings are compatible with what Thompson and Harel (Thompson, Carlson, Byerley, & Hatfield, 2014) called *ways of thinking* – meanings that become so routine or habitual that a person (consciously or subconsciously) anticipates situations involving the associated concept to entail that meaning.

Our intention is not to discredit conventions, nor to convey that conventions are unimportant. Nor do we intend to imply that curricula and educators can realistically be expected to address every convention in mathematics. Instead, we agree with researchers (i.e., Hewitt, 1999, 2001; Thompson, 1992; Zazkis, 2008), who have argued for ensuring that students and teachers become aware of conventions as choices that do not impact the underlying mathematics. One reason for educators to support individuals in becoming explicitly aware of conventions specific to a particular group or field is that conventions vary within and among fields (i.e., it is standard in economics to represent the independent variable on the vertical axis and the dependent variable on the horizontal axis). Hence, collaborating successfully across discipline boundaries requires that an individual become operative with the conventions and practices common to each field, or at least that an individual hold meanings that enable her or him to accommodate conventions of other fields. Another important and more fundamental reason that educators should support individuals in becoming aware of conventions is the restrictions in individuals' ways of thinking that result from constructing a system of mathematical meanings dependent on "conventions". If the goal of mathematics education is to prepare students to provide correct answers in canonical settings, then such restrictions are not an issue. However, if our goal as educators is to support students in constructing a generative mathematics that helps them organize their experiences among and within fields, as well as take on advanced and abstract mathematical ideas that require students to differentiate between what is essential to an idea and what is not, then it is important that they construct mathematical knowledge that has assimilatory capacity in canonical and unconventional settings.

In closing, we argue that our results call into question the entrenched place of conventions in school curricula and instruction. Addressing this issue requires that those designing curricula and instruction take more seriously the negotiation of conventions among students and their teachers. In short, if students and teachers are to understand a convention *qua* convention, then they need opportunities to come to understand mathematical ideas in ways that enable a subsequent negotiation of conventions within the context of those ideas. That is, a productive negotiation of conventions should occur in conversations where a mathematical idea—which is understood as remaining invariant in canonical and unconventional contexts—remains the focus, as opposed to conversations that obscure conventions.

Borough of Manhattan Community College at the City University of New York

*This study describes the creation and validation of the first concept inventory for elementary algebra at the tertiary level. A 22-item multiple choice/multiple answer instrument was created through a combination of literature review, syllabus review, and collaboration with instructors. The instrument was then revised and tested for content, construct and concurrent validity as well as composite reliability, using a circular process that combined feedback from experts (mathematicians, instructors, and mathematics education researchers), cognitive interviews with students, and field tests using both classical test theory and item response theory. Results suggest that the inventory is a valid and reliable instrument for assessing student conceptual understanding in elementary algebra, as conceptualized in this study.*

*Keywords:* elementary algebra, conceptual understanding, concept inventory

Elementary algebra and other developmental courses have consistently been identified as barriers to student degree progress and completion. Only as few as one fifth of students who are placed into developmental mathematics ever successfully complete a credit-bearing math course in college (see e.g. Bailey, Jeong, & Cho, 2010). At the same time, elementary algebra has higher enrollments than any other mathematics course at US community colleges (Blair, Kirkman, & Maxwell, 2010). Moreover, groups traditionally underrepresented in higher education and in STEM fields are significantly more likely to be placed into elementary algebra. For example, the National Center for Education Statistics reported that from 2003 to 2009, 51.6% of African Americans and 49.5% of Hispanics were enrolled in developmental mathematics courses in college, compared to only 39.4% of whites (2012).

There is evidence that students struggle in these courses because they do not understand fundamental algebraic concepts (see e.g. Givvin, Stigler, & Thompson, 2011; Stigler, Givvin, & Thompson, 2010). Conceptual understanding has been identified as one of the critical components of mathematical proficiency (see e.g. (National Council of Teachers of Mathematics (NCTM), 2000; National Research Council, 2001), and many research studies have documented the negative consequences of learning algebraic procedures without any connection to the underlying concepts (see e.g. J. C. Hiebert & Grouws, 2007). However, developmental mathematics classes at community colleges currently focus heavily on recall and procedural skills without integrating reasoning and sense-making (Goldrick-Rab, 2007; Hammerman & Goldberg, 2003), often because there is pressure for students to pass standardized exit exams that can be exclusively procedural in nature. This focus on procedural skills, divorced from conceptual reasoning, can create a vicious cycle in which the developmental students most in need of explicit instruction in conceptual understanding do not receive it.

At the same time, no validated assessments currently exist to assess conceptual understanding for elementary algebra in the postsecondary context. As a result, instructors cannot systematically detect which incorrect or underdeveloped algebraic conceptions are impeding student progress, and thus they cannot target instruction to address these conceptions explicitly. For these reasons, our team developed an elementary algebra concept inventory (EACI), which we tested for validity and reliability. Research questions included:

1. To what extent does the concept inventory have content, construct, and face validity?
2. How strong is the composite reliability of the instrument?
3. Does the instrument show concurrent validity in being able to distinguish between students with low versus high levels of conceptual understanding in elementary algebra?

## Conceptual understanding

The definition of conceptual understanding (and its relationship with other dimensions of mathematical knowledge, particularly procedural fluency) has been much debated and discussed (e.g. Baroody, Feil, & Johnson, 2007; Star, 2005), with as yet no clear consensus. Conceptual understanding and procedural fluency (as well as other mathematical skills) are strongly interrelated (e.g. J. Hiebert & Lefevre, 1986; National Research Council, 2001). However, it can be important to focus on conceptual understanding explicitly, since without explicit instruction in concepts, students may interpret mathematics as a sequence of algorithms, arbitrarily applied, without understanding (e.g. J. C. Hiebert & Grouws, 2007) and may be unable to correctly apply procedures (e.g. Givvin et al., 2011; Stigler et al., 2010).

This study recognizes the interrelatedness of conceptual understanding with other mathematical skills, and defines it this way: An item tests ***conceptual understanding*** if *logical reasoning* grounded in mathematical definitions is necessary to answer correctly, and it is *not* possible to arrive at a correct response *solely* by carrying out a procedure or restating memorized facts. We define a ***procedure*** as a sequence of algebraic actions and/or criteria for implementing those actions that could be memorized and correctly applied with or without deeper understanding of the mathematical justification. For example, consider the following questions:

***Sample procedural question***

If $a < b$, which of the following expressions must ***also*** be true? There may be **more than one** correct answer—select **ALL** that are true.

a. $-a < -b$
b. $2a < 2b$
c. $\frac{a}{2} < \frac{b}{2}$
d. $a - 1 < b - 1$
e. $a + 1 < b + 1$

***Sample conceptual question (similar to one from the inventory)***

Consider the numbers $a$ and $b$ on the number line below. Which of the following must be true? There may be **more than one** correct answer—select **ALL** that are true.

a. $-a$ is to the left of $-b$ on the number line
b. $2a$ is to the left of $2b$ on the number line
c. $\frac{a}{2}$ is to the left of $\frac{b}{2}$ on the number line
d. $a - 1$ is to the left of $b - 1$ on the number line
e. $a + 2$ is to the left of $b + 2$ on the number line

In the procedural question, it is possible to answer correctly with no understanding of the mathematical reasoning behind the properties of inequality; technically a student could correctly answer this question by using a standard memorized algorithm for manipulating inequalities, even if they do not understand the concepts behind it. For the conceptual question, it is not possible to answer it completely correctly using only memorized procedures without understanding. For example, there is no obvious expression or equation on which to apply procedures. Students could translate the information given by the number line into the inequality $a < b$ and then apply procedures, but this would require conceptual understanding of how to translate between graphical representations of the number line and inequalities.

**Conceptualizations of algebra domains in the research literature**

There is no one clear consensus about what the core concepts of algebra are. Attempts have been made to categorize algebra by the types of structures or types of actions that are involved (see e.g. Aké, Godino, Gonzalo, & Wilhelmi, 2013; Bell, 1996; Gascón, 1994-1995; Godino et al., 2015; Kaput, 1995; Kieran, 1996; Lee, 1997; Lins, 2001; Mason, Graham, & Johnston-Wilder, 2005; Pinkernell, Düsi, & Vogel, 2017; Rojano, 2004; Smith, 2003; Star, 2005; Sutherland, 2004; Usiskin, 1988), and national standards for algebra have been developed (Common Core State Standards Initiative, 2017; Mathematical Association of America, 2011; National Council of Teachers of Mathematics (NCTM), 2000), although those elementary algebra standards are aimed at K-12 rather than adult learners, which may be problematic since adult learners have been shown in some cases to use different mathematical reasoning from K-12 students (Masingila, Davidenko, & Prus-Wisniowska, 1996; Scribner, 1984).

In order to develop a list of concepts fundamental to elementary algebra at the tertiary level, we conducted a literature review to compile a list concept domains that are both common in research in algebraic thinking and relevant to elementary algebra curricula in the college context (Wladis, Offenholley, Licwino, Dawes, & Lee, n.d.). We began by consulting reviews on the topic (e.g. (Kieran, 2006; Kieran, 2007; Wagner & Kieran, 1989) as well as papers that were cited by, or that cited these reviews. Then, since the last of these larger systematic reviews was published in 2007 (Kieran, 2007), we searched nine mathematics education research journals, nine general education research journals, and five sets of mathematics education conference proceedings, to find any research focused on algebraic thinking; references listed in these papers were also explored. This systematic review (limiting to topics relevant to elementary algebra in the college context) led to a classification of the existing research into four common domains:

- (C1) **Variables and symbolic representation** (see e.g. Bardini, Radford, & Sabena, 2005; Bloedy-Vinner, 2001; Dubinsky, 1991; Furinghetti & Paola, 1994; Knuth, Alibali, McNeil, Weinberg, & Stephens, 2005; Kuchemann, 1978; Malisani & Spagnolo, 2009; Philipp, 1992; Sfard, 1991; Stacey & MacGregor, 1999; Ursini & Trigueros, 2004; Usiskin, 1988)
- (C2) **Equality/Equivalence** (see e.g. Alibali, Knuth, Hattikudur, McNeil, & Stephens, 2007; Falkner, Levi, & Carpenter, 1999; Kieran, 1981; Kieran, Boileau, Tanguay, & Drijvers, 2013; Knuth et al., 2005; Knuth, Stephens, McNeil, & Alibali, 2006; Mevarech & Yitschak, 1983; Rittle-Johnson & Alibali, 1999; Steinberg, Sleeman, & Ktorza, 1990; Zwetzschler & Prediger, 2013)
- (C3) **Algebraic structure sense** (see e.g. Christou & Vosniadou, 2008; Christou & Vosniadou, 2012; Hoch & Dreyfus, 2004; Hoch & Dreyfus, 2005; Hoch & Dreyfus, 2010; Hoch, 2003; Hoch & Dreyfus, 2006; Hoch, 2007; Linchevski & Livneh, 1999; Menghini, 1994; Musgrave, Hatfield, & Thompson, 2015; Novotná & Hoch, 2008; Tall & Thomas, 1991; Thompson & Thompson, 1987)
- (C4) **Functions, proportional reasoning, and covariation** (see e.g. Blanton & Kaput,

2005; Breit-Goodwin, 2015; Carlson, Oehrtman, & Thompson, 2005; Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Carlson, Oehrtman, & Engelke, 2010; Goldenberg, Lewis, & O'Keefe, 1992; Heid, 1996; Heid & Blume, 2008; Oehrtman, Carlson, & Thompson, 2008; Sitomer, 2014; Thompson, 1994)

In addition, elementary algebra syllabi were also consulted (30 community colleges randomly selected from IPEDS) and participatory action research was conducted with five experienced elementary algebra instructors to outline domains of elementary algebra in the college context and to generate appropriate questions for the inventory (Wladis, Offenholley, Lee, Dawes, & Licwinko, 2017; Wladis, Offenholley, Licwinko, Dawes, & Lee, 2017).

## Results and Discussion

### Initial Pilot Testing

For an initial pilot test of the instrument, the inventory (V1) was given to a sample of 23 college algebra students at the Borough of Manhattan Community College, City University of New York (BMCC/CUNY) in order to identify problematic questions, issues with wording, and to assess how long it would take students to complete particular problems. Based on these results, the wording of questions was simplified, and some questions were broken into simpler parts. The revised inventory (V2) was given to a group of 160 students who had recently taken elementary algebra; they were asked not only to complete the inventory, but to give feedback on the difficulty and clarity with which problems were posed, as well as to give written explanations of their experiences with the individual questions, and any other feedback that they wanted to share. The time that students spent on each problem was also tracked. Problems that were identified as particularly difficult or unclear or were were missed by a significant number of students, or on which students spent a particularly long time were revisited and revised jointly by the whole group of instructors. Roughly half of the inventory questions was revised at this stage.

### Content and Face Validity

In order to assess content and face validity, the revised inventory (V3) was given to 52 instructors who had recently taught elementary algebra at the community college or university level. Instructors came from four different states, many different ethnic/racial and immigrant backgrounds, included faculty who taught at both two- and four-year colleges, and included faculty with a variety of different degree backgrounds. In addition to taking the test, instructors were also asked to give feedback on each question, assessing the clarity and difficulty and giving suggestions for corrections or improvements. They were also asked to assess the topics and concepts covered by the questions and were asked to suggest concepts that were overrepresented, underrepresented, or missing from the current version of the concept inventory. Based on the feedback of faculty, the instrument was revised further.

For example, the following question was included on V3, but was then replaced with other questions in V4 because it was pointed out that it could be answered correctly by applying procedures without understanding:

Which of the following equations are true? There may be **more than one** correct answer—select **ALL** that apply.

a. $2x + 3x = 5x$
b. $2x + 3x = 5x^2$
c. $x^2 + x^3 = x^5$

d. $x^2 \cdot x^3 = x^5$
e. $x^2 \cdot x^3 = x^6$

This question was subsequently replaced with two different questions aimed at testing the conceptual understanding of the algebraic reasoning behind combining like terms and properties of exponents, one of which is similar to the question below:

A student has written: $2x^2(3y-4) + 5x^2(3y-4) = 6x^2(3y-4)$

Which of the following statements is true?

a. The students' work is incorrect because the correct answer is $6x^4(3y-4)$.
b. The student's work is incorrect because the two terms cannot be combined.
c. The student's work is correct because 2 and 5 can be seen as coefficients for the common expression $x^2(3y-4)$.
d. The student can only simplify this expression if they distribute the $2x^2$ and the $5x^2$ first, and then combine like terms.

**Reliability, Structure, and Convergent Validity**

The resulting instrument was administered to elementary algebra students across four semesters; we report results from the first two semesters (V4 and V5) here. V4 was administered to 28 sections of elementary algebra taught by 23 different instructors, once during the first week of classes (pretest) and once during the last week of classes (posttest). This resulted in 484 completed pretests and 315 completed posttests. Item response theory was used on V4 to assess the extent to which individual items provided good discrimination and were at an appropriate level of difficulty. Items that seemed to be very difficult or very easy, as well as those with negative or low discrimination were revised (V5). V5 was administered to 33 sections taught by 21 instructors, resulting in 431 completed pretests and 192 completed posttests.

**Construct Validity**

Twenty students who were currently enrolled in elementary algebra were invited to participate in cognitive interviews. Each student was asked to complete the items on their own, and then were asked to participate in a "retrospective think-aloud" interview (Sudman, Bradburn, & Schwarz, 1996), in which they explained what possible approaches to answer the question they considered while completing the questions. Research suggests that concurrent and retrospective think-aloud protocols reveal comparable information, and that retrospective think-alouds may be preferable to concurrent think-aloud protocols because they are less likely to have a negative effect on task performance, especially for complex or challenging tasks with a high cognitive load (see e.g. (Van Den Haak, De Jong, & Jan Schellens, 2003).

Students were then asked to explain what they were thinking about as they considered each question, and then to explain for each answer choice why they did or did not select it. The cognitive interviews focused in particular on several main aims: whether student answers were consistent (i.e. (in)correct thinking yielded (in)correct answers; whether the activities and thinking elicited by the questions was conceptual and in the algebra domain intended by the question; and whether students used test-taking strategies. Cognitive interviews revealed strong consistency of student responses, with almost all students choosing (in)correct answers only when they exhibited evidence of (in)correct reasoning. The vast majority of student responses (including incorrect responses) exhibited some degree of conceptual thinking—for example, even when students were using incorrect reasoning, they were often attending to structural aspects of the expressions or equations on the exam, rather than attempting to apply procedural algorithms to them. There was a low-incidence of use of test-taking strategies.

## Reliability and Internal Consistency

Both structural equation modeling (SEM) and item response theory (IRT) were used to assess the reliability of the instrument.

**Classical test theory: Using structural equation models for confirmatory factor analysis.** Confirmatory factor analysis using structural equation modeling (SEM) was used to model items as predictors of a single latent construct. Average variance extracted (AVE) ranged from 0.76-0.99, indicating very good convergent validity; composite reliability (CR) ranged from 0.99 to 0.9998, indicating excellent reliability (Hair, Anderson, Tatham, & Black, 1998), consistent with requirements for high-stakes testing (Nunnaly, 1978); the standardized root mean square residual (SRMR) ranged from 0.06 to 0.08, suggesting that the model fit was good and supporting the operationalization of the inventory as having a single latent construct (Hu & Bentler, 1999). RMSEA was acceptable, ranging from 0.061-0.064, further supporting the goodness of model fit (MacCallum, Browne, & Sugawara, 1996).

**Item response theory.** First hybrid three-parameter logit models were explored, with items grouped into three separate groups (based on the underlying probability of randomly guessing that item correctly), each with its own pseudoguessing parameter (Birnbaum, 1968). However, since pseudoguessing parameters were not significantly different from zero, a two-parameter logic model was used. Reliability was assessed using the test information function (tif), where $reliability\ = 1 - \frac{1}{tif(\theta)}$. In IRT, reliability is dependent upon the value of theta, with $\theta = 0$ representing a mean score on the instrument, and other values ta representing the number of standard deviations (SDs) that a score is above or below the mean (e.g. $\theta = -1$ is one SD below the mean). Peak reliability of the test ranged from $\theta = -1.11$ to $0.56$, suggesting that the instrument is most reliable for students who are around the mean in algebraic conceptual understanding as measured by this instrument. Both post-tests obtained excellent reliability ($\geq 0.9$) (Nunnaly, 1978) around the peak, from about 1.5 SDs below the mean to about 0.5 above the mean (see Table 1). Farther away from the peak the reliability remained strong, with acceptable reliability within a minimum of two SDs of the mean on either side on all test administrations (see Table 1). This suggests that the reliability of the test is quite strong for a broader range of students across the ability spectrum. We note that the peak reliability is higher, and overall reliability somewhat stronger, for the posttests than the pretests; this is not surprising, since students have been exposed to algebraic instruction prior to the posttest, but not necessarily prior to the pretest. For example, this may help students to be more familiar with terminology or symbolic representation used on the exam, and that may lead to more reliable results.

*Table 1. Reliability values for various values of $\theta$*

| **$\theta$ values** | **V4 pretest** | **V4 posttest** | **V5 pretest** | **V5 posttest** |
|---|---|---|---|---|
| Peak reliability | $-1.11$ | $-0.52$ | $0.56$ | $-0.44$ |
| Acceptable[a] reliability ($\geq 0.7$) | $[-3.4, 2.1]$ | $[-3.7, 2.4]$ | $[-2.9, 3.6]$ | $[-3.7, 2.5]$ |
| Good[a] reliability ($\geq 0.8$) | $[-2.4, 0.6]$ | $[-2.7, 1.6]$ | $[-1.7, 2.6]$ | $[-2.9, 1.7]$ |
| Excellent[a] reliability ($\geq 0.9$) | *NA* | $[-1.5, 0.5]$ | *NA* | $[-1.4, 0.5]$ |

[a]Based on the criteria set forth by Nunnaly (1978)

## Pre-Test Versus Post-Test Scores

Mean and median scores on the post-tests each semester were not significantly different from the pre-test scores, suggesting that on average, students are likely not gaining any conceptual understanding after one semester of instruction in a traditional algebra class. This is in line with the findings of concept inventories in other subjects, where it was found that some types of instruction could improve aggregate student gain stores, but that on average traditional instruction did not improve outcomes (see e.g. Epstein, 2013; Hake, 1998).

*Table 2. Test scores, calculated by percentage of questions answered correctly, for each test administration*

| | **pretest** | **95% CI** | **posttest** | **95% CI** |
|---|---|---|---|---|
| V4 | 54.2% | [53.3%, 55.1%] | 52.9% | [51.6%, 54.2%] |
| V5 | 56.4% | [55.5%, 57.3%] | 54.2% | [52.3%, 56.1%] |

**Limitations**

We note that this concept inventory is based on a very specific conceptualization of elementary algebra and of conceptual understanding for this subject as well. Because of this, student scores on this inventory reflect only these constructs, and do not necessarily reflect other ways in which conceptual understanding in elementary algebra may be conceptualized.

One major limitation with many previously-developed tests and instruments historically has been that they were developed among a predominately white, middle class population and then were applied to wider populations, including many ethnic minorities and lower-SES students for whom they were not necessarily valid. The City University of New York, which will be used for this research, is highly diverse with an undergraduate population that is roughly 40% first-generation American, more than 75% students of color, roughly 20% first-generation college students, and more than 50% eligible for Pell grants. This diversity makes CUNY an excellent source of information about the validity of the instrument among this population; however, more work with various populations, including rural and suburban populations, is necessary.

**Implications**

This research demonstrates that it is possible to create valid instruments that can reliably measure some aspects of conceptual understanding in algebra. Some future avenues of research would be to explore further validation of this inventory, e.g., to determine to what extent scores on the EACI differ from scores on validated exams that test procedural fluency in algebra. In addition, future studies that consider which factors correspond to higher versus lower gain scores for whole classes in elementary algebra could help to shed light on which teaching approaches and curricula, etc. can increase student conceptual understanding in elementary algebra.

For practitioners, this study illustrates that it is possible to create questions that target conceptual understanding in elementary algebra specifically. Instructors wishing to create their own questions that would assess this skill could follow some of the process described here and in (Wladis et al., 2017; Wladis et al., 2017). In addition, this study raises important questions about curricula and assessment. Students in this study showed no gains on average in conceptual understanding over the course of one semester of algebra instruction. At the college in which this instrument was tested, all of the learning outcomes on the syllabi are entirely procedural, and as a result, it is likely that most instructors (even those who employ more active learning techniques, of which there were many in this study) do not directly address concepts in their teaching. While this study presents no conclusive evidence of the relationship between these two things, the patterns observed by looking at the pre- and post-test results of the EACI for students in elementary algebra in this study suggest that teaching algebra procedures alone likely does not in and of itself lead on average to gains in conceptual understanding.

## An Undergraduate Mathematics Student's Counterexample Generation Process

Kristen Lew
Texas State University

Dov Zazkis
Arizona State University

*This paper illustrates the processes and struggles involved in a student's generation of a counterexample. The data involves one student's at-home proving while working on homework for his introduction-to-proof course. In this paper, we present an episode where a student engaged in substantive efforts in order to generate a proof by counterexample. We compare and contrast this episode against results from the literature on example generation to provide insights regarding the similarities and differences between example and counterexample generation as they relate to proof.*

*Key words:* counterexample, example space, disproof, undergraduate, at-home proving.

### Introduction

Examples and counterexamples are in many ways inextricably linked. Goldenberg and Mason (2008) emphasized this association when they wrote, "In a mathematical context there is little difference between an example and a counterexample: it all depends where your attention is anchored, and what you are attending to" (p. 184). To illustrate this idea, consider $1/\pi$. It is simultaneously an example of an irrational number and a counterexample to the claim that for all real numbers $x$, $x^2>x$. Given this link between examples and counterexamples, it might be reasonable to extrapolate that the process of generating examples and the process of generating counterexamples are similar. However, since one counterexample can disprove a statement and an infinite collection of examples are insufficient to prove a statement, the underlying reasons for counterexample and example generation in a proof context are fundamentally different. This disparity in purpose may affect the process meaning that in the context of proving, example and counterexample generation processes maybe very different. These two conflicting arguments for why counter-example generation and example generation might be different or similar to each other provide the impetus for the propose study.

### Related Literature and Theoretical Perspective

The mathematics education literature has explored the role example generation plays in proving but currently has less to say about the process of counterexample generation and how it relates to proving and example generation. Moreover, the literature provides no definitive answer to how the processes of example generation and counterexample generation relate to each other.

Research on learners' example generation can be broadly partitioned into two categories: studies involving tasks which prompt learners to generate examples and studies involving problem solving tasks which do not explicitly prompt for example generation. Studies with tasks that prompt for example generation often use "and then another" tasks, where students are asked to generate increasingly more examples of a particular mathematical concept (e.g., Watson & Mason, 2002, 2005; Zaslavsky, & Peled, 1996; Zazkis & Leikin, 2007). Typically, these tasks follow a predictable trajectory where first a learner generates immediately accessible examples of the concept (e.g. Goldenberg and Mason, 2008). The learner then works to generate new examples by combining examples and/or varying parameters. The second type of study involves students working on tasks which do not specifically prompt for example generation and highlights instances where example generation occurs as a problem solving strategy. These studies illuminate the utility of example generation as a strategy rather than the process of example generation itself.

### Counterexamples

Much of the mathematics education research relevant to counterexamples has focused on their pedagogical uses (e.g., Zazkis & Chernoff, 2008, Zazkis, 1995). Such work, however, does not discuss how students might evaluate a claim to determine that it may be false or subsequently generate counterexamples toward the end of proving a claim to be false. Overall, research on counterexample generation is relatively sparse. Meanwhile, several researchers have worked with graduate students who were prompted to evaluate the truth of mathematical claims (e.g., Alcock & Inglis, 2008, Weber, 2009). Such evaluation typically involves either the generation of a proof that establishes the claim as true or generation of a counterexample showing the claim to be false. However, these studies had either students produce counterexamples in such a quick manner that little can be inferred about the counterexample generation process (Weber, 2009) or focused on documenting the differences in the number of examples/counterexamples generated rather than the process by which they were generated (Alcock and Inglis, 2008). We begin to address this gap in the literature by discussing an episode where a student engaged in substantive efforts in order to generate a proof by counterexample.

## Methods

The research study was conducted at a large university in the southwest United States. Data were collected from two introduction-to-proof courses taught by the second author of this paper over two semesters. In this study, we discuss work related to the prompt:

*True or False and why: If $a$ and $b$ are both irrational then $a^b$ is irrational.*

This task's prompt was intentionally chosen because it does not indicate whether the statement is true or false. As such, the data related to this task includes both students' work to determine whether the claim is true/false and, in the cases where a successful proof was produced, an exploration which led to an appropriate counterexample which forms the basis of a proof. Thus, this task affords the opportunity to not only investigate the process of constructing proof via counterexample, but also investigate the process of how a student may realize the necessity for a counterexample.

Each student in the course was provided with a Livescribe® smart pen and notebook and was instructed to include all work done while working on the assignments, from their initial thoughts on the problems to the final solutions to be submitted for grading. We received 56 assignments with student work relevant to the prompt. The data presented here comes from one of these students.

## Results

Given the limited space, this paper's analysis focuses on a single student, Alex, and his associated work on the task. This work involves multiple shifts in notation. It also involves shifts between (1) attempts to formally prove the statement, (2) attempts to disprove the statement via counterexample (counter example generation), and (3) his work on proving related results. The core observation we wish to convey is that these three activities inform each other, with insights and notation from one affecting work in the others. This means that the counterexample generation process described here is more nuanced (and draws from more sources) than the processes of example generation described in the literature. Given the multiple shifts in activities and notation we include Figure 1 below to provide a top level view of these shifts. This also aides the reader in keeping track of how segments of the proving process relate temporally to the process as a whole and when segments of the process are omitted due to space limitations.

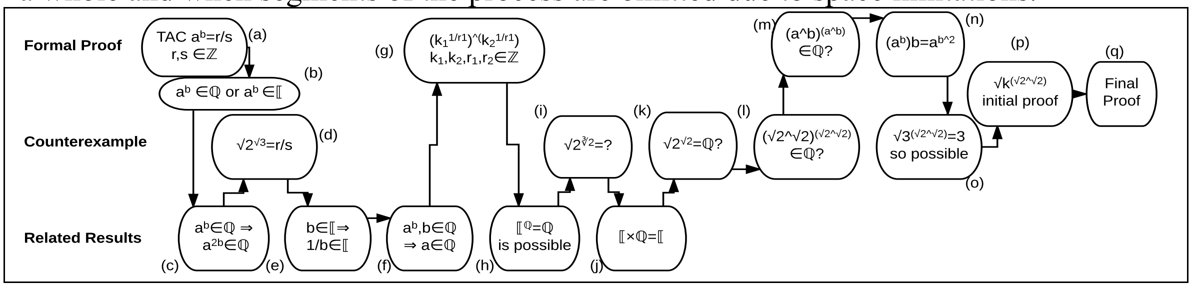

**Figure 1.** Alex's work on the counterexample task.

***Segments a-b: Alex's initial approach to the task***

In Alex's initial approach to the problem, he wrote "$a, b \in \mathbb{I} \Rightarrow a^b \in \mathbb{I}$", repeating the statement being considered in the task but using the symbol $\mathbb{I}$ to represent the set of irrational numbers, and "[toward a contradiction] assume $a^b = \frac{r}{s}$ $r, s \in \mathbb{Q}$". From here, Alex attempted to syntactically manipulate this equation and arrived at the statement, "$ar^b = s^b$". However, this did not show the contradiction he sought and adjusted his approach to consider both possibilities of the rationality of $a^b$ by explicitly indicating "either $a^b \in \mathbb{I}$ or $a^b \in \mathbb{Q}$". This is the first time where we see Alex considering these two possibilities of rationality. Since he is simultaneously considering both approaches, in figure 1, segment (b) sits between the counterexample and formal proof trajectories.

***Segments c-f: Irrational numbers as square roots***

After making a note of the set of rational numbers is closed under multiplication, Alex then wrote "Counterexample $a = \sqrt{2}$ [,] $b = \sqrt{3}$[.] Assume $\sqrt{2}^{\sqrt{3}} = \frac{r}{s}$". Here Alex considers the use of specific examples of irrational numbers $\sqrt{2}$ and $\sqrt{3}$, in an attempt to find a counterexample. We note that Alex's choice of irrational numbers is consistent with the typical first examples of irrational numbers in example generation literature (e.g., Goldenberg & Mason, 2008). However, after noting that $\sqrt{2}^{\sqrt{3}}$ is not rational, Alex quickly abandoned this specific counterexample strategy in favor of returning to working with abstract representations to seek a contradiction. We offer Alex's speedy dismissal of his examples $\sqrt{2}$ and $\sqrt{3}$ as evidence that Alex may prefer general counterexamples.

Next, Alex further evoked his knowledge of irrational numbers and exponents, proving the lemma "if $b$ irrational, then $\frac{1}{b}$ irrational". With this lemma established, he attempted to utilize it to create the desired contradiction. In particular, under the assumption that $a^b$ is rational, he wrote, "then $(a^b)^{1/b} = a^1 = a$". This establishes that it is possible to take $a^b$ to an irrational power to yield $a$. For example, setting $a = 2^{\sqrt{2}}$ and $b = \frac{1}{\sqrt{2}}$, yields a counterexample to the claim. While Alex did not use this approach, we will see that this was a productive stepping-stone toward his eventual solution.

***Segments g-j: Irrational numbers as n-th roots***

In the next portion of Alex's proof progression, Alex explicitly restricted his consideration of irrational numbers to only roots of natural numbers. This is consistent with his solely considering irrational numbers in his earlier counterexample generation attempts. More specifically, he wrote "if $b$ irrational then $b$ is an $r$-th root of some number say $b = {k_0}^{1/r_0} \in \mathbb{I}$" and similarly defined the variable $a = {k_1}^{1/r_1} \in \mathbb{I}$ (two lines below, he wrote that $b^{r_0} = k_0 \in \mathbb{N}$.) We note that this example space of irrational numbers is again consistent with the example generation literature (e.g., Goldenberg & Mason, 2008), which identifies n-th roots as the second most accessible class of examples after square roots of non-square integers. Based on this restriction, we cannot say if Alex's example space is restricted to roots or if this represents a restricted evoked example space for the purpose of this task.

Regardless of his understanding of various forms of irrational numbers, Alex uses this new (restricted) representation of irrational numbers to continue his formal, syntactic exploration of $a^b$ as a rational number, where $a$ and $b$ are irrational. In particular, Alex represented $a^b$ as $({k_1}^{1/r_1})^{({k_0}^{1/r_0})}$ and considered the expression $(a^b)^{({k_0}^{1/r_0})}$. He proceeded to again attempt to prove the statement is true via contradiction using this new notation, resulting in a dead end. Beside this work, he wrote several observations related to the original statement. In particular, he acknowledged that a rational number raised to a rational power yields a rational number and that it is possible for an irrational number raised to a rational power to yield a rational number. He justified this latter observation via the specific example $(\sqrt{2})^2 = 2 \in \mathbb{Q}$.

Next, Alex wrote "Shows possible $a, b \in \mathbb{I}$ and $a^b \in \mathbb{Q}$ counterexample?" followed by the use of specific numbers ($a = \sqrt{2}$ and $b = \sqrt[3]{2}$) in attempt to generate a counterexample. After noting this did not yield the desired result, Alex returned to his formal exploration using the $({k_1}^{1/r_1})^{({k_0}^{1/r_0})}$ notation. Once again, these attempts were not fruitful and Alex considered the properties of the products of rational and irrational numbers as shown in Figure 2. In this figure, we see Alex once again moving between general and specific attempts to generate a counterexample.

***Segments l-m: Numbers of the form $(a^b)^{a^b}$***

In the subsequent portion of Alex's proof progression, he expanded his consideration of irrational numbers beyond $a$'s and $b$'s which are roots of integers; he introduced the use of irrational numbers that are composed of a base and an exponent both of which are irrational numbers. This can be viewed as the counterexample generation process being filtered through the task (e.g., Zazkis & Leikin, 2007) where the previously generated pairs of irrational numbers, $a$ and $b$, are filtered through the task to place $a^b$ under consideration. When $a^b$ is not rational, and thus does not serve as a counterexample to the statement, it can instead serve as a new example of a single irrational number.

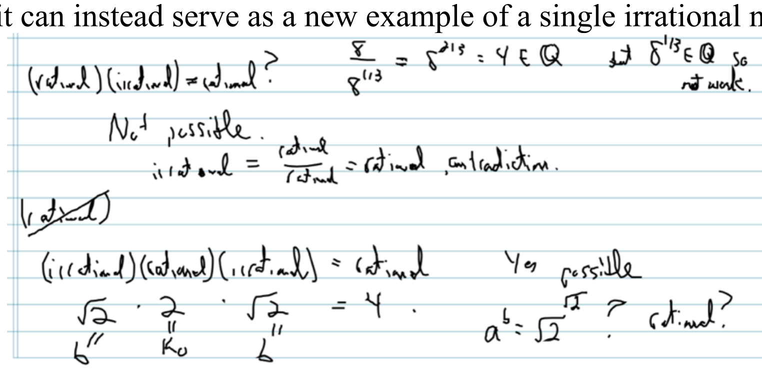

**Figure 2.** Alex's consideration of the products of irrational and rational numbers.

This behavior first emerged as Alex wrote $(a^b)^{a^b} = a^{b \cdot a^b} = a^r$ indicating the leftmost expression as an irrational base to an irrational exponent and the rightmost expression as a rational number. Alex further considered the possibilities of rationality of the products and powers of irrational and rational numbers. Here $(a^b)^{a^b}$ structure of in his proof attempt is informed by his work with $\left(\sqrt{2}^{\sqrt{2}}\right)^{\sqrt{2}^{\sqrt{2}}}$ when attempting to generate a counter example.

Further, Alex noted that $\sqrt{2}\sqrt{2} = 2$, which led to a reiteration that it is possible to create a rational number by taking an irrational number to a rational power. In this reiteration, he wrote "$a^r = \mathbb{I}^{\mathbb{Q}} \in \mathbb{Q}$ if $a = \sqrt{2}$, $r = 2$". Given his infrequent use of specific examples and the immediacy of Alex's use of this example following the statement indicating an irrational number raised to a rational power can yield a rational number, we interpret this as Alex reverse engineering a rational number from irrationals and to apply this to the task at hand.

Despite this use of specific examples, Alex next attempted to construct a proof as shown in Figure 3. We see in Figure 3 that Alex's progress was limited when trying to formalize his counterexample. In subsequent attempts to formalize his counterexample, Alex returns to his syntactic representations of irrational and rational numbers rather than attempting to generate a specific counterexample. We offer this as further evidence that Alex may have a preference toward using general counterexamples.

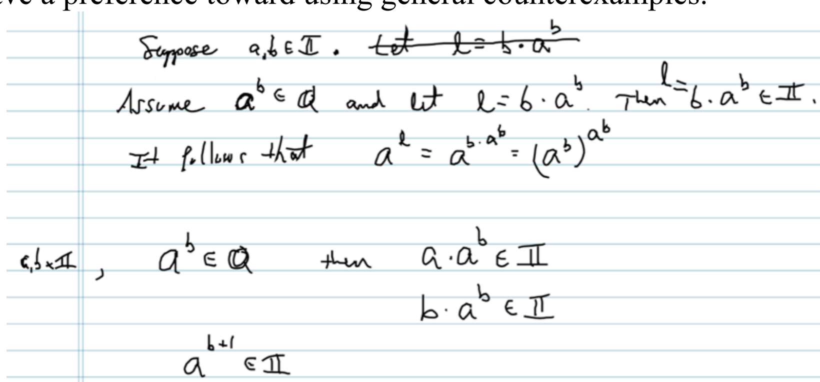

**Figure 3.** Alex's attempt to formalize a counterexample.

***Segments n-q: Numbers of the form $(a^{\sqrt{2}})^{\sqrt{2}}$***

Following his unsuccessful attempt to formalize his counterexample in a proof, Alex builds off of his previous approach by modifying the variables and applying specific numbers. Rather than using strictly $a$'s and $b$'s, Alex applied numbers to his previous expression "$a^b = (a^b)^b = a^{b^2} = \sqrt{3}^{\sqrt{2}^2} = \sqrt{3}^2 = 3 \in \mathbb{Q}$" and noted "so possible." This building off of his previous approach is consistent with the literature on example generation (e.g., Goldenberg and Mason, 2008; Zazkis & Leikin, 2007) and is an instance where his attempt to create a proof using abstract $a, b$ notation informed his later generation of a counter example. Further, based on Alex's note of "so possible" next to this expression, we believe Alex has knowingly identified a counterexample that shows the possibility of an irrational base to an irrational exponent to be equal to a rational number. However, it is unclear whether Alex realized that this single counterexample was sufficient to form a basis of a proof that the claim is false. In fact, rather than using the counterexample he generated, Alex continued working towards a general counterexample. One explanation for Alex's preference for general counterexamples may be that his behaviors are an instantiation of the belief that abstract mathematical objects must be the focus of proving activity.

In the proof sketch shown in Figure 4, Alex used $a = \sqrt{k}^{\sqrt{2}}$ and $b = \sqrt{2}$ to show a contradiction that it is not true that if $a, b \in \mathbb{I}$, then $a^b \in \mathbb{I}$. In figure 1, both this and the final proof appear between the formal proof and counterexample axes because they are proofs that utilize counterexamples. It is noteworthy that after having generated a suitable, specific counterexample above ($a = \sqrt{3}^{\sqrt{2}}$ and $b = \sqrt{2}$), Alex generated an additional counterexample ($a = \sqrt{k}^{\sqrt{2}}$ and $b = \sqrt{2}$). Thus, we highlight that the counterexample generation process does not necessarily stop when a counterexample is found. Specifically, in Alex's case, we see that the motivation for this additional counterexample may be focused on supplying a general counterexample. Based on the evidence available, we cannot be sure whether this proof using a general counterexample is a result of 1) a belief that proving activity must usually center around work with abstract mathematical objects, or 2) a lack of understanding of the role a single counterexample plays in relation to a mathematical claim.

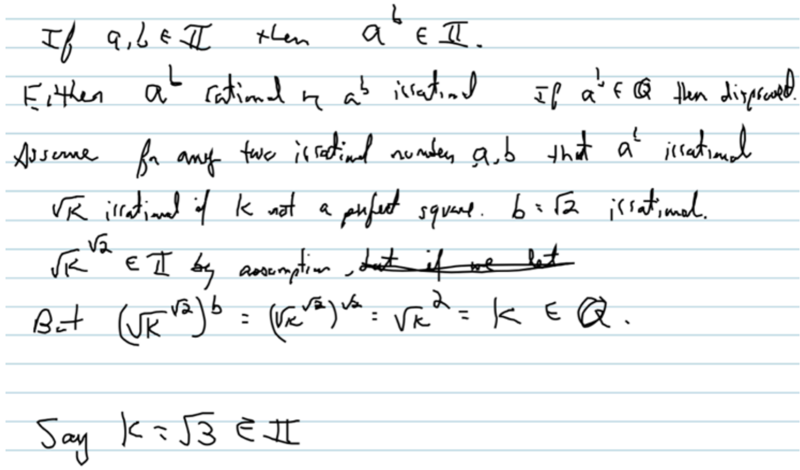

**Figure 4.** Alex's proof sketch.

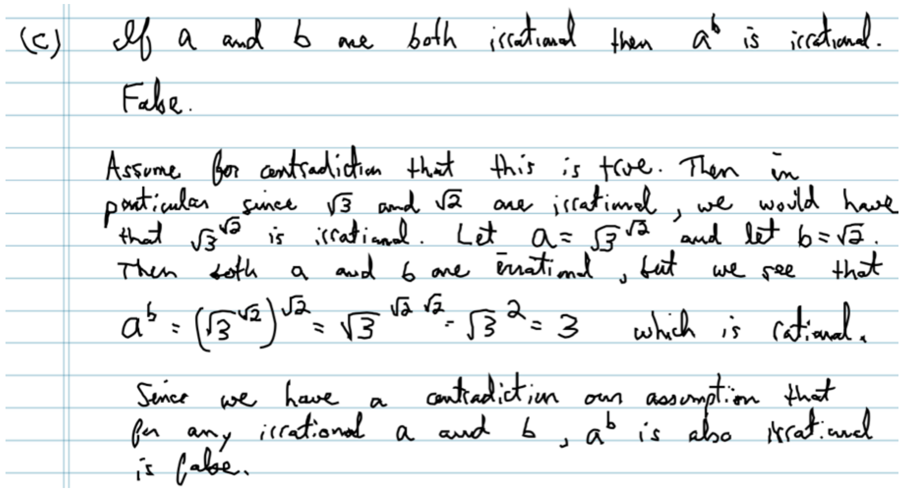
Meanwhile, in Alex's final proof, we see that he used the specific counterexample he first presented where $a = \sqrt{3}^{\sqrt{2}}$ and $b = \sqrt{2}$ to show a contradiction that it is not true that if $a, b \in \mathbb{I}$, then $a^b \in \mathbb{I}$. It is unclear what influenced Alex's change from using k=2 to k=3. Moreover, we do not have evidence to indicate why Alex shifted from his more formal approach shown in his proof sketch to using the specific counterexample where $a = \sqrt{3}^{\sqrt{2}}$ and $b = \sqrt{2}$. One possible interpretation of this shift in Alex's approach is the above proof sketch's reliance on the assertion that "$\sqrt{k}$ irrational if $k$ not a perfect square" – a non-trivial claim that warrants a justification.



(c) If $a$ and $b$ are both irrational then $a^b$ is irrational.

False.

Assume for contradiction that this is true. Then in particular since $\sqrt{3}$ and $\sqrt{2}$ are irrational, we would have that $\sqrt{3}^{\sqrt{2}}$ is irrational. Let $a = \sqrt{3}^{\sqrt{2}}$ and let $b = \sqrt{2}$. Then both $a$ and $b$ are irrational, but we see that $a^b = \left(\sqrt{3}^{\sqrt{2}}\right)^{\sqrt{2}} = \sqrt{3}^{\sqrt{2}\sqrt{2}} = \sqrt{3}^{2} = 3$ which is rational.

Since we have a contradiction our assumption that for any irrational $a$ and $b$, $a^b$ is also irrational is false.

**Figure 5.** Alex's final homework submission.

## Conclusion

There are several important points to be made about Alex's work on this problem. When he generated examples of pairs of irrational numbers $a, b$ and considered the rationality of $a^b$, this process was consistent with the example generation literature. This is true not only in terms of his movement from directly accessible examples to less accessible examples, but also the filtering of the example generation through the task itself. However, generating a counterexample was not Alex's primary goal. Rather he was attempting to assess the veracity of the claim and generate a proof that justified that veracity. As a result, the proving process was more complex than generating pairs of irrational numbers $a, b$ in the hope that one had the property that $a^b$ is rational.

The process also included several failed attempts to prove the claim was true via contradiction and the incorporation of several representations of $a$ and $b$. Moving between these attempts to generate a counterexample (as seen in Figure 1) influenced the generation process in fundamental ways. For example, his use of the pair $a = \sqrt{2}$ and $b = \sqrt[3]{2}$, when attempting to generate a counterexample was influenced by his attempts to use other roots ($b = {k_0}^{1/r_0} \in \mathbb{I}$). Alex's proof attempt encouraged a particular type of example and thus made that notation readily accessible to his counterexample generation process.

## Discussion

This proposal offers evidence that proving activities that are not focused specifically on generating examples can influence counterexample generation. That is, proof attempts can influence a students' counterexample generation. The mutual influence of counterexample generation and proof attempts points to the complexity of the process of evaluating the truth of a mathematical claim currently absent in the processes discussed in the example generation literature. This observation regarding the complexity of evaluating the truth of a mathematical claim points to the limitations of the example generation literature for informing this related process. Possible avenues for future research include investigations of learners' potential preference for abstract or general counterexamples to specific ones and more targeted and systematic investigations into the processes by which students generate counterexamples. A natural next step may be to conduct interviews with students working on similar counterexample generation tasks.

Mathematics Graduate Teaching Assistants' Growth as Teachers: An Unexamined Practice

Erica R. Miller, Karina Uhing, Meggan Hass, Rachel Zigterman,
Kelsey Quigley, Yvonne Lai, & Nathan Wakefield
University of Nebraska-Lincoln

*In recent years, providing teaching professional development for graduate teaching assistants has become more common in mathematics departments in the US. Following this trend, mathematics education researchers have begun to conduct studies on professional development programs and on graduate students as novice teachers. The purpose of this literature review is to examine the current status of research in this field and make recommendations for future research on graduate teaching assistants and professional development. In examining the literature, we utilize an existing framework for collegiate teaching practices and focus on studies that attended to growth. As a result of this literature review, we recommend that researchers begin developing models or theories for how and why graduate students grow as teachers.*

*Keywords:* Post-secondary, professional development, graduate teaching assistants, teaching practices, growth

## Introduction

In recent years there have been many efforts made to improve the quality of instruction in first-year undergraduate mathematics courses, which often have low pass rates. For many students, these are the only undergraduate math courses they experience. Also, graduate teaching assistants (GTAs) are often the primary instructors for these courses. In an effort to improve the quality of instruction in these courses, it has become increasingly common for math departments to offer teaching professional development (PD) for their GTAs. In addition, math departments have begun evaluating the impact of these PD efforts, but the results have been mixed.

At the K-12 level, researchers have found that PD interventions aimed at improving teaching tend to be more effective when they are theory-based and use an explicit model accounting for features of the PD, school contexts in which teachers work, and how the PD is intended to shape the practices of teachers participating in it. In a similar vein, it is reasonable to expect that attempts to improve teaching among GTAs would benefit if informed by models of how these novice college mathematics instructors learn to teach.

With this in mind, we reviewed the research on how mathematics GTAs learn to teach. Our intended goal was to identify and characterize the models and theories that have informed studies of GTAs' growth as teachers. While there are many aspects of GTA teaching in which growth might occur, we chose to focus explicitly on teaching practices in this paper because they directly relate to the professional work that GTAs engage in. We sought to take stock of what is known about improving GTAs' teaching, what gaps there may be, and how to move forward. To do this, we asked:

1. *What GTA teaching practices do researchers attend to?*
2. *How do researchers attend to GTAs' growth as teachers over time?*
3. *What models or theories of growth do researchers use?*
4. *What stances do researchers take regarding GTAs' growth as teachers?*

In our literature review, we searched three major research databases from 2005 to 2016: Education Resources Information Center (ERIC), PsycINFO, and Web Of Science, the RUME proceedings from 2010 to 2016, and the AMS Notices from 2005 to 2016. We chose these as the foundational sources because undergraduate-focused math education research is often published in these sources.

We found there is little empirical or theoretical research that explicitly or implicitly describes GTAs' growth. Here we define growth as the process of changing along an identifiable trajectory. For something to be considered growth, it must be true *that* something has changed and that exactly what has changed can be *identified.* We take our definition of teaching practices from our theoretical framework, which will be taken up again later. In later sections, we will review the results of our search, summarize the few results we did find, and discuss how researchers attended to GTAs' growth as teachers. After providing some background and the results of the literature search, we propose a refinement of Speer, Smith, and Horvath's (2010) framework for collegiate teaching practice. The refinement emerged from our analysis in order to address more recent research on GTAs and their teaching. Finally, the central claim that we make is that *GTAs' growth as teachers is a largely unexamined practice*.

**Background**

In many departments, GTAs are assigned to teach first-year undergraduate courses, including remedial math, college algebra, pre-calculus, calculus, and mathematics for pre-service K-12 teachers. Since students are stakeholders in instruction, we first highlight ideas from research published about student experiences in lower division undergraduate courses. In calculus, student experiences vary greatly (Bressoud, Mesa, Rasmussen, 2015; Burn, Mesa, & White, 2015). Students traditionally under-served by *status quo* K-12 education continue to be at a disadvantage in post-secondary settings (Bahr, 2010; Cuellar, 2012; Kena et al., 2016; Nuñez, Hurtado, & Calderón Galdeano, 2015). Difficulty passing initial college mathematics courses has a negative impact on persistence of STEM-intending students (Thompson, Castillo-Chavez, et al., 2007). While these phenomena are influenced by a variety of factors, instruction is a key element in student success. For that reason, research on how professional development can help improve the quality of instruction is an important facet of research on undergraduate mathematics education.

While providing teaching professional development for GTAs has only recently become more common, there is a wealth of research on professional development for pre- and in-service K-12 teachers (Chen & McCray, 2012; Desimone, 2009). However, measuring effective PD can be difficult and results are mixed and influenced by many external factors (Guskey & Yoon, 2009). Moreover, these studies focus primarily on professional development for teachers who have earned at least a bachelor's degree in education, stressing the importance of discipline-specific scaffolds for teacher learning. In contrast, GTAs often have a great deal of experience in doing mathematics but little to no formal training in teaching and instruction. Consequently, they are a different audience for professional development than K-12 teachers.

## Frameworks

To guide our analysis of teaching practices, we drew on Speer et al.'s (2010) framework for examining teaching practices at the collegiate level. Speer et al. define *teaching practices* to be the instructional judgments, decisions, and actions employed by instructors in and outside of the classroom. Note that this is distinct from *instructional activities*, which are activities used to organize student learning and stimulate student engagement with classroom resources (e.g., using group work). Teaching practices and instructional activities are interwoven and the distinction between them is often not made clear, or even mentioned, in research publications. Both are important teaching elements examined by researchers and were present in the articles we analyzed. See Table 1 for a full description of the teaching practices identified in Speer et al.'s (2010) framework.

*Table 1. Framework for collegiate teaching practice of Speer et al. (2010)*

| Teaching Practice | Description |
|---|---|
| Allocating time within lessons | Deciding how much time to allocate among topics and within individual class periods |
| Selecting and sequencing content within lessons | Choosing and sequencing the mathematical content presented in an individual class period; for example selecting problems and deciding which theorems to present |
| Motivating specific content | Introducing, motivating, and providing a rationale for sequencing topics, specifically to promote student engagement |
| Posing questions, using wait time, and reacting to student responses | Deciding what questions to ask, how long to wait for a response, and how to respond to students' answers |
| Representing mathematical concepts and relationships | Deciding which mathematical ideas to present in the classroom and how to present them |
| Evaluating and preparing for the next lesson | Reflecting and evaluating on individual class periods, and using (or not using) this information to inform the next lesson |
| Designing assessment problems and evaluating student work | Developing assessment problems by considering content coverage, expected difficulty level, sequencing of problems, and relevance to particular elements of content |

## Methodology

All articles considered for inclusion in the review were peer-reviewed and contained at least one search term from each of four categories: teaching, domain, level, and participants (see Table 2 for exact search terms). This yielded 1,889 articles. We read each abstract to determine if an article could reasonably address our research questions. We double-coded until we reached consensus on the criteria for inclusion, with an inter-rater reliability of 97%. Our intent was to focus on mathematics GTAs, but we also decided to code for STEM fields in general that way we could keep track of articles that might be relevant if we decided to extend our literature review. After discussion, we agreed to seven articles that were relevant. To capture other relevant research on this topic, we then read the abstracts of the RUME proceedings for the years 2010 through 2016 (we restricted our time frame due to infrequency of relevant articles), again coding for inclusion, and found 17 relevant articles. Finally, we searched the AMS Notices using an advanced Google Scholar search for the years 2005 through 2016 (using the same search terms in Table 2, excluding the "domain" category). This yielded an additional two articles, which gave us a total of 26 articles relevant to our research questions.

Each article was then open coded for teaching practices, attention to growth over time, use of an explicit or implicit model or theory of growth, and stances on growth. Six articles were double-coded, at which point the team discussed preliminary findings and how to adjust the coding procedure. After consensus was reached, the rest of the articles were coded. Using the Speer et al. (2010) framework, we conducted a second cycle of coding that categorized our open codes to fit into the given framework.

*Table 2. Search Terms*

| Category | Terms |
|---|---|
| Teaching | teach*, instruct*, "professional development", PD, training, TD |
| Domain | STEM, math*, science, physics, chemistry, biology, statistics, engineering |
| Level | undergrad*, collegiate, tertiary, college |
| Participants | "graduate student", GST, GSI, GI, novice*, "future faculty", beginning, GTA, TA |

## Findings

While all 26 articles focused on GTA teaching, the participants involved in the studies still varied. The majority included graduate student participants who were currently teaching or who would be teaching in upcoming semesters. In addition, one mixed-methods study included "novice college math instructors," who were defined as instructors with less than seven years of teaching experience and included non-graduate students. A few studies explicitly stated that the graduate students were in their first or second year as instructors, but many studies did not specify how long the GTAs had been teaching. In addition, the researchers gathered data in a variety of ways, including interviews, classroom observations, observations of GTA PD classes, and surveys. Details of our findings are given below and summarized in Tables 3 and 4.

### Teaching Practices and GTA Growth

Of the 26 articles, we were able to utilize Speer et al.'s (2010) framework to categorize the teaching practices studied in 14 of the articles. Each of the specified teaching practices was addressed in at least one article, suggesting that their framework is consistent with the current research efforts surrounding GTA PD. However, we suggest two refinements to the framework based on our review. First, we suggest adding "anticipating student thinking" to the framework. We found eight articles out of the 26 that examined this teaching practice. This teaching practice is implicitly part of "selecting and sequencing content within lessons" and "motivating specific content," but we suggest that it be explicitly stated. Also, anticipating student thinking plays a central role in facilitating productive mathematical discussions (Stein, Engle, Smith, & Hughes, 2008) and is something that novice teachers often struggle with. Second, we suggest that the practice of "representing mathematical concepts and relationships" be refined to include verbal descriptions. One of the articles we coded with this teaching practice specifically focused on "speaking with meaning" (Musgrave & Carlson, 2016). Although Speer et al.'s (2010) description does not explicitly exclude verbal representations, it emphasizes *what* is shared rather than *how* it is shared. This refinement also reflects recent work on teachers' coherent mathematical meanings (Thompson, Carlson, & Silverman, 2007).

*Table 3. Number of articles addressing the teaching practices in adapted Speer et al. (2010) framework*

| Teaching Practice (* Adapted) | Number of Articles |
|---|---|
| Anticipating student thinking* | 8 |
| Allocating time within lessons | 2 |
| Selecting and sequencing content within lessons | 4 |
| Motivating specific content | 1 |
| Posing questions, using wait time, and reacting to student responses | 5 |
| Representing mathematical concepts and relationships including how concepts are described in words* | 3 |
| Evaluating and preparing for the next lesson | 4 |
| Designing assessment problems and evaluating student work | 3 |
| Does not examine any specific teaching practice | 12 |

After coding for teaching practices, we then coded to identify articles that focused on how GTAs grow over time, provided models or theories of growth, and took stances regarding growth. These are discussed in the next few subsections.

*Table 4. Number of articles that attended to growth*

| | Number of Articles |
|---|---|
| Focused on growth over time | 11 |
| Used models or theories of growth | 3 |
| Took a stance regarding growth | 13 |
| Did not attend to growth | 9 |

**Growth over time.** We found 11 articles out of the 26 that addressed growth in GTAs' teaching practice over time. For example, Raychaudhuri and Hsu (2012) conducted a longitudinal study to explore how beliefs and pedagogical approaches evolve over the span of a year. Based on their preliminary analysis, Raychaudhuri and Hsu present stages of GTA beliefs regarding students moving from teacher-centered knowledge to student-centered knowledge. Musgrave and Carlson (2016) studied GTAs' descriptions of average rate of change before and after one semester of PD. They found that graduate students who participated in the PD described average rate of change more conceptually than their counterparts, but still struggled to verbalize the meaning of average rate of change. In another study, Duncan (2016) used a teaching experiment methodology to examine how one GTA's mathematical meanings and instructional planning decisions changed while creating a hypothetical learning trajectory (HLT) on angles, angle measure, and the radius as a unit of measurement. Duncan's results suggest that having GTAs work through tasks in a researcher generated HLT can cause changes in what GTAs identify as being important to teach.

**Models or theories of growth.** We found three articles out of the 26 that employed a specific model or theory of growth. Beisiegel (2011) utilized Lave and Wenger's (1991) theory of legitimate peripheral participation to describe the process by which GTAs gain knowledge and understanding about the practice of teaching post-secondary mathematics. In particular, Beisiegel studied how "the attention to legitimate peripheral participation in a mathematics department [might] prevent graduate students from adopting alternate modes of teaching" (p. 20). In a study examining the teaching philosophies of GTAs, Nepal (2014, 2015) used a cognitive apprenticeship model, which stems from situated cognition and Vygotsky's (1978) sociocultural theory. Nepal applied this model to explain how and why GTAs' teaching philosophies change as they "accumulate knowledge about teaching and learning gradually through the interaction with other people and their own teaching experiences" (2015, p. 5). Some papers mentioned a model or theory of growth but did not incorporate it as a key aspect of the study. For example, Yee, Rogers, and Sharghi (2016) claimed that reflecting, revising, and collaborating help GTAs "actively engage with teaching theories" (p. 1458) and "develop a community of practice" (p. 1459). However, an explicit model or theory of growth was not referenced or used.

**Stances regarding growth.** Thirteen articles took stances on teaching quality that referenced knowledge for teaching, cognitive demand, pedagogies, and student achievement. Firouzian (2014), Speer and Firouzian (2014), and Firouzian and Speer (2015) cited the large body of work on mathematical knowledge for teaching (MKT) as evidence for why it is important for GTAs to develop MKT. Roach, Noblet, Roberson, Tsay, and Hauk (2010) cited Smith and Stein's (1998) work on cognitive demand to describe the (limited) variety in cognitive demand in the questions TAs asked. Finally, Yee et al. (2016) drew upon *Principles to Actions* (National Council of Teachers of Mathematics, 2014) as evidence for why specific teaching practices are associated with effective teaching.

## Discussion

Based on our findings, we argue that GTAs' growth as teachers is a largely unexamined practice. We assume that the purpose of most, if not all, GTA PD programs is to foster growth as teachers, but were surprised to find that only a small percentage of the research on GTA PD addresses growth. Of the 26 articles we reviewed, nine of them did not focus on growth at all. Only three of them provided explicit models or theories of growth, but none of these focused on teaching practices. Current research gives a general sense of what GTAs may be doing in the classroom, but how their teaching practices change as they gain experience and participate in PD is understudied. It should also be noted that the four studies that address growth demonstrate that growth is possible, so further research is warranted. As a result, we suggest that the field would be greatly enhanced by additional longitudinal studies exploring how GTAs grow as teachers.

In particular, it would be beneficial to begin developing an accepted definition of GTA growth. We argue that part of this process is being clearer on our stances as a research field on teaching quality and how these relate to models or theories of growth in teaching. Moreover, most studies assume a common understanding of the term "teaching practice" rather than attempting to define it. This leads to a lack of clarity about which aspects of teaching are analyzed in research as well as the researchers' stances on teaching quality. It is striking that there were no articles that were explicit both about their stance on teaching quality *and* a model or theory. We call for future research to take an explicit stance on teaching quality and how teaching quality is related to models and theories of GTA growth.

Finally, our findings suggest a need for explicit models or theories of growth in teaching linked to stances on teaching quality. There has been some progress on this (e.g., development of MKT by Thompson, Carlson, & Silverman, 2007), but more development is needed. We call for the research community to begin developing the models of growth that will allow research on GTA PD to grow into a rich body of literature such as exists in the research literature on K-12 teacher PD.

## Future Directions

Although we did not find many articles on mathematics GTAs' growth as teachers to include in our literature review, there was a larger body of work on STEM GTAs in general. Since there are many similarities between mathematics and other STEM disciplines, it would be fruitful to see how researchers have attended to STEM GTAs' growth as teachers. In particular, if studies on STEM GTAs attend to teaching practices or define GTA growth or use explicit models or theories of growth, then we could build upon this in the RUME community. However, it is also important that we attend to the ways in which the teaching and learning of mathematics differs from other STEM disciplines.

# Our Mathematical Ideas are Part of Our Identity

Jeffrey D. Pair
California State University Long Beach

Stanley M. Lo
University of California San Diego

*This paper explores the notion that our mathematical ideas are part of our identity. This notion, which was a significant result of a qualitative dissertation study, will be explored in depth through an examination of data in connection with the educational research related to identity. The story of Binary, a first generation college student completing a transition-to-proof course in his final semester of college, provides the context in which we explore this complex notion.*

*Keywords:* Identity, Nature of Mathematics, Mathematician's Practice, Transition-to-Proof

One day in Foundations of Higher Mathematics, a student called Binary[1] says, "I think no one really understands my idea. I think people are just so focused on $2k + 1$ that they are not looking at the bigger picture here." This comment came on the second day of classroom discussion, the bulk of which consisted of students debating the merits of Binary's suggestions regarding a proof of the claim that "the sum of any two odd numbers is even." Notice the language Binary uses: "I think no one really understands *my* idea." Binary identifies the idea as his own. In this paper, we explore the notion that the idea is part of his identity.

## Theoretical Frameworks On Identity

Identity is a powerful construct used to examine and understand the interactions between learners and mathematical content and practices (e.g. Boaler & Greeno, 2000; Langer-Osuna 2015). Gee (2000) defined identity as "being recognized as a certain 'kind of person' in a given context" (p. 99). Identity is related to how an individual views her or himself, and how others view an individual. Drawing on work done by Boaler and Greeno (2000) and Martin (2000), Cobb and Hodge (2010) distinguished between core identity, normative identity, and personal identity. Observing student behavior, the authors noted that core identity refers to how students "viewed themselves and who they wanted to become" (p. 187). Normative identity does not refer to how students view themselves or one another as individuals, but rather, the focus is on how students become a "mathematical person" or "doer of mathematics" (p. 187). An important component or normative identity is mathematical competence (Cobb, Gresalfi, and Hodge 2009). What students perceive as necessary to become a doer of mathematics may be in conflict with who they are and want to become (their core identity). Personal identity is developed as students "participate in (or resist) the activities of particular groups and communities, including those of the mathematics classroom" (Cobb & Hodge, 2010, p. 187).

To understand the overlapping but separate notions of personal identity and normative identity, we can use an additional framework called figured worlds. A figured world is "a socially and culturally constructed realm of interpretation in which particular characters and actors are recognized, significance is assigned to certain acts, and particular outcomes are valued over others" (Holland, Lachicotte, Skinner, & Caine, 1998, p. 52). In mathematics education, this

[1] Students in the course completed an assignment in which they chose a number type that best represented themselves. For this assignment, the student we call Binary, a computer science major, wrote this description of why he chose Binary as his number type: "Very simple once you get to know me. But can be very confusing if you don't."

framework has been used to understand how students navigate one figured world of the mathematics classroom and the figured worlds of their other identities, such as being an athlete, under-represented minority, etc. Boaler and Greeno (2000) described an inquiry-based mathematics classroom as a different figured world than a traditional classroom, the latter of which may be much more misaligned with promoting the development of students' normative identities. Nasir, Hand, and Taylor (2008) examined the lack of intersection between students' figured worlds of the mathematics classroom and the basketball court. Langer-Osuna (2015) extended this notion to examine the challenges of under-represented minority students in mathematics, as the figured world of a mathematics classroom overlaps much more with that of dominant cultures versus that of non-dominant cultures. In all of these cases, the figured world of mathematics is misaligned with the various figured worlds of students outside of the mathematics classroom, thus leading to unsuccessful learning.

## Methodology and Analysis

The theoretical frameworks of identity will be used to shed light on a finding from a qualitative dissertation study. The importance of identity emerged from the data, and the construct was not used to frame the original study. The original purpose of the study was to create a humanistic framework for the nature of pure mathematics. Two questions guided the study: What is the nature of pure mathematics? And what should undergraduate students in a transition-to-proof course understand about the nature of pure mathematics? In seeking to answer these questions, the researcher incorporated the methodological framework of heuristic inquiry (Moustakas, 1990). This form of inquiry has roots in humanistic psychology, and it leverages the researcher as instrument. Douglass and Moustakas (1985) wrote, "It is the focus on the human person in experience and that person's reflective search, awareness, and discovery that constitutes the essential core of heuristic investigation" (p. 42).

To understand the nature of mathematics and consider what students should understand about the nature of mathematics, the researcher (first author) collaborated with a graph theorist and co-taught an undergraduate introduction-to-proof course. In regards to this discussion on identity, to the most relevant data collected come from the transition-to-proof course and the researcher's reflective journal. The data gathered from the course included audio recordings of discussions the researcher had with a co-instructor, audio of whole-class discussions, student homework, classwork, exit tickets, and all other class materials. Twenty-three students from the course agreed to participate in the study.

The researcher employed the processes of heuristic inquiry and other qualitative analysis techniques to arrive at several possible characteristics of the nature of mathematics that may be valuable for students to know and understand. The end of heuristic inquiry is what Moustakas (1990) called the creative synthesis:

> Finally, the heuristic researcher develops a creative synthesis, an original integration of the material that reflects the researcher's intuition, imagination, and personal knowledge of meanings and essences of the experience. The creative synthesis may take the form of a lyric poem, a song, a narrative description, a story, or a metaphoric tale. In this way the experience as a whole is presented, and, unlike most research studies, the individual persons remain intact. (p. 51)

The creative synthesis for this study includes the IDEA Framework for the Nature of Pure Mathematics and ten stories that illustrate key characteristics of the nature of mathematics.

## Results

A main result of this study is the IDEA Framework for the Nature of Pure Mathematics and ten corresponding stories that illuminate the characteristics of the framework. The IDEA framework consists of four foundational characteristics: Our mathematical ideas and practices are part of our ***I***dentity; mathematical ideas and knowledge are ***D***ynamic and forever refined; mathematical inquiry is an emotional ***E***xploration of ideas; and mathematical ideas and knowledge are socially vetted through ***A***rgumentation. In this paper we present a story, *If Nobody Agrees With You*, highlighting the notion that our mathematical ideas are part of our identity.

### If Nobody Agrees With You

One day in Foundations of Higher Mathematics some small groups are working to create group proofs for different theorems and presenting their proofs of those theorems to the class. The Yellow Team create and present the poster shown in Figure 1.

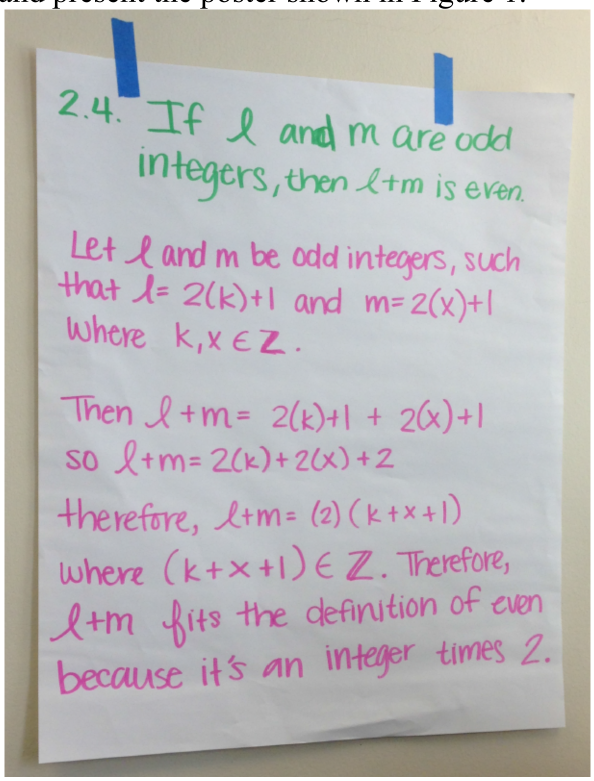

*Figure 1. Yellow Team's Poster*

In general, the class as a whole likes the group's argument and does not have many questions. Infinitely Repeating Decimal's comments are representative of the class: "It is pretty straightforward, it doesn't get more concise than that." However, Binary does have an important question. He asks, "If instead of having the *x*, if you did put *k*, would it make the argument less strong?" We see Binary is referring to the original delineation of the odd numbers *l* and *m* as $l = 2k + 1$ and $m = 2x + 1$ where *k* and *x* are integers. Would the argument be less strong if we simply defined $l = 2k + 1$ and $m = 2k + 1$? One of the presenters, Odd, responds "Oh, so like *k* here and *k* here?" (pointing to the *k* and *x* in the original delineations). "Yeah," Binary replies. Odd explains, "Yeah, because basically what you did was, you didn't say that it's any two odd integers, you said the same integers. So you basically just said $l + l$." Binary tries to explain that he thinks $k$ is sufficient, by appealing to the definition of odd number; but he is interrupted as another student, Whole, interjects: "If you want to stick with $k$ you could be like $k$ subscript 1 and $k$ subscript 2." The dialogue continues:

Binary: I just feel like if they both were $k$ it would still make a strong argument.

Odd: If $l$ equals $2k+1$ and $m$ equals $2k+1$, as $k$ increases the other $k$ is increasing so $l$ and $m$ would always be equal.

Binary: But it's still going to be odd. That's what I am saying.

Odd: It's an odd number but it's the same odd number. So it doesn't cover any combination of two odd numbers. So basically you would only be able to say like 3+3 or 6 or 7+7. But with this, because these are different, we could say let $l$ be equal to 3 and $m$ be equal to 7.

Infinitely Repeating Decimal: If you really wanted them to be k's you could use subscripts like $k_1$ and $k_2$.

Odd: Yeah.

Infinitely Repeating Decimal: You just need to show that they are not the same integer.

Binary: Yeah. I am just trying to figure out if I just left that as $k$, and he had that. Would I get less points?

At this point several members of the class laugh and some chime in that indeed the argument would receive less points. Dr. Amicable and Surreal[2] (the co-instructors) bring the class's attention back to the mathematics. Dr. Amicable asks for a show of hands to see how many students understand Odd's explanation, and asks Infinity to explain in her own words.

Infinity: Yeah. If you made both the variables, the $k$ and the $x$ the same. If you did make them both $k$ then they would be the same number. So you would get the same outcome of $l$ and $m$. And so your numbers wouldn't vary. So, like he was talking about how the answer would be consistently the same throughout. … If you make both of those $k$'s in the equation where x is. Then you are going to get the same exact number.

Dr. Amicable: Hmm. So is it right, if I were to summarize what you are saying Infinity; would it be right to say that essentially we are changing this condition to if $l$ and $m$ are the same odd integers? Then $l + m$…

Infinity: Yea. Because you would be plugging in…. You would be using the same variables.

Dr. Amicable: Okay. Binary what do you think?

At this point the instructors, Dr. Amicable and Surreal, expected Binary to jump on board with the class consensus. But he stands firm.

Binary: I am just saying. In general if you were to use examples, then yeah. But just in general I feel like no matter what you put in, by the definition of an odd number, it's going to come back to the exact same thing.

Whole (interrupting): You have to have some kind of variance in it when you are adding two.

Binary: But not in the way he did, maybe in another proof, yes. But…

Whole: It's the same principle though.

Composite: Okay. But if you do use $k$ in both $l$ and $m$... If you say $2k + 1$ is equal to $l$ and $2k + 1$ is equal to $m$. You are going to go to the next step where it adds, and you will have $2k + 1$ plus $2k + 1$. And then instead of being $2k + 2x$ it's going to be $2k + 2k$ which equals $4k$. And you are going to have $4k + 2$ which is not going to be something that looks like the definition of an even number.

Binary: [emotional] Yes you will. You pull out 2.

---

[2] Surreal is the researcher and first author.

Odd: It would still be even.

Binary: It would still be even.

Binary stated "It would still be even" with conviction. Then several people in the class begin to discuss. Of course, the result $4k + 2 = 2(2k + 1)$ is in the form of an even number and several members of the class agree. But they also stress that by using $l = 2k + 1$ and $m = 2k + 1$, the result is "more narrow" because "you've got to cover the spectrum." Subsequently the students and instructors begin to consider examples that may serve to change Binary's mind. Binary still does not. He says, "I understand what ya'll are saying. It makes perfect sense to me what ya'll are saying. Don't get me wrong. What ya'll are saying is 100% correct. But I'm saying that this way still satisfies everything to me for an odd number." Time runs out for the class and the students are required to write one big idea for the day and one question they have for their exit tickets. Binary's big idea was "If no one agrees with you, you're wrong."

After class, Surreal and Dr. Amicable were very happy about the discussion students had regarding Binary's question. As students left the room, Even asked if she could stop by Dr. Amicable's office. Later on, Dr. Amicable and Surreal had this e-mail exchange:

Dr. Amicable: … We will need to chat about Even's concern. In brief, she felt that Binary was under attack today in class and it made her feel very uncomfortable. She recognizes that Binary may not have felt under attack, but she felt that for him. I appreciated her coming to share her feelings. Perhaps we can address the best ways to critique and also remain professional in our classroom setting (at the beginning of next class), but I'd like to chat with you about your thoughts.

Surreal: Okay we can chat. I did not think Binary was under attack. Only his idea was under attack! But I also recognize that students have never experienced mathematical argumentation and so it may be hard for some of the students to deal with it. Although I do not have immediate thoughts about what we would tell students, I think engaging in a dialogue with students may be productive.

Dr. Amicable: I agree. I did not see it as an attack on Binary either, but it wouldn't hurt to talk with the students about critiquing an idea rather than a person.

Notice that Surreal's initial thought was that Binary was not under attack. "Only his idea was under attack!" But are our ideas not also our selves? When we criticize another person's ideas, are we not criticizing the person as well?

The next day in class Surreal began by asking students to talk about their big ideas and questions from the previous class. Many of the students said they had conversations outside of class about Binary's idea. Others said they were trying to think of new ways to convince Binary of their point of view. Infinitely Repeating Decimal's big idea was "I'm really struggling to figure out a different way to represent that $l = 2k + 1$ and $m = 2k + 1$ only satisfies $l = m$. There has got to be a way though!" He expanded upon this idea during class.

> Infinitely Repeating Decimal: You know, to me, the discussion we had on Tuesday, it was very clear that set of restrictions only satisfies $l = m$, but to someone else if it is not clear—like they think that can be interpreted differently. I think you have an obligation to make sure that everyone is on the same page. Whether one person or another changes their position, I think it is very important that everybody agrees on a given definition or theorem, etcetera. But I couldn't figure out any other way to represent that, to possibly represent it in another way that might make it more clear.

The classroom dialogue continues:

Real: Yeah I think clearly we spent a lot of time in class on it the other day, and it's an important point. Generality, or proving that something is universally true, is more valuable than obviously proving specific cases. I think it is important that we help Binary get to that point. But I just wasn't sure exactly how to persuade him that we needed to differentiate the k's in that specific example to ensure that we have a general case that our proof covers all the bases.

Surreal: So it seems like Infinitely Repeating Decimal and Real are thinking, "We've got this idea and we want to convince Binary of it." And Binary felt, I think; how did you feel Binary? [Recall Binary's big idea: "If no one agrees with you, you're wrong."]

Binary: The big idea is like, yeah I agree with ya'll 100%. But ya'll are not listening to me when I say that. With Infinitely Repeating Decimal, what he's trying to say, I completely agree. But I'm not looking at it as just "$k$." When I see that definition of odd—For me, I feel like two times any number in the world plus one would be odd. So I'm feeling like, when I see a definition I am taking that definition plussing that definition to get this new definition. So when I see that I just take $k$ and I make it like $z$or like $2z + 1$ equals odd, and that's how I'm seeing it. [3] So even though the $k$ only satisfies $l = m$. To me, I feel like just the definition alone, no matter the variable, is enough to prove the theorem.

The dialogue continues. Dr. Amicable and Surreal discuss the nature of mathematical argumentation for mathematicians, and the importance of criticizing ideas rather than people.

Dr. Amicable: I know when I have been to math conferences, and mathematicians are presenting their work, sometimes it gets fairly heated in the room, right? … I have seen things that were similar to what we saw in class on Tuesday where it's back and forth like "I'm not sure I understand why you can say that because I see it this way." … Actually there is a lot of emotion involved in mathematics. … we need to keep thinking about one another's ideas, and really try to understand the other idea. The more we can understand someone else's idea, the deeper our own understanding will become. Alright?

Binary: I think no one really understands my idea. I think people are just so focused on 2k+1 that they are not looking at the bigger picture here.

Whole (interrupting): Well earlier before class today, Complex brought it up and we were talking about this ... And he brought it up that what you were saying break it down by the definition of variable—what the actual definition of variable is …

Over the course of two days, this was at least the fourth time that Whole interrupted Binary. Complex shares an idea, and Surreal, wanting to move on to other course content, asks Binary to explain his idea one last time.

> Binary: For me when I see $k$, I pretty much in my head, I put an odd number times $2$, and I put the $z$ which means any real integer, plus 1. So I know if I see $2z + 1$ that represents any possible odd number. So I put $(2z + 1) + (2z + 1)$ equals an even number. That's what's in my head. So when I see $z$ I know I can put in any number imaginable and get an even number. And for this example I feel like that was enough proof. You didn't need an example. You didn't need any other variables, and that is the idea that I had.

A couple weeks later one of the instructors, Surreal, in his research journal, wrote:

> Emotions today. I remember Binary hasn't talked the last two class periods. … We said we were not criticizing Binary, just his ideas. But Even took it as criticisms of him. Our ideas are our selves. Mathematics involves criticism of people's ideas and argumentation.

---

[3] It is unclear if Binary is referring to z as an integer or ℤ as the set of integers.

> Students are not ready for a class in which their ideas (and hence their selves) are criticized against the "objective" standard. … I guess what typically happens is that students are told the "right" ideas. Take away the creative act. … I have a vision of pre-service teachers afraid to speak in class. Mistakes are okay! Push our thinking forward as a community. Courage and humility.

## Discussion

For many students, the mathematics classroom and the learning of mathematics represent different and non-overlapping figured worlds with their other identities (Boaler 2000, Langer-Osuna 2015). In many of these cases, students do not see themselves as mathematical persons and struggle to understand the relevance of the mathematical ideas to other parts of their lives (Nasir 2008). Such failure in mathematical learning stems from the students' divergent normative and personal identities. Contrary to the examples in existing literature, we identify and examine in this paper a unique case study, where the student's (Binary) figured worlds of mathematics and his other identities seem inseparable (at least in the eyes of the student Even). The data revealed that Binary did not speak in whole class discussions for the two class periods following those described here. The convergence of Binary's normative and personal identities, instead of leading to successful mathematical learning, is also the key in hindering Binary's progress in his progression toward being a mathematician in the transition-to-proof course.

Binary emphasized that "no one really understands *my* idea" and "if no one agrees with you, *you're* wrong." When his ideas are challenged, a classmate Even also points out that Binary himself is being attacked. In these students' minds, the notion of mathematical idea, and thus an individual's normative identity, are one and the same as the individual's personal identity. There is no separation. However, for a professional mathematician (or mathematics educator as in the case of Dr. Amicable and Surreal), the separation is clear. Surreal points out that "[he] did not think Binary was under attack" and that "only his idea was under attack," and Dr. Amicable agrees. When discussing this separation with students, Dr. Amicable brings up her experiences at professional conferences where "mathematicians are presenting their work, [and] sometimes it gets fairly heated in the room." Dr. Amicable also explains to students that "there is a lot of emotion involved in mathematics" and that "[students] need to keep thinking about one another's ideas, and really try to understand the other idea." The focus of Dr. Amicable's point is clearly on the ideas rather than on individuals.

## Reflections and Questions

What can undergraduate instructors do so that students come to see mathematical ideas as part of their own identity in a productive manner? In terms of identity, we believe we can learn from a study of school mathematics done by Magdelene Lampert 27 years ago. Drawing from the work of Póyla and Lakatos, Lampert (1990) argued that courage and humility are mathematical virtues that students must develop if they are to participate in authentic mathematical discourse. Students must have courage to put forth their own ideas for examination by the classroom community. They must also have humility, and understand that their ideas may need to be revised in light of this public examination. More research is needed to understand how these virtues can be cultivated at the undergraduate level.

Boaler (2015) claimed that, "children are wrongly led to believe that all of the ideas already have been had and their job is simply to receive them" (p. 172). Do we teach undergraduates the same? Or do we support students in being creators of mathematical ideas? If the instructor tells students what the right ideas are, then it is up for the students to conform. Student identities may be in conflict when becoming mathematically competent means submitting to authority in a particular classroom (Cobb & Hodge, 2010). If students are to see mathematical ideas as part of their own identity, then the mathematics classroom needs to be a site of idea-generation rather than a site of indoctrination into what is "right." However, what is normative, and what it means to be mathematically competent, in inquiry-based classrooms is significantly different than what students experience in traditional courses. Students need more opportunities for idea generation in lower-level undergraduate mathematics classrooms so that by the time they reach their upper-level courses, they have more confidence in their own ideas, and hence their selves.

# Connecting the Study of Advanced Mathematics to the Teaching of Secondary Mathematics: Relating Arcsine to the Study of Continuity, Injectivity, Invertability, and Monotonicity

Keith Weber[1], Nicholas Wasserman[2], Juan Pablo Mejia-Ramos[1], and Tim Fukawa-Connelly[3]
[1]Rutgers University [2]Columbia University [3]Temple University

*Prospective mathematics teachers are usually required to complete courses in advanced mathematics to be certified to teach secondary mathematics. However, most teachers do not find these advanced mathematics courses as relevant to their teaching. In this paper, we describe a novel way to teach real analysis to future teachers that connects the content of real analysis to the activity of teaching secondary mathematics. We illustrate this method by describing a module that links the study of the relationship of continuity, injectivity, and strict monotonicity in real analysis to the teaching about the arcsine function and solving trigonometric equations in secondary mathematics. We describe a teaching experiment in which this module was implemented and present evidence of the efficacy of this instruction.*

*Keywords:* Inverse; Real analysis; Teacher preparation; Trigonometry

In the United States and elsewhere, prospective secondary mathematics teachers are required to complete extensive coursework in undergraduate mathematics to become certified to teach secondary mathematics. This coursework usually includes advanced upper-level coursework for mathematics majors (e.g., CBMS, 2001), with many institutions currently requiring that future mathematics teachers complete the equivalent of an undergraduate degree in mathematics (Ferrini-Mundy & Findell, 2001). However, many teachers find the advanced mathematics courses that they complete as irrelevant to their teaching (e.g., Wasserman et al., 2015; Goulding, Hatch, & Rodd, 2010; Rhoads, 2014; Zazkis & Leikin, 2010). In this paper, we focus on how we can design advanced mathematics courses to better meet the needs of prospective teachers.

## Relevant literature

### The influence of advanced mathematics on subsequent teaching

Although prospective secondary mathematics teachers are usually required to complete many courses in advanced mathematics, several scholars have noted there is little research on whether or how these courses influence prospective teachers' future pedagogical practice (e.g., Deng, 2008; Moriera & David, 2007; Ticknor, 2012). Here, we discuss two findings that suggest that completing such courses have only a modest effect on prospective teachers' pedagogical behavior. First, large-scale studies have found a weak relationship between the number of advanced mathematics courses that a teacher has completed and the achievement of that teacher's students (Darling-Hammond, 2000; Monk, 1994).

Second, when practicing secondary mathematics teachers have been asked how their experiences in advanced mathematics courses have influenced their teaching, many teachers claimed that their advanced coursework did not contribute to their development as teachers (e.g. Goulding, Hatch, & Rodd, 2000; Rhoads, 2014 Ticknor, 2012; Zazkis & Leikin, 2010). For instance, Zazkis and Leikin (2010) surveyed or interviewed 52 practicing secondary mathematics teachers about how their understanding of advanced mathematics influenced their teaching. The majority of the participants in Zazkis and Leikin's study claimed that they rarely used their knowledge of advanced mathematics in their teaching and few could cite any specific instances of their knowledge of advanced mathematics actually informing their teaching. Wasserman et al. (2015) found that this occurred even when the teachers demonstrated an understanding of the advanced mathematics that they were taught.

**Reasons why advanced mathematics may not benefit prospective mathematics teachers**

Researchers have proposed two reasons for why advanced mathematics courses might not benefit prospective mathematics teachers, even if the prospective teachers understood the content that they were studying. The first reason relates to what Klein (1932) has referred to as a "double discontinuity" between K-12 mathematics and advanced mathematics: the K-12 mathematics that students learn bears little resemblance to the advanced mathematics that is taught at universities and the advanced mathematics that prospective K-12 mathematics teachers learn in university is irrelevant to their future pedagogical practice. In the last decade, researchers have explored this double discontinuity in more detail.

A primary reason that advanced mathematics can inform the teaching of secondary mathematics is because there is an overlap between the content covered in advanced mathematics and the content and disciplinary practices covered in secondary mathematics (Wasserman & Weber, in press). For instance, a first real analysis course deals with concepts such as the real numbers, functions, continuity, and inverse functions, all of which are important concepts in high school algebra, trigonometry, pre-calculus, and calculus. Even though the same concepts and disciplinary practices are covered in advanced mathematics courses and secondary mathematics courses, the way these concepts and practices are treated differs significantly. For instance, Moriera and David (2007) presented a theoretical analysis of how advanced mathematics courses framed concepts from the secondary curriculum. Moriera and David noted that in advanced mathematics courses, concepts usually were introduced using a single canonical formal representation. For example, the familiar concept of fractions was defined as an equivalence class of ordered pairs in $\mathbf{Z} \times \mathbf{Z}\backslash\{0\}$ where $(a, b)$ and $(c, d)$ were equivalent if $ad = bc$. However, Moreira and David argued that effective teaching of secondary mathematics often required the use of multiple representations, many of which were visual but not necessarily formal. For example, fractions might be represented both numerically and pictorially as pie charts, which students will not usually witness in an advanced mathematics course. Similarly, continuity is defined in advanced mathematics formally in terms of epsilon-delta definitions. This treatment bears little resemblance to the informal graphical manner in which continuity is treated in secondary mathematics (e.g., Tall, 2012; Winslow, 2013). Consequently, teachers who study concepts such as fractions and continuity in advanced mathematics may see few implications for teaching secondary mathematics because the advanced treatment of these concepts will not meet the needs of their students (Deng, 2008).

A second disconnect between the activities that in which university students engage in advanced mathematics and in which instructors engage while teaching secondary mathematics (e.g., Ticknor, 2012). For instance, students in advanced mathematics spend a substantial amount of time studying and producing proofs. However these proofs would be usually be inappropriate to use in secondary mathematics classrooms because they employ technical vocabulary, abstraction, and methods of reasoning beyond what secondary students are capable of following (Wasserman et al., 2015). It is not obvious how studying and writing proofs should inform pedagogical activities such as designing activities, grading students' work, and providing informal explanations that a secondary student can understand. Further, prospective mathematics teachers often think these links are non-existent (Wasserman et al., 2015).

## Theoretical perspective

### Why prospective mathematics teachers must take advanced mathematics: A trickle down model

From our perspective, the anticipated benefits of having prospective teachers complete a course in advanced mathematics can be modeled by the "trickle down" model presented in Figure 1 that considers the relationships between i) advanced mathematics; ii) secondary mathematics; and iii) *teaching* secondary mathematics. This model highlights that most of the material covered in an advanced mathematics course consists of advanced mathematics, where little attention is paid to secondary mathematics. However, the hope is that the advanced mathematics provides an opportunity for the prospective teacher to better understand certain aspects of the content of secondary mathematics. For instance, by learning the zero divisor property about rings in abstract algebra, the prospective teacher may develop a deeper understanding for why you can solve polynomial equations by factoring polynomials (e.g., Murray & Star, 2013). Or by engaging in disciplinary practices such as proving, the prospective teacher may develop a better appreciation about the nature of those disciplinary practices (e.g., Even, 2011). Some instructors of advanced mathematics may be explicit about the connections between advanced mathematics and the content of secondary mathematics, but in often prospective teachers are asked to make the connections themselves. Next, the expectation is that prospective teacher's better understanding of the secondary mathematics content will inform their future *teaching* of mathematics. In our experience, exactly how prospective teachers should teach differently is rarely discussed in advanced mathematics courses. Prospective teachers are expected to use their understanding of advanced and secondary mathematics to improve their teaching on their own or the connections between advanced mathematics and teaching secondary mathematics will be provided in a subsequent education course (Murray & Star, 2013).

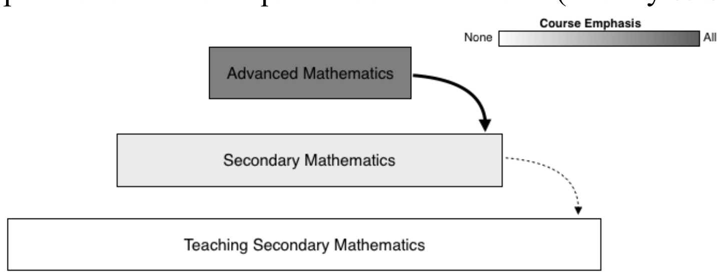

*Figure 1.* Implicit model for real analysis courses designed for teachers

### Our alternative model for teaching advanced mathematics to prospective teachers

We present an alternative instructional model for how advanced mathematics can be taught to prospective teachers in Figure 2. We begin by presenting a realistic pedagogical situation from secondary mathematics. From there, we discuss the secondary mathematical concepts that are in play and problematize the mathematical challenges inherent in the situation that we provide, highlighting fundamental issues that lie beneath the surface that are handled in real analysis. Next we discuss the issue in terms of real analysis. We cover the associated concepts with a formal treatment and make explicit what connections this has for high school mathematics. Finally, and importantly, we describe how this knowledge can inform our response to the initial pedagogical situation that we posed in the beginning of the lesson.

We designed our pedagogical situations to satisfy three criteria. First, there should be a relationship between the real analysis being taught and a topic from the Core Curriculum State Standards in Mathematics (CCSSM, 2012). We do this so that the topic is present in the secondary mathematics curricula and we are not merely preparing students to engage in enrichment activities. Second, the pedagogical situation invites or requires students to engage in what Deborah Ball and her colleagues refer to as a "High Leverage Practice" (HLP), where an HLP "is an action or task central to teaching" (TeachingWorks, 2013). HLPs include providing explanations or models to explain a concept and analyzing and critiquing instruction for the purposes of improving it. We used HLPs so the teachers were engaging in activities that are central to their practice. Finally, we strove to create situations that PSTs would perceive as authentic.

## Research methods

### Broad research context

The data reported in this paper are part of a larger study supported by the National Science Foundation. Our analysis focuses on the 7th of our 12 modules. The real analysis covered in this module include definitions and theorems concerning the relationship between continuity, injectivity, and strict monotonicity. Particularly important is the theorem that a continuous function is invertible on an interval if and only if the function is strictly monotonic on that interval. The secondary mathematics that we cover involves introducing the arcsine function to a trigonometry class and grading and providing feedback on a student's incorrect solution to a trigonometric equation. Hereafter we refer to this model as the Trigonometry Module.

In this paper, we report on the third iteration of a teaching experiment in which the Trigonometry Module was implemented. The Trigonometry Module was initially informed by a study in which we probed 14 prospective and in-service teachers understanding of inverse and the arcsine function as well as the relevance of real analysis for understanding these topics (Wasserman et al., 2105). We developed and implemented the Trigonometry Module, first in an unpublished constructivist teaching experiment (Steffe & Thompson, 2000) with three PSTs and then in the context of a university real analysis course with 32 prospective and in-service teachers (Wasserman, Weber, & McGuffey, 2017). Following the principles of design research (e.g,. Cobb et al., 2003), we used our analysis of the first two iterations of our Trigonometry Module to refine our models of PST's thinking, how we anticipated the PSTs would engage in our activities, and the activities themselves. For the sake of brevity, we do not describe these refinements here, but will do so during our talk.

**Data collected from this iteration**

The third iteration of the Trigonometry Module occurred at a large state university in the northeast United States. At this university, mathematics education undergraduates were required to complete a mathematics major and a real analysis course was a requirement for this major. In spring 2017, the mathematics department offered x sections of real analysis, one section of which was advertised as a special section that was taught by our research team; the third author of the paper was the lead instructor of the course. This section was advertised as a special section of the course for prospective teachers, although the course was open for all mathematics majors. In total, 17 students enrolled in the course, 13 of these students were in the mathematics education program, two expressed an interest in teaching, and two did not express an interest in teaching.

The class met three times a week. Roughly one out of the three weekly class meetings was devoted to implementing a real analysis module, one of the three weekly class meetings consisted of a traditional lecture covering real analysis content that we did not find relevant to teaching secondary mathematics (e.g., compactness and uniform continuity), and one of the three weekly class meetings was a workshop in which students were given practice and assistance solving problems and writing proofs. When we implemented our modules, we had the students sit in four groups of three to five students. For three of the groups, a member of the research team observed and facilitated the group's discussion. We collected the following data: We videorecorded all of the instructor's actions, we audiotaped each group as they worked on the activities in the module, we had electronic copies of the students' reflective journal entries, performance on a pre-test and post-test, and their homework, and we archived the instructor and researchers' field notes.

**Analysis**

Following the principles of design research (Cobb et al., 2003), prior to conducting our instruction, we had anticipated models for how the PSTs would understand the central concepts of our module, such as inverse function and the arcsine function, desired understandings that we wanted students to develop by the end of the module, and a hypothetical learning trajectory (Simon, 1995) for how students' engagement with the module's activities would foster these desired understanding. For each activity in the module, we had anticipated behaviors for how the PSTs would engage with each activity. These theoretical models were informed by experiences teaching trigonometry (Weber, 2005), prior laboratory studies in which we interviewed PSTs about their understanding of inverse functions and the arcsine function (Wasserman et al., 2015), and significantly by the first two iterations in which we implemented the Trigonometry Module. In the retrospective analysis (Cobb et al., 2003), we analyzed the extent that PSTs' actual behavior aligned with our anticipated behaviors and developed theories to account for any revisions.

In our analysis of the pre-test and post-test data, we first coded PSTs' responses for mathematical correctness. One item asked students how they would introduce the arcsine function to their class. We noted whether PSTs said in their explanations that the arcsine function was the inverse of the sine function with the domain of $[-\pi/2, \pi/2]$ (a correct response) or that the arcsine function was the inverse function of sine with no domain restrictions (an incorrect response). Another item presented PSTs with the a situation in which a student presented the following solution to a trigonometric equation:

$$\begin{aligned} \sin(2x) &= .7 \\ \arcsin(\sin(2x) &= \arcsin(.7) \\ 2x &= 0.7754 \end{aligned}$$

x = 0.3877 + 2πk

This solution contains two mistakes. The correct solution is x = 0.3877 + πk and 1.1831 + πk. So the student work contained two errors. When taking the arcsine of both sides, the student neglected one of the solutions in the [-π,π] interval (π – arcsin(.7) = 2.3662) and the student added the 2pk at the last step, rather than the third, thus missing solutions of the form 0.3877 + πk when k is an odd integer. In evaluating the PSTs response to the student's work, we documented which mistakes, if any, the PST identified. After coding for the mathematical accuracy of the PSTs' responses, we analyzed the ways in which the PSTs would respond to students qualitatively and interpretatively using thematic analysis (Braun & Clark, 2006).

## Results

### Lesson and behaviors

Given space constraints, we give only a quick synopsis of what transpired in our implementation of the Trigonometry Module, but a more extensive analysis will be presented in our talk. As we anticipated from our prior research (Wasserman et al., 2015), PSTs did poorly on the pre-test. Most thought that sin $x$ and arcsin $x$ were inverse functions and few spotted either of the mistakes in the student solution that they were asked to evaluate.

To step up to secondary mathematics, the instructor provided the students with the definitions of injective functions and (strictly) monotonic functions. Then PSTs were asked to explore the relationship between continuity, strict monotonicity, and invertability by debating about whether four statements were always true, sometimes true, or never true. For instance, one statement was that if a function was strictly monotonic on an interval, then it had an inverse on that interval. (This is always true). The purpose of these activities was to engage PSTs in "productive struggle" as they wrestled with these ideas so that the subsequent real analysis would be motivated. Next, we stepped up to real analysis by having the lecturer present two theorems. The first theorem was that strictly monotonic functions were always invertible. The second theorem was "Let $I \subseteq \mathbb{R}$ such that I is an interval. Suppose f(x) is a continuous function from A to $\mathbb{R}$. Then f(x) has an inverse if and only if f(x) is strictly monotonic."

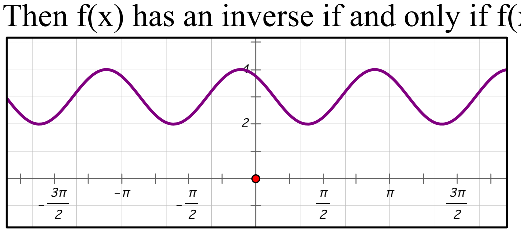

*Figure 3.* Graph of *f(x)* that students were asked to consider

We had the PSTs step back down to secondary mathematics. PSTs were given a worksheet specifying that "If we want an inverse for a continuous real-valued function *f(x)* but *f(x)* is not one-to-one, **by convention,** we seek to find the largest interval *A* on which *f(x)* is monotonic such that *A* contains 0 and at least one positive number". They were then asked to revisit the relationship between sin x and arcsin x. They were also shown a graph of *f(x)* in Figure 3 and asked to identify the conventional domain restriction in which *f(x)* would have an inverse, if *f(x)* would have an inverse on domains such as [π/4, π/2], and how they could justify their answers using the theorems that were previously discussed.

The lecturer presented a proof of the following theorem: Suppose *f(x)* is a continuous real-valued function *f(x)* that is one-to-one on an interval *I*. Suppose $a \in f(I)$. Then, $x = f^{1}(a)$ is unique solution to the equation $f(x)=a$ in the interval $I$. The lecturer discussed how in secondary mathematics, periodicity and symmetries were used to find the solutions to equations of the form $f(x) = a$ outside of the domain in which $f(x)$ was conventionally restricted. Finally, in stepping back down to practice, in the post-test, participants were again asked how they would introduce sine to the students and then they were asked to provide feedback to students who solved the trigonometric equation cos(3x) = .5, making errors similar to the students on the pre-test.

**Pre-test and post-test comparison**

On the pre-test, when asked how they would introduce arcsine to students, only one of the 10 PSTs mentioned domain restrictions. Eight PSTs said they would begin their presentation explaining the nature of inverse and that arcsin x was the inverse of sin x with no mention of domain restrictions. On the post-test, nine of the ten PSTs explicitly mentioned domain restrictions (with the remaining PSTE vaguely saying that he would explain that "arcsin x undoes the sine function to a certain extent"). Many PSTs used creative student-centered activities to illustrate the points (e.g., presenting students with the graph of sin x on the blackboard and inviting students to erase parts of the graph until the function had an inverse).

On the pre-test, only one PST found both errors in the student-generated solution, one PST found one error, one PST gave an ambiguous response, and the other seven PSTs found no errors, focusing instead on issues such as the student "rounding too early". On the post-test, seven PSTs found both errors, two PSTs found one error, and one PST gave the same ambiguous response that he did on the pre-test. The PSTs generally provided feedback to the student by pointing out how arcsin x was only the inverse of the sine function on its restricted domain.

## Summary and Discussion

In this proposal, we presented evidence that by studying real analysis while participating in our Trigonometry Module, PSTs were better able to engage in high leverage practices about teaching inverse trigonometric functions. This includes providing an explanation or a model for explaining what the arcsine function is as well as evaluating and providing feedback to a students' argument. We have provided evidence that PSTs lacked the mathematical knowledge to engage in these HLPs effectively before our module; they gave mathematically incorrect explanations about the meaning of arcsin x and they did not recognize mistakes that a student made in his solution to a trigonometric equation. After the class, most PSTs did not make these errors. In the talk, we will also document how they provided pedagogical responses that were not only mathematically correct, but thoughtful and appropriate.

More broadly, we have described a pressing issue—PSTs are required to take advanced mathematics courses but are not benefitting from doing so. We have described an innovative method for addressing this problem by linking the content of real analysis to the high leverage practices that PSTs must engage in. Finally, we have provided an illustration of a module built in accordance with our theory and refined from several iterations of design research, along with evidence that we have achieved our desired learning goals when we implemented this module. Consequently, what we are presenting is a theoretically driven existence proof that our innovative model has the potential to make advanced mathematics relevant for practicing teachers.

# An APOS Study on Undergraduates' Understanding of Direct Variation: Mental Constructions and the Influence of Computer Programming

Cynthia L Stenger James A Jerkins Jessica E Stovall Janet T Jenkins
University of North Alabama

*This study explores undergraduates' understanding of direct variation before and after instruction using computer programming to teach generalization over the concept. Based on an initial genetic decomposition for direct variation, the four math/CS researchers developed a research design that included lessons featuring computer programming and mathematical proof writing activities. This study shares results from an application of the instructional research design to N=33 undergraduates interested in teaching. Lessons were from a secondary education math methods course. Follow up interviews were conducted with seven participants. The analysis, using APOS as a framework, categorized mathematical behaviors at the Action, Process or Object level. The study identified obstacles that may have prevented progression through deeper levels of understanding such as deficient prerequisite skills and an affinity for routine algebraic manipulation rather than considering underlying relationships. The student data demonstrated how computer programming activities influenced undergraduates' mental images.*

*Key words:* Direct Variation, Generalization, Computer Programming, Pre-Service Teachers

## Introduction

The ability to generalize is considered an essential skill for reasoning about and deeply understanding mathematical concepts by mathematics education researchers. Many researchers have investigated how to explicitly induce students to develop generalizations in the context of mathematical explorations (Tall et al., 1991). Many mathematics education researchers believe that using computer programming activities designed to parallel the construction of an underlying mathematical process may stimulate or accelerate the development of the associated mathematical construction (Dubinsky and Tall, 2002; Authors, 2012). In prior work, we developed an explicit method for motivating students to generalize into mathematical constructions using computer programming exercises and proof writing based on the theoretical perspective of APOS theory. In this study, we extend our previously published preliminary report examining student's understanding of direct variation (Authors et al., 2016). The research questions we investigate are: (1) Does our genetic decomposition of direct variation adequately describe the observed students' constructions; and (2) Do our instructional treatment's computer programming activities influence students' mental constructions as described in the genetic decomposition?

## Proportional Reasoning and Theoretical Framework

Mathematics education researchers have dedicated considerable energy to proportional reasoning with elementary and middle school students, high school students, undergraduates and graduates. Collectively these researchers have shown that students and adults have difficulty with problems involving proportional reasoning (Noelting 1980; Vergnaud, 1983; Hart, 1988; Lesh et al., 1983; Kaput and West, 1994). We found that explanations for the difficulties undergraduates experience with the concept of direct variation are sparse in existing literature. Hence this study will contribute to the literature on how undergraduates understand direct variation by examining students' mental constructions and exploring how computer programming activities support the development of mathematical constructs.

The theory of reflective abstraction was described by Piaget (1985) as a two-step process, beginning with reflection on one's existing knowledge, followed by a projection of one's existing knowledge onto a higher plane of thought. Further, Piaget (1985) and Dubinsky et al. (2005a, 2005b) wrote that during the process of cognitive development, reflective abstraction could lead to the construction of logico-mathematical structures by the learner. The conviction that reflective abstraction could serve as a powerful tool to describe the mental structures of a mathematical concept led Dubinsky to develop APOS theory.

In APOS theory the mental structures are Action, Process, Object, and Schema. A mathematical concept develops as one acts to transform existing physical or mental objects. Actions are interiorized as Processes and Processes are encapsulated to mental Objects. It is tempting to view the progression as linear, but APOS practitioners hold that learners move back and forth between levels and hold positions between and partially on levels. In other words, the progression is not linear. This nonlinear behavior and the resulting mental structures may explain the different ways learners respond to a mathematical situation (Arnon et al., 2014).

## Genetic Decomposition for Direct Variation

The genetic decomposition was developed as a conjecture of the mental constructions, Actions, Processes, and Objects, that may describe the construction of mental schema for the concept of direct variation as it develops in the mind of the learner. The genetic decomposition served as a model for the design of this research study as well as the analysis of the results. It was also the basis for the computer activities in the lessons that were developed for the students. The pervasive impact of the genetic decomposition is consistent with an APOS theoretical framework (Asiala, et al., 1996).

The prerequisite concepts to start the construction of direct variation are an Object conception of multiples of a number, a Process conception of variable and an Object conception of constant. The notion of equality (=) needs to be used as a relation between corresponding elements of two sets. The learner must have a Process level conception of one-to-one correspondence between two sets X and Y, and be able to recognize and compare corresponding members.

### Action

The Actions needed are simple algebraic manipulations involving division and/or multiplication of numbers. The learner will apply the Actions to substitute in known values and solve for an unknown value in the equation. For example, she or he might find a constant ($k$) by dividing the first value ($x$) by the second value ($y$), and then multiply a subsequent number by $k$ to find the answer. Each activity is viewed by the learner as a single instance, isolated from subsequent similar instances. At this level, $k$ is viewed as a specific value, not as an arbitrary constant. The learner may or may not see the relationship between $x$ and $y$, they may work several examples without seeing a general pattern.

The same Actions described above can take place in different settings with different representations of the relation, such as a table, mapping, graph, and an analytical example.

### Process

These Actions are interiorized into Processes as the learner repeats the Action with different values of $k$ or different values of $x$ or $y$. They might iterate through values of $x$, but instead of checking specific numbers, the student can determine in general and in his or her imagination, for example, that as values of $x$ increase, corresponding values of $y$ will increase. The learner recognizes a general behavior that $x$ and $y$ vary.

As the learner iterates over $x$, this Process with $x$, $y$, and $k$ is coordinated into a new Process where the learner can view a sequence of numbers X and can determine if elements $x$ in a set X vary with corresponding values $y$ in a set Y without multiplying each value of $x$ by $k$ but by imagining each value of $x$ as a multiple of its corresponding value of $y$. While they imagine multiplying by $k$ or dividing by $x$ and $y$ to get $k$, they may not see that $y$ is locked into a value by $x$ and $k$, into a pattern that is carried out no matter what value is given. They may or may not see the rate of variation as a constant rate.

**Object**

The Process of checking if elements of a sequence of numbers X are equal to a constant multiple $k$ of corresponding values of Y, (or quotient of $x$ and $y$ is constant) encapsulates into an Object when the individual is able to apply Actions or Processes to it. The Actions that can be carried out on the Process conception of direct variation include comparing and contrasting it with other generalized properties of multiples such as doubling or halving, and to interpret the role of varies directly in the possibility that the two sets X and Y have a constant $k$ when any corresponding elements are divided. For example, they may understand that the ratio between corresponding elements of X and Y is a constant $k$. They may double the values in X and observe that values in Y are doubled. Then they may halve the values in X and observe that values in Y are halved, and so on. The learner may generalize the process that the subsequent values are determined by $k$, the constant of proportionality, locked in a pattern that is carried out no matter what value of $x$ you select. Another Action on the process may be reversing the process to determine X when $k$ and Y are known.

## Methodology

We applied our instructional treatment to the concept of direct variation for this study. Our investigation was carried out with 33 upper level undergraduates who were interested in teaching mathematics. Each subject participated in a complete lesson including the pre-test, response sheets, and post-test. The format of the lesson was as follows. A brief introduction to the programming environment was given along with the code template shown in Figure 1. A cursory review of the relationship distance is rate times time ($d=rt$) was also presented. Using the code template with an increasing rate and fixed time, participants were asked to complete the program to output the associated distance. Learners were encouraged to experiment with their computer programs and make observations about any relationships. Once this initial table was constructed, the participants were ushered through a series of program modifications and written responses. For example, they were asked to add columns to their programs to depict the doubling or halving of the rate with time fixed and the resulting distance. Programs were modified to show the results of doubling, tripling, and halving the rate with time fixed. Written responses to questions and reflections on their observations were recorded by the participants on their response sheets including generalizations of behavior. Observations on variation and direct variation were solicited as general expressions and participants were taught how to denote the general expressions in mathematical language. For example, participants might observe that if rate doubles and time is fixed, then distance doubles. The instructional treatment was designed so that repetition with various program modifications would stimulate the desire to generalize the observed behavior and make conjectures about the mathematical construct. The final stage of the lesson involved making conjectures and convincing arguments. Participants were shown how to use general expressions to support, or refute, a conjecture using mathematical language. They were then asked to attempt their own convincing arguments with the general expressions they recorded during their inquiry. All of the participant's responses were collected on written response sheets during the lesson. Additional data was collected in the form of interviews. We recorded interviews with seven of the participants which were then transcribed and analyzed. All of the collected data was reviewed and scored using APOS theory. We devised a ranked set of scores to denote pre-action, action, process, and object levels for the direct variation concept based on our genetic decomposition and recorded scores for each subject's pre-test, response sheets, post-test, and where applicable interview data. In the event that authors disagreed, a discussion and further analysis of the data was used to reach consensus.

```
print("r", "t", "d", sep="\t")
t = 5
r = 1
while r < 11:
  print(r, t, "?", sep="\t")
  r = r + 1
```

*Figure 1. Computer programming template for lesson*

## Results

In the discussion that follows, R denotes the researchers and U0001 to U0033 identify undergraduates. Results are presented that show how student mathematical behavior correlated to the genetic decomposition. Results also illustrate the influence of computer programming on students' ability to generalize over the concept of direct variation.

### Action

Student responses to questions were scored at Action level based on the description in the genetic decomposition. Action level responses were analyzed by the authors for common mathematical behaviors. Student responses during the lesson and in interviews following the lesson fell into three categories of mathematical behavior:

- Category 1. Using specific values or thinking about specific instance
- Category 2. Balancing the equation
- Category 3. Substituting a value in the equation

**Action Category 1. Using Specific Values or thinking about specific instance.** In the follow-up interview, the researcher asked the student to explain their thinking on a response.

R: What were your thoughts on this? (pointing to post-test response)

U0001: I like having values just cause[sic] it helps distinguish what we're already going over like variables are fine but when I actually have a number to place with the variable it makes it easier to keep up with where I'm going and what I'm doing. So I would place a random value somewhere just so I know how to get from point A to point B.

**Algebraic manipulations of a general expression.** It is not unexpected that students at the Action level for a concept would use specific values to direct their problem solving. Surprisingly, this study found that ten of the eleven Action level students did not rely on specific values but performed algebraic manipulations on a general formula. What looked like a general argument, which might imply an Object conception, was instead an explicit, step-by-step procedure to balance the equation. This is similar to Frith, et al. (2016) who found students could work proportion problems applying “mechanical knowledge or algorithmic procedures” without actually reasoning about the relationship. Mechanics of algebra included either trying to balance the equation (9 instances) or to substitute general expressions into the equation (8 instances). Students at this level did not meet the prerequisite skills, as defined in the genetic decomposition, two students were at the pre-action level for the concept of multiples, eight did not meet the prerequisite process level for the concept of variable, two did not meet the prerequisite for constant, and one did not meet the prerequisite for the concept of one-to-one correspondence.

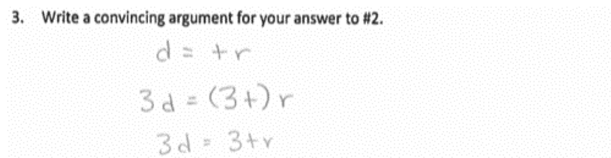

*Figure 2. Action Category 2 – Balancing the equation*

The snip of student U0005 in Figure 2 shows a typical response in Action Category (2). The student carried out the step by step procedure, multiplying both sides of the equation by a constant, e.g., if *d=tr* then *3d=(3t)r*. This student wrote in their response of a “need to balance”, as they multiplied both sides by 3.

The snip of student U0029 in Figure 3 shows a typical response in Action Category (3). The student carried out the step-by-step procedure, substituting *3r* for *r* in the equation *d=rt*. This work demonstrates a lack of the prerequisite requirement for a process understanding of variable, as *d* takes on the role of the first distance and the second distance.

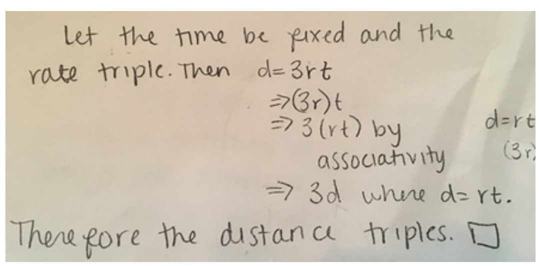

*Figure 3. Action Category 3 – Substitution*

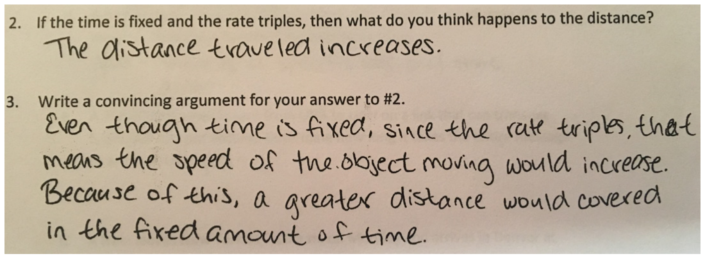
**Process**

Of the 14 students at the process level, 10 demonstrated the notion of varies without demonstrating a notion of varies directly. Student concept of varies fell in two categories: (1) *x* increased (or decreased) then *y* increased (or decreased) or (2) *x* increased (or decreased) by some multiple, then *y* increased (or decreased). In either case, whether or not they repeated the given information about *x*, for their part in the solution they did not mention the multiple. They did not indicate an awareness of the “locked relationship” between *x* and *y* that is determined by the constant of proportionality *k*.

A typical response for varies in Process Category (1) was demonstrated by student U0003 who described a dependence between rate and distance where the rate increased then the corresponding distance “will increase as well”. The parenthetical statement by the student “The same time frame in a quick pace" indicated they were imagining a process in their mind, where rate and distance varied in a coordinated way.

The snip of work from U0007 in Figure 4 shows a typical response for varies in Process Category (2). The student described a dependence between rate and distance where the rate tripled then the corresponding distance traveled increased. They are imagining a process where an object is moving at a faster speed so "a greater distance would be covered in a fixed amount of time". There was a Process in their mind where rate and distance varied in a coordinated way.



2. If the time is fixed and the rate triples, then what do you think happens to the distance?
The distance traveled increases.

3. Write a convincing argument for your answer to #2.
Even though time is fixed, since the rate triples, that means the speed of the object moving would increase. Because of this, a greater distance would covered in the fixed amount of time.

*Figure 4. Process Category (2) - Varies*

In neither case did the students in Process Category (2) demonstrate a knowledge of the "locked in" relationship between $x$ and $y$ that is a part of direct variation and is fully determined by the constant of proportionality.

**Object**

The responses that indicated Object level understanding of direct variation, according to our genetic decomposition, fell in two categories: (1) Relationship between X and Y locked in place by $k$, (2) Elements of X were dependent on values in Y and the dependency determined by $k$. Although 32 of the 33 students correctly identified two general expressions relating $d$, $r$, and $t$, only two students demonstrated an Object level knowledge of the fixed relationship between X and Y, determined by $k$, before the instructional treatment.

### Influence of Computer Programming on Generalization

The influence of writing computer programs to explore the concept of direct variation was demonstrated by 16 of the 33 students. These students referenced their programming activities in their responses, in multiple instances, even though neither the question (nor the instructor) suggested responding with program code. Students naturally and intuitively adopted language from their programs. Twelve of the sixteen, who referenced programming in their responses concerning general expressions, improved at least one level during the instructional treatment, while two stayed the same and two went down a level. The students who referenced their programs when asked to give a general expression fell into two categories: (1) Computer Input: Print Statements and (2) Computer Output. In both cases illustrated below by typical responses, the students imagined generating code in their mind, and copied their imagined code onto their response sheet.

The response from Student U0007 in Figure 5 shows a typical response for Computer Category (1). The student imagined writing a computer program with the displayed print statement as an input statement. The response below was after the first computer programming activity. The print statement was stuck in between the answers for Response #3 and Response #4. It appears as a transition between the English statement "the distance is also doubled" and the general expression *(2r)t*. The transitory work is seen as the student wrote “*d = r2*t*” above the print statement “*(r*2)*5”*.

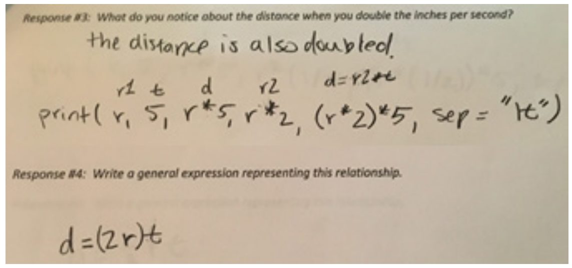


*Figure 5. Category (1) – Computer program*

Two students demonstrated evidence that running a computer program in their mind and reflecting on the output in table form was a transition from English language to mathematical language. The response from Student U0002 demonstrated the typical response for Computer Category (2) by constructing a table for Response #5 in the left margin after concluding, “halving the rate also halves the distance”. The same student then responded in Response #6 with “d2 = $\frac{rt}{2}$.”.

In the following interview snip, U0004 described how they developed a “mindset of generalizing” during the instruction. They did not demonstrate a general notion using variables in their expression until after the first programming activity.

R: Just describe when you were writing the last couple of proofs or either one of the proofs
U004: I was thinking more of just the letters and generalizing it after we had done those together and the ones on the other response sheets because I think I was in a mindset of generalizing it…
R: Right
S: So the way I wrote it out, I put more notation the second time on the post-test.

## Conclusion

In this study, students explored direct variation through an explicit method for teaching generalization that uses computer programming and convincing arguments. The researchers found that scoring and assessing undergraduates' conception of direct variation was complex due to the task-dependent and context-dependent nature of conception. The genetic decomposition adequately described the students’ constructions observed in the data. We noticed students at the Action level tended to manipulate algebraic expressions without understanding the underlying structure. We found many students in our study have a notion of vary but not directly varies. We observed some students who needed to construct the property vary, at the Process level, before constructing the property varies directly, at the Object level and conjectured that a notion of vary is a prerequisite to directly vary. Therefore, we have modified our genetic decomposition to account for this in future studies. We found that prerequisite deficiencies corresponded with the inability to progress through levels of understanding as measured by APOS. We found that students naturally turned to their computer programs to help find general expressions for the concept. Some students considered the inputs to their programs and others reflected on the outputs of their programs when asked to write general expressions for observed relationships. The programming activities influenced students and served as a catalyst to move from purely English descriptions of their conceptions to using mathematical symbols and a “mindset of generalizing”.

Building Models of Students' Use of Sigma Notation

[1]Kristen Vroom, [1]Sean Larsen, & [2]Stephen Strand

[1]Portland State University, [2]California State University, Chico

*Summation notation is a widely-used standard that can represent all kinds of sums. Despite its utility, the literature on this topic points to the notation being difficult for students. Our research project gives insight into how students think about summation notation and why it is so challenging. This report builds off of the first phase in our project, which proved the existence of students' uncertainties with elements of the notation. Survey data from 285 undergraduates suggested that uncertainties are common amongst students. We also found that the act of encoding a sum in sigma notation is more cognitively demanding than interpreting a summation notation expression. In this paper we present models of students' ways of thinking about summation notation.*

*Keywords:* Summation notation, calculus, cognitive models

Sigma Summation notation is a widely-used standard for expressing all kinds of sums, from infinite series to probabilities to approximate area under a curve. However, there is little in the research literature regarding this notation. There is consensus that the notation presents difficulties for students. For example, we were able to find papers discussing issues that contribute to student struggles in statistics (Ramsey, 1999) and engineering (Armstrong & Croft, 1999) that mention summation notation. Little and Jones (2010) provide empirical evidence that the notation is challenging for students and they observed that, "The use of algebraic language such as sigma notation and iteration formulae added substantially to the difficulty of questions" (p. 141). However, Little and Jones' study provides no information regarding why students might struggle with this notation or how they might come to make better sense of it.

Summation notation appears in some research articles on infinite series (e.g., Martínez-Planell, Gonzalez, DiCristina, & Acevedo, 2012) and integration (e.g., Sealey, 2014) but is not the focus of these studies. Martinez-Planell et al., focus on the distinction between seeing an infinite series as an infinite sum and seeing it as the limit of a sequence of partial sums. They do not investigate possible challenges involving the sigma notation used to represent partial sums and infinite series. Sealey presents a framework for understanding Riemann sums that includes a "summation layer" but acknowledges that her study, "did not require students to use the notation of $\sum_{i=1}^{n} f(x_i)\Delta x$ to represent the Riemann sum, nor did it explore students' understanding of this notation" (p. 243). Additionally, Brijlall and Bansilal (2010) proposed a genetic decomposition of the Riemann sum that explicitly attended to summation notation. Specifically, they included two abilities related to summation notation in their model proposing that students who understand Riemann sums 1) "can represent finite or infinite sums as expanded sums, when given its compact form using sigma notation" and 2) "can represent finite or infinite sums in compact form using sigma notation when given its expanded representation." (p. 133-134). While this study provides no information about whether (and if so, why) students struggle with these two activities, this pair of activities provides a structured way to think about what it may mean for students to be able to make sense of and work fluently with this notation.

What little information exists suggests that students struggle with summation notation and that this likely contributes to difficulties with concepts that rely on this notation such as probability, infinite series, and integration. However, the research literature contains very little insight into *how* students think about this notation and *why* it is challenging. Our research project endeavored to investigate how students think about summation notation and was completed in two phases.

In the first phase, summation notation was not the focus. We conducted an exploratory design experiment with two students, Betty and Kathy, where we actively investigated post-calculus students' understanding of integral. During the experiment, summation notation came up and the students displayed some interesting thinking about how the notation functioned. When we investigated their thinking we found that Kathy and Betty were aware that sigma notation provides a shorthand way to write a sum. They seemed keenly aware of the kinds of information needed to expand a sum (or that should be captured in the notation when encoding a sum). However, they were unsure exactly how this information was supposed to be recorded in the notation. For example, they were uncertain whether the value on top of the sigma was supposed to represent the terminal input value or the number of terms (Strand, Zazkis, & Redmond, 2012).

After working with Betty and Kathy we wondered if their uncertainties are common amongst other undergraduate students. For this reason we designed a second phase specifically targeting student thinking about summation notation. The results from the second phase of our project will be the focus of this paper. We aim to address the following research questions: (1) If students do struggle with sigma notation, what kinds of difficulties do they have and how might such difficulties be explained? (2) Is there a difference in difficulty between expanding (interpreting) sums expressed in summation notation and compressing (encoding) expanded summations using summation notation?

## Methods

### Survey Instrument

Our survey instrument consisted of three tasks. The first task involved encoding a Riemann sum, which required the student to express the input variable of a function as a function of the index variable. The second task was a basic encoding task in that the index variable could serve as the input variable. The third task was an interpretation task. We conjectured the first task was the most difficult and the third task to be the least difficult. This study focuses on student responses of the second and third tasks. Here we will describe the two tasks (in reverse order) and the rationale for their design.

The Interpreting Task (Task 3) instructed students to write out the expanded ("longhand") sum represented by a given sigma notation expression (Figure 1). We expected a student adhering to the standard convention of summation notation to write, "$(2+1)^2+(3+1)^2+(4+1)^2+(5+1)^2+(6+1)^2+(7+1)^2$." Specifically, the "2" below the sigma represents the starting value of the index, the "7" above the sigma represents the terminal value of the index, and each step in the index is incremented by 1. We chose to start the index at two so that we would be able to tell if the seven above the sigma sign was interpreted as the number of terms or the terminal value of the index. Betty and Kathy vacillated between these two interpretations of the index and so we wished to know how common this particular difficulty was. In general we wished to see what kinds of errors students might make in interpreting the different elements of summation notation (the index, the sigma, the summand, the numbers above and below the sigma).

**Task 3:** Write out the given summation longhand:

$$\sum_{k=2}^{7}(k+1)^2$$

*Figure 1. The Interpreting Task.*

The Encoding Task (Task 2) asked students to encode the sum of the first ten odd integers using summation notation (Figure 2). There are many possible expressions that would follow the standard convention of summation notation but an example would be "$\sum_{k=1}^{10} 2k-1$ " or possibly "$\sum_{k=0}^{9} 2k+1$". With this task we were interested in what challenges encoding with summation notation would present to the students. We were also interested in exploring the relative difficulty of encoding and interpretation tasks.

**Task 2:** Using $\sum$-notation, write an expression for the sum of the first ten odd integers.

*Figure 2. The Encoding Task.*

The Interpreting and Encoding Tasks were exactly the same as tasks given to Betty and Kathy during the design experiment. We chose to give these tasks to Betty and Kathy so that we could investigate what kinds of errors students might make with summation notation in less complex contexts than the first task. The consistency across the two phases of the projects allowed us to leverage Betty and Kathy's reasoning when we analyzed the survey data.

**Participants**

Two hundred eighty five undergraduate students participated in the second phase of our study. These students were enrolled in a course in the calculus sequence, differential equations, linear algebra, or a course in an undergraduate advanced calculus sequence and received extra credit for their participation. We invited students enrolled in this set of courses in hopes of receiving responses from students with various summation notation experiences. In total, 567 students were enrolled in at least one of 15 sections of the 8 courses. 50.3 percent (285/567) of the students completed at least part of the survey, 42.3 percent (242/567) of the students completed both Task 2 and Task 3.

**Analysis**

There are four stages of analysis for the Interpreting and Encoding Tasks. During the first stage we went through each survey and counted how many had errors of any kind; these were sorted by task. In the first pass we looked to see if each solution was perfect; if it was then the response was marked 'correct' and if not it was marked as 'incorrect'. We did not attempt to analyze or describe the errors at that stage.

In the second stage of analysis we recorded error types made on the Interpreting Task. To do so we first read each survey's responses and discussed common errors. We came up with 6 categories of error types, including: gave a sum with seven summands, substituted only even values for $k$, not enough summands, used sigma with the expanded sum, used only one value as the input, and other.

In the third stage we turned to the Encoding Task. While coding error types for the Interpreting Task involved low inference, we felt this would not be the case for the Encoding Task. For instance, one student produced the following expression: "$\sum_{i=0}^{10} i + 1$" (Figure 4). We could conjecture that the student incorrectly substituted index values starting at $i = 0$ and ending at $i = 10$; however, this would rely heavily on our interpretation. Later, we will argue that this is probably not how this student would explain their encoded sum. In order to match the level of inference used to code the Interpreting Task, we recorded each piece of the given summation expression. For instance, we recorded what (if anything) was written below and above the sigma. We also recorded the type of expression within the sigma into the following categories: outputs odd values when incrementing the inputs by 1 (e.g., $2x - 1$), outputs odd values when not incrementing the inputs 1 (e.g., $x + 1$), and seemingly unproductive expression (e.g., $\frac{(-1)^x}{x}$). In this stage we also sorted responses that we tagged as 'correct' into three categories: correct and summed $2i + 1$ (or equivalent) from $i = 0$ to $i = 9$, correct and summed $2i - 1$ (or equivalent) from $i = 1$ to $i = 10$, or correct with other encoding.

The last stage of analysis involved comparing each student's Interpreting Task response to the Encoding Task response. This process included separating surveys based on error type and then looking at the frequency of the Encoding Task tags. For example, we found that 16 of the 27 students that gave an expression with seven summands in the Interpreting Task also wrote a "10" above the sigma in the Encoding Task.

## Sample Results

### A Model for Interpreting Summation Notation

We found that most students were able to answer the Interpreting Task correctly; 73.2 percent (186/254) of the students that attempted the task correctly answered the question. We will first attempt to explain the thinking of the 69 students that incorrectly answered the Interpreting Task. We found the most common error type (27 responses) involved summing seven terms. There were 4 different subcategories within this error type, which are listed with their frequency in Table 1.

*Table 1. Categories for summing seven terms.*

| Category | Frequency (n=27) |
|---|---|
| Summed $(k+1)^2$ from $k = 2$ to $k = 8$ | 16 |
| Substituted 2 seven times | 6 |
| Did not increment by 1 | 3 |
| Did not substitute values for $k$ | 2 |

Summing seven terms suggests that these students took the number atop the sigma as the number of summands. Kathy and Betty also considered this during the first phase of the project. While this is not the standard convention (i.e., the value above the sigma represents the terminal index value), it *is* a viable convention and it is analogous to a "count loop" in computer science.

However, the non-standard usage is still problematic because a user who respected the standard usage would be unable to recreate the expanded sum the students meant to encode.

We can test whether or not the 27 students truly take the number above the sigma to be the number of summands by considering their responses to the Encoding Task. The 27 students should write "10" above the sigma when they are prompted to encode the sum of the first *ten* odd integers if they are using the nonstandard convention.

The following section will investigate how students who 'summed $(k+1)^2$ from $k=2$ to $k=8$' responded to the Encoding Task.

**Subcategory 1: Summed $(k+1)^2$ from $k=2$ to $k=8$.** Figure 3 gives a typical response of the 16 students under the "summed $(k+1)^2$ from $k=2$ to $k=8$" subcategory. Responses in this subcategory include 7 summands, each of which correspond to an output of the function $f(k)=(k+1)^2$ with $\{2,3,\ldots,8\}$ as its domain.

$$(2+1)^2+(3+1)^2+(4+1)^2+(5+1)^2+(6+1)^2+(7+1)^2+(8+1)^2$$

*Figure 3. Typical Interpreting Task response with 'summed $(k+1)^2$ from $k=2$ to $k=8$' tag.*

Now consider an Encoding Task response from one of the students that made a subcategory 1 error in the Interpreting Task (Figure 4). Notice, this student did indeed place a "10" above the sigma. In total, 10 of the 16 responses did so as well.

$$\sum_{i=0}^{10} i+1$$

*Figure 4. Student response to Encoding Task.*

Two of the 6 students that did not place a "10" above the sigma left the Encoding Task (seemingly) incomplete; both responses did not include an expression to sum. Additionally, it appears as though another student misread the Encoding Task to say 'write an expression for the sum of odd numbers less than ten.' (See figure 5.) This is evidenced by the list "{1, 3, 5, 7, 9}". Under this assumption, the number above the sigma, "6", corresponds to the number of odd values less than 10.

$$\sum_{i=1}^{N}(x_i)4x, \{1,3,5,7,9\}$$

$$\sum_{i=0}^{6}(N+1) \quad 0,1,,3,,5,7,9$$

*Figure 5. Possible misinterpretation of Encoding Task prompt.*

It is also interesting to note that it is possible for the students to assign the number above the sigma to mean the total number of summands *and* give a 'correct' answer to the encoding task. In this situation, a student could interpret "$\sum_{k=1}^{10} 2k-1$" to mean: substitute natural numbers for

$k$ until there are 10 summands. We found 3 of the 10 student responses that placed a "10" above the sigma was tagged as 'correct'.

However, this convention is problematic whenever the starting variable is not equal to 1. In this situation, the number of summands does not equal the number of values to substitute using the standard convention. There were 40 Encoding Task responses that were tagged 'correct' because they gave the expression "$\sum_{k=0}^{9} 2k + 1$". This response suggests that these students do *not* take the number above the sigma to mean the number of summands since the prompt asked students to sum the first *ten* odd numbers. We found that only 1 of the 40 students that answered "$\sum_{k=0}^{9} 2k + 1$ " to the Encoding Task also wrote seven summands for the Interpreting Task.

**Task Hierarchy**

While most students were able to correctly answer the Interpreting Task, only 38.4 percent (96/250) of the students that attempted the Encoding Task wrote a correct response. We conjectured that encoding is more cognitively demanding than interpreting a summation-notation expression. This is because if a student were able to encode a sum, then the student would be familiar with the structure and workings of the elements of the summation notation; that is, the student would have the ability to accurately interpret a given summation-notation expression. Additionally, in order to correctly verify their encoding, a student would necessarily be able to interpret their own summation notation accurately.

With respect to the Tasks we expected this to play out in a contrapositive manner. That is, we expected that students who could not successfully complete the Interpreting Task would not be able to successfully complete the Encoding Task. Table 2 shows the number of students that correctly answered both tasks correctly, neither of the tasks correct, Interpreting Task correctly but Encoding Task incorrectly, and Encoding Task correctly but Interpreting Task incorrectly.

*Table 2. Combination of correct responses to Interpreting and Encoding Task.*

| Tasks Correct | Frequency (n=242) |
|---|---|
| Both Interpreting and Encoding Tasks | 86 |
| Neither Interpreting nor Encoding Tasks | 54 |
| Only Interpreting Task | 93 |
| Only Encoding Task | 9 |

Notice, of the 64 participants that were not able to answer the Interpreting task correctly, 9 participants were able to answer the Encoding task correctly. This seemed to be a high percentage until we looked further into how the 9 students responded. In particular, 4 of these students attempted to answer the Interpreting Task by expanding $(k + 1)^2$. One of these students then made an algebraic error (unrelated to the notation). The 3 other students distributed the sum across the three terms, evaluated the first two summations correctly, and then incorrectly reduced "$\sum_{k=2}^{7} 1$ " to "$1 \cdot 7$" (Figure 6). It seems as though evaluating the sum of a constant function over an index set might be more difficult for students since the students were able to correctly evaluate the first two terms after they distributed the sum.

$$\sum_{k=2}^{7}(k+1)^2$$

$$= \sum_{K=2}^{7} (K^2+2K+1)$$

$$= \sum_{K=n}^{7} K^2 + 2\sum_{K2}^{7} K + \sum_{K=2}^{7} 1$$

$$= 2^2+3^2+4^2+5^2+6^2+7^2+2(2+3+4+5+6+7)+(7\times1)$$

$$= 4+3+16+25+36+49+2(27)+7$$

$$= 200 \text{ Ans.}$$

*Figure 6. Student 'incorrect' response to Interpreting Task.*

An additional 2 students answered the interpreting task incorrectly by summing seven terms. These students then answered the Encoding task by writing "$\sum_{k=1}^{10} 2k - 1$". This is a situation that we described before in the previous section. That is, it is likely that these students interpret the number above the sigma to mean the number of summands, not the terminal index value. When students assign the initial value of the index to be 1 (and increment by 1) both ways of thinking will produce the same expression.

We also hypothesized that the ability to interpret a summation notation expression would not be sufficient for successfully encoding with the notation. This is because encoding sums with summation notation requires an understanding of functions and their domains above and beyond what is required to accurately interpret a given summation-notation expression. Specifically one must *construct* a function; this entails coordinating the construction of a rule with the construction of an appropriate domain (i.e. indexing set, in this case). For example in the Encoding Task, a student must first construct a function that will output odd values when the student inputs natural numbers (e.g., $f(x) = 2x - 1$). Then the student must restrict the natural numbers in such a way that the indexing set will output the first ten odd numbers (e.g., $\{1, 2, 3, \dots, 10\}$). In contrast, to interpret a student does not have to coordinate the construction of a rule with the construction of an appropriate domain. Instead, the student only coordinates the inputs from the given index set with the outputs of a given function. For this reason we expected a number of students to successfully complete the Interpreting Task who would not successfully complete the Encoding Task. Table 1 shows that this was indeed the case: 93 participants were able to successfully complete the Interpreting Task but were not able to complete the Encoding Task.

## Conclusion

We found that undergraduates struggle with summation notation. Like Betty and Kathy, many students were unsure about the structure and workings of the elements of summation notation. In particular, our data suggest that some students are unaware of (or at least do not follow) the standard summation notation conventions. However, often students do follow a non-standard convention (e.g., assign the number above the sigma to mean the number of summands, increment by a value other than 1, etc.). The conventions we witnessed are viable options; however, they are problematic because they are not standard. In particular, issues may arise when communicating with others that adhere to the standard convention.

We also found that encoding is more cognitively demanding than interpreting a summation-notation expression. We presented evidence supporting that being able to expand sums expressed in summation notation is necessary to being able to encode an expanded sum using summation notation. However, the ability to interpret an expression in sigma notation is not enough to encode a sum in sigma notation.

# Developing Understanding of the Partial Derivative with a Physical Manipulative

Jason Samuels
City University of New York

Brian Fisher
Lubbock Christian University

*Multivariable calculus education is an area of growing investigation, and in this study we specifically target the topic of partial derivatives. Data was collected on students learning in an innovative curriculum using physical manipulatives. We trace the complex path as students developed both their mathematical knowledge and their use of the artifacts at their disposal, and analyze the interaction between them. Implications for the classroom and for research are noted.*

*Keywords*: multivariable calculus, partial derivative, instrumental genesis, utilization scheme

## Introduction & Literature Review

Multivariable calculus education has seen a surge of interest in recent years. A presidential panel emphasized it as a key course for the introduction of ideas that are complex and essential for STEM students (PCAST, 2012). Some research has been done on student conceptions in multivariable calculus of function (e.g. Martinez-Planell & Trigueros-Gaisman, 2012), derivative (Martinez-Planell, Trigueros-Gaisman & McGee, 2015), and integral (Jones & Dorko, 2015). Significant research has been done on student conceptions for single variable calculus, much of it in the last several decades, and some research has addressed how students construct multivariable calculus knowledge on those foundations (Dorko, 2016).

One central idea is that of rate, which underlies the derivative. During the typical curricular progression, students must develop an increasingly sophisticated conception of rate. They encounter a single constant rate with first linear single-variable functions, then a single nonconstant rate with nonlinear single-variable functions, then multiple nonconstant rates with multivariable functions. The first conception, including coordinating change in the input and output variables into a quotient, has been shown to be essential to developing the second conception (Pustejovsky, 1999; Zandieh, 1997).

The results reported here are from the implementation of an innovative curriculum designed to introduce important topics from multivariable calculus through student exploration with physical manipulatives. Students use, as representations of two-variable functions, surfaces which are molded from clear plastic and have a dry erase surface. Accompanying tools include an inclinometer (used to measure the slope at a point on the surface in a given direction), and domain mats (dry erase sheets with coordinate lines or contour lines). Students in small groups complete activity sheets in-class, which emphasize collaborative learning, student inquiry, and measurement with quantitative reasoning (for further details see Wangberg & Johnson, 2013). A previous investigation examined one aspect of how students learn about tangent plane and linear approximation using these tools (Fisher, Samuels & Wangberg, 2017).

## Research Question

Even in light of the recent burst of research in multivariable calculus, little research has been done into how students develop conceptions of the partial derivative for functions of two variables. Further, for students who use physical tools to complete tasks and answer questions in their activities on multivariable calculus, little is understood about how they enhance their understanding of calculus, or what role the tools play in that process. At the nexus of these issues lies the following research question:

How do students develop conceptions of the partial derivative during exploration with a physical manipulative?

## Theoretical framework

Verillon & Rabardel (1995) presented Rabardel's theory of instrumental genesis to explain the complex process by which a person engaged in achieving a goal adopts the use of some assisting object. The material object when first introduced is an artifact. For it to be a productive tool, the user must attach to the artifact a role in completing the present task. Actions and behaviors cognitively organized by the user for a class of situations comprise a utilization scheme. Schemes can be constructed personally by the user as derived schemes, or received in a social context as adopted schemes. The process of instrumental genesis produces an instrument, an artifact endowed with a set of utilization schemes for tasks, which is therefore a combination of material object and cognitive structures. During instrumental genesis, the artifact shapes the user through interactions which enhance the user's understanding of the subject matter, a process known as instrumentation. Additionally, the user shapes the artifact by developing utilization schemes for interacting with the artifact, a process known as instrumentalization. Thus, as user and instrument develop their partnership, each one causes a transformation in the other. Subsequent to the development of the theory, instrumental genesis was applied in mathematics education to understand student use of graphing calculators, computer algebra systems (Artigue, 2002), and dynamic geometry software (Leung & Chan & Lopez-Real, 2006).

## Methodology

The data for this report were obtained from four students who worked as one group on an activity sheet designed to introduce the concept of the partial derivative. The first author, present as the instructor, asked questions to help make student thinking explicit and to encourage discussion and resolution of any disagreements within the group. The session was video recorded, the recording was transcribed, and the data were coded for instances of instrumental genesis by each author. Any differences of opinion were discussed until agreement was reached.

In the activity the students were tasked with measuring the partial derivative at a point on the surface using the inclinometer. The inclinometer used by the students had two rods, one round and one square with a bubble level attached, connected at the ends by a joint (see Figure 1).

Students could successfully complete the activity sheet with a utilization scheme for finding the partial derivative consisting of the following utilization schemes: one for the direction of the derivative, aligning the parts of the inclinometer in the proper vertical plane; one for the tangent line, positioning the round rod tangent to the surface at the selected point; one for representing the "run" ($\Delta x$ or $\Delta y$ in this context), positioning the square rod horizontal using the level; one for representing the "rise" ($\Delta z$), indicating a vertical displacement between the rods; and one for measuring change between two values for a variable, for which two possibilities are using a ruler or laying the inclinometer on the domain mat grid and counting boxes. As a result, they could calculate the quotient and find the partial derivative.

*Figure 1. Student using the surface, inclinometer, and ruler over a domain mat.*

The recorded session was split into episodes. Each episode consisted of discussion on approximately the same topic or in the same vein. Each episode was then coded with respect to utilization schemes. The students introduced two other utilization schemes in addition to the five schemes which comprised the partial derivative scheme described above: a scheme representing the normal line and a scheme measuring the interior angle of the inclinometer. Each scheme, when mentioned, was coded as attempted and completed (C), attempted with partial progress (P), or attempted with no progress (N), with an indication if it occurred specifically in the two-dimensional *y=f(x)* context (2).

## Results

Here we present some results on the student work to find the partial derivative for a two-variable function at a given point, where the function is represented by a 3-dimensional plastic model. In the activity given to the students, the input variables *x* & *y* represented position, and the function value *T(x,y)* represented temperature. The following episode is presented with its coding and short description.

*Interviewer*: Okay, so, how would you use the same structure, the same orientation [as in the *y=f(x)* context], if you used it on the surface?
*Student A*: (put inclinometer on surface, round leg tangent, see Fig 2)
*Student B*: Like this?
*Interviewer*: Okay, so now describe to me what you are doing there.
*Student A*: Well I'm basically taking the point (lifting inclinometer and indicating the point), and I'm putting this on there, like, tangent.
*Interviewer*: Okay, so go ahead, do that.
*Student A*: (placing inclinometer tangent again) So this has to be...
*Interviewer*: Okay, so you got that one tangent.

*Figure 2. Student A places the inclinometer tangent to the surface.*

In the excerpt, the group had just transitioned from the two-dimensional, *y=f(x)*, context to the three dimensions, *z=f(x,y)*, context. The group, for the first time, demonstrated a complete utilization scheme for tangency, as well as directionality. However, with the square leg not horizontal, they did not implement the complete utilization scheme for $\Delta y$ (which they had done before). They did not attempt to represent $\Delta z$, or to measure any displacements.

The coders identified 13 episodes in the recorded student activity, and the above description provides an example of how the coding was executed. The results are summarized in Table 1.

## Discussion

Analyzing the students' actions through the lens of instrumental genesis gave valuable insight into describing both their struggles and achievements.

### The Role of Instrumentation

In instrumentation, the artifact shapes the user through interactions which enhance the user's understanding of the subject matter. One example of successful instrumentation occurred in the episode below, in which students used the level to make the square rod parallel to the *xy*-plane to help represent displacements in the domain.

*Student B*: What is this for (indicating the level)?
*Interviewer*: Yeah, so what is that for?

*Table 1. Utilization schemes and how they arose in each episode of the activity.*

C: attempted and completed. P: attempted with partial progress. N: attempted with no progress. 2: in 2-dimensional *y=f(x)* context

*Student C*: To make it parallel.
*Interviewer*: That's to make sure that it's parallel. So why do you want it to be parallel?
*Student B*: *xy* parallel, right?

In this excerpt, the students observed a physical aspect of the artifact, the bubble level. Then, they proceeded to assign to it a functionality connected with mathematical content, being parallel to the *xy*-plane.

One early example of failed instrumentation occurred when the inclinometer shaped the thinking of one student in unproductive ways.

*Interviewer*: So tell me, tell me what you need to do, and then tell me how you're going to use the tool to do it.
*Student B*: First of all, the, perpendicular, the point, and we can find the right point, the bubble in the circle, and we can get the theta. So it means, this surface, this plane (indicating the *xy*-plane) and this plane (indicating the square leg) is parallel, so it means we can get this theta (indicating the angle, see Figure 3), and this theta is same. So-
*Student C*: -we can get-
*Student B*: -if we know theta...I don't know.

*Figure 3. Student B indicates the angle on the inclinometer.*

In this excerpt, the students focused on the angle presented by the tool. Using the angle was the very first idea suggested. One can hypothesize the reason, based on the appearance of the artifact. The primary physical characteristics of the artifact are two legs connected at their ends, and this mimics the standard instantiation of an angle. Further, the mobile joint allows for manipulation to any angle, which mimics the standard method to compare different angles. It is indeed possible to calculate the slope knowing the angle, however the students decided it was too complicated and did not pursue it. Thus, they did not devise a way to measure either the angle or the rate with this strategy, so this did not lead to new mathematical knowledge.

**The Role of Instrumentalization**

In instrumentalization, the user shapes the artifact by developing schemes for interacting with the artifact based in existing knowledge. One example of successful instrumentalization included using the inclinometer to represent the tangent line (as detailed in the first excerpt in the results section).

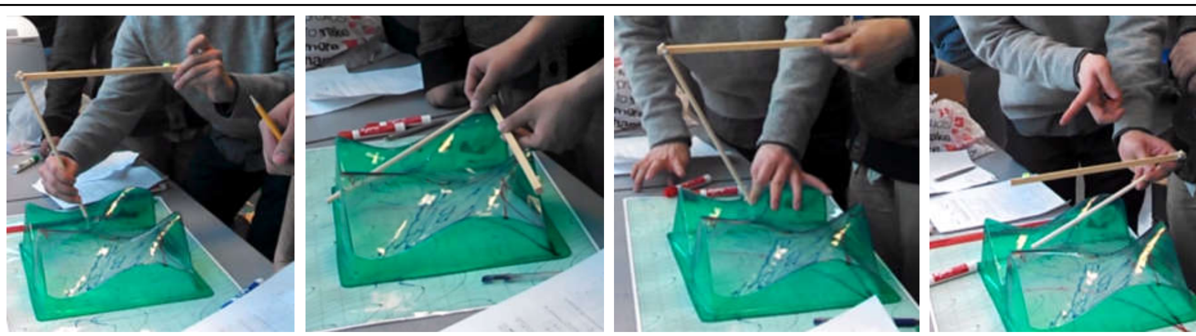
One example of failed instrumentalization included an attempt to measure $\Delta z$. The students previously demonstrated awareness of 3-dimensional rectangular coordinates, thus possessed the requisite mathematical knowledge, however the ruler was positioned between the ends of rods and not vertically (see Figure 4).

*Figure 4. Student C measures the length between the rods' ends.*

**Extending Utilization Schemes from the 2-Dimensional *y=f(x)* to the 3-Dimensional *z=f(x,y)***

One recurrent unproductive move during attempts to find the slope was placing the inclinometer's round rod perpendicular to the surface for $z=f(x,y)$. One possible explanation is that the normal line is uniquely determined, while the tangent line is not. The students did not offer a justification for placing the inclinometer perpendicular to the surface, despite multiple prompts to do so. Yet when subsequently presented with the two-dimensional $y=f(x)$, they quickly placed the inclinometer tangent and found the derivative at a point.

Previous research has documented how the transition from single to multi-variable calculus presents significant challenges (Dorko, 2016; Jones & Dorko, 2015). The analysis with instrumental genesis revealed how students were grappling with an issue more pervasive for two variable functions, that of directionality. Early on in the activity, the student group lined up the entire inclinometer (both legs) in the appropriate direction (see Figure 5a). However, when forced to grapple with other considerations, particularly a utilization scheme for the tangent line by making the round leg tangent (while making the square leg parallel simultaneously), the complete directionality scheme was lost (see Figure 5b). Subsequently, the correct directionality scheme returned but the correct tangent line scheme again disappeared (see Figure 5c). Only then was the group able to merge all the correct schemes simultaneously to form the utilization scheme for finding the partial derivative (see Figure 5d).



*(5a) (5b) (5c) (5d)*

*Fig 5. Students losing and regaining the utilization schemes for directionality and tangent line.*

**Equivalence between Utilization Schemes**

One interesting deduction made by the students was the equivalence between certain utilization schemes. When calculating a derivative for $y=f(x)$, the students' utilization scheme to measure both the rise and the run consisted of laying the inclinometer flat on grid paper and counting boxes. When calculating a derivative for *z=f(x,y)*, their utilization scheme for measurement at one moment consisted of counting grid boxes. Later in the activity, it consisted of using a ruler. They used the results in equivalent fashion, referring to them in both cases as *dx* (or *dy, dz, dT*), and subsequently dividing the two numbers to calculate the rate. Members of the group were satisfied with both methods, and no one insisted on switching for either scenario.

The reasons for this difference in practice may come down to previous experience. For *y=f(x)*, by common instructional practice, students would have prior experience determining the slope of a straight line by counting grid boxes, and the inclinometer already lay on the grid paper when they reached this step. For *z=f(x,y)*, students in this class had prior experience determining the z-value (i.e. height) of a point using a ruler. Although the students were drawn to different utilization schemes in different contexts, their actions reflect that they used different schemes to get the same outcome.

**Adaptation of a Previous Utilization Scheme**

When students found the slope for *y=f(x)* using the inclinometer, they used what for them was a well-known process in a well-known scenario, but with an artifact they had only recently encountered. This was an example of adaptation of a previous utilization scheme. For the utilization scheme for tangent line on the surface, students initially used a pen as their tool to represent a tangent line on the surface. Subsequently, they used the (round leg of the) inclinometer to manifest the tangent line.

Another type of adaptation of a previous scheme occurred when the students moved from discussing derivative in the *y=f(x)* context to discussing it in the *z=f(x,y)* context. This progression actually occurred twice, first with the actual tools and second in discussion only. For *y=f(x)*, the students quickly and effectively created a utilization scheme to find the derivative. (As discussed previously, modifying the scheme for *z=f(x,y)* did not happen quickly or without struggle, either the first or second time.) In this case, the artifact was the same but the scenario had changed.

**Utilization Schemes Disappear and Reappear**

Students seemed to "forget" what they already knew, only to "remember" it subsequently. Students produced a utilization scheme for directionality almost immediately, and it stayed present in their manipulations and discussion for some time. However, in the process of grappling with certain obstacles that seemed to give them great difficulty, directional fidelity disappeared. The utilization scheme for tangent line took the longest to appear for the first time. Perhaps the group's greatest challenge was changing the relationship of the inclinometer round rod to the surface from normal to tangent. During the discussion before it happened, the group laid the inclinometer on the surface in new ways which ignored their previous directionality scheme.

One possible explanation is that the more challenging obstacles produced so much cognitive load (Sweller, 1988) that the students could not simultaneously consider or maintain directionality. Only after it was resolved, reducing cognitive load, could students return to considering their already-determined utilization scheme for directionality.

**Instrumentalization during Development of a Utilization Scheme**

Student mathematical knowledge and artifacts can interact in dynamic ways during instrumental genesis. At one point, Student A said "dee-T. Hold on, something over 12, I think. Dee-T should be 12. No, dee-T should be this one (measuring in the z-direction). Yeah, four." He incorrectly coordinated the numerator and denominator in a slope calculation, before correcting himself. The apparent reason was that the triangle is upside down from typical usage, with the horizontal side higher in space than the vertical side (as in Figure 1). During the development of the scheme, the student confronted the signal from the inclinometer regarding the spatial relationship between $\Delta T$ and $\Delta x$ (referred to by the student as dee-T and dee-x, respectively), initially accepting it before ultimately, and correctly, rejecting it. During this act of instrumentalization, it was necessary for the student to determine which information from the artifact to utilize (the lengths), and which to ignore (the relative positions of $\Delta T$ and $\Delta x$).

### Linking Utilization Schemes

Students linked utilization schemes, to form what one might call a utilization super-scheme. They linked five schemes to form a scheme for finding the partial derivative. The formation of this linkage was clear when working on subsequent questions, and students found partial derivatives quickly, using the utilization scheme formed in the present activity.

## Conclusion

Multivariable calculus is an essential course with numerous crucial ideas for students pursuing STEM. Innovation has been encouraged to improve learning and retention; concomitant with that is a need to analyze and understand student learning in these innovative contexts.

### Implications for the Future

The students studied here had a tremendously difficult time generating a tangent line for a two-variable function. It was the last idea proposed and utilization scheme generated, and arose only after the interviewer introduced the *y=f(x)* context and scaffolded from there. Instructors might consider emphasizing tangent lines and planes early in multivariable derivative instruction to overcome this obstacle.

The transition from single variable calculus to multivariable calculus is one that students will continue to have to make, and one which presents considerable challenges. Previous studies considered the transition for the equation of a variable equal to a constant (Dorko, 2016) and integration (Jones & Dorko, 2015). In the current study, students needed to transition ideas such as tangent line and derivative. Further study of all aspects of this key transition is essential.

### Summary

In this report we engaged in a study of four students in a group learning about the partial derivative through the use of a physical model while completing an activity sheet. We continued from previous work (Fisher, Samuels & Wangberg, 2017) our original approach to extend use of the instrumental genesis framework to contexts involving physical manipulatives. The use of the physical manipulatives illuminated the gaps in student knowledge, and also provided a path to fill them in. It is important to note that the data analyzed here covers the work of only four students, at a particular place and time, and we make no claims regarding generalizability to other students in other contexts. The students described here encountered numerous challenges as they extended their robust knowledge in the 2-dimensional *y=f(x)* context to the 3-dimensional *z=f(x,y)* context. They struggled to find a rate for a two-variable function, plumbing various parts of their mathematical knowledge while manipulating the artifacts at their disposal.

Reflected in their work were the role of instrumentation and instrumentalization as the students engaged in the mental constructions which turn the artifacts into tools. On this complex journey, the students devised utilization schemes, during which the student learning developed and manifested in noteworthy ways. This culminated in the development of the scheme for finding the partial derivative, which required coordinating the developed schemes. Thus, analyzing student actions through the lens of instrumental genesis proved effective and insightful to describe student learning activity in this context.

Beit Berl College

*Beliefs have long been recognized as a "hidden variable" in mathematics education. Epistemological beliefs are an inherent, although often implicit, component of curriculum goals in the cognitive domain. Connections between acquiring and accessing higher order cognitive strategies and epistemological beliefs are gradually becoming better understood. Israeli guidelines for mathematics teacher preparation emphasize of view of mathematics as a complex body of knowledge and knowing mathematics as a dynamic process. We present a case study of Israeli preservice secondary mathematics teachers' epistemological beliefs about mathematics, assessed via concept maps at the beginning and end of undergraduate studies. A mixed-methods approach was used to analyze maps. Results suggest that students' beliefs shifted to align with Israeli goals. Implications for STEM curriculum design are discussed.*

*Keywords:* Preservice Secondary Mathematics Teachers, Epistemological Beliefs, Concept Maps, Curriculum Design

## Introduction:

Complex interactions between cognition, metacognition and epistemological beliefs impact selection and application of cognitive strategies (Hofer & Sinatra, 2010). Epistemological beliefs, therefore, play an inherent role in education policy; they are implicit, often hidden (Leder, Pehkonen, & Torner, 2002), components of curriculum objectives in the cognitive domain.

We present a case study assessing alignment of students' beliefs with goals for the preparation of secondary mathematics teachers in Israel. During the three-year course of studies, beliefs that mathematical knowledge is simple and disconnected became less central; beliefs that mathematics is absolute knowledge of procedures evolved to a nuanced system of beliefs about a mathematics of procedures, concepts and processes.

## Theoretical Background:

Learning objectives in undergraduate STEM education include retention of knowledge over time, the application of knowledge to solve unfamiliar problems, and commitment to lifelong learning (Fairweather, 2008) which are associated to higher order cognitive processes (Fink, 2003). Acquisition of higher order thinking skills is a necessary, although not sufficient, component of solving complex problems and responding innovatively to changing circumstances (Binkley et al., 2012). Students must also internalize a deep approach to learning (Bromme, Pieschl, & Stahl, 2010) as an active, self-driven process of deep thought and construction of knowledge and understanding (Marton & Saljo, 1976).

Students' epistemological beliefs about the nature of knowledge, knowing and learning (Hofer & Pintrich, 1997; M. Schommer, 1990) are connected to their adoption of surface or deep learning approaches (Vermunt, Van Rossum, & Hamer, 2010) Beliefs that knowledge is absolute--facts with or without accompanying understanding--correspond to a surface, outcome-oriented approach to learning. Beliefs that knowledge is dynamically constructed and context-dependent aligns with a deep-learning, process-oriented approach (Vermunt et al., 2010).

Epistemological beliefs and metacognition are connected (Schraw & Moshman, 1995); the ability to access the cognitive tools needed to engage in critical thinking and problem solving is mediated through beliefs about knowledge and knowing (Hofer & Sinatra, 2010; Kuhn, 1991). Holding non-availing beliefs impedes acquisition of higher cognitive skills (Schraw, Crippen, & Hartley, 2006) and limits the range of cognitive strategies that are accessed (Hofer, 2004; Louca, Elby, Hammer, & Kagey, 2004). Since beliefs impact the acquisition and application of higher order cognitive skills (Hofer & Sinatra, 2010; Schraw et al., 2006), they are an inherent, although often hidden (Leder, Pehkonen, & Torner, 2002) component of curriculum objectives.

In mathematics, higher order cognitive skills include discovery, making connections and building understanding, which characterize (deep) *conceptual knowledge* (Hiebert & Lefevre, 1986; Star, 2005). Mathematics-related beliefs are strongly related to the cognitive processes of mathematics (McLeod & McLeod, 2002). For example students who believe that knowledge is simple, isolated facts (M. Schommer, 1990) are less likely to use higher level cognitive strategies and have lower levels of achievement (Cano, 2005); a belief that knowledge is simple affects self-regulation in learning (Muis, 2007) and has been shown to negatively impact student achievement in remedial mathematics courses in university (Briley, Thompson, & Iran-Nejad, 2009). Fostering dynamic beliefs about mathematics as process of discovery (Ernest, 1991; Grigutsch & Törner, 1998) is an inherent component of cognitive curriculum goals; neglecting epistemological beliefs as a component of mathematics education goals is a potential source of inequity of access to career and educational opportunities for which mathematics is a gateway (Leder, Pehkonen, & Törner, 2002).

Epistemological beliefs of mathematics education students have been widely studied (e.g., Ball, 1990; Schmidt et al., 2008) because mathematics teachers' beliefs impact their teaching practice (Beswick, 2005; Blömeke & Delaney, 2012; Thompson, 1992), student learning (Staub & Stern, 2002) and student achievement (Tatto et al., 2008). While some countries, for example the United States, explicitly include belief-related goals in guidelines for mathematics teacher preparation (CBMS, 2012), the guidelines of other countries, *e.g.,* Israel do not contain explicit belief-goals (Gutfreund & Rosenberg, 2012).

Despite the absence of explicit belief-related goals, the importance of addressing belief-development in programs for mathematics teacher preparation has long been recognized (Brownlee, Purdie, & Boulton-Lewis, 2001; Wilkins, 2008). For example, a cross-country study of 23,000 pre-service mathematics teachers from six countries examined the structure of mathematics teacher training programs and the mathematics-related beliefs of the programs' students at the end of their studies. Following Grigutsch (1998) beliefs were characterized as static/absolute and/or dynamic. End-of-program beliefs varied by country and by program across all six countries graduates held dynamic beliefs, but the extent to which graduates also held absolute beliefs varied by country (Schmidt et al., 2008). In addition, preliminary research indicates that the number and type of mathematics and mathematics education courses in mathematics teacher preparation programs impact beliefs (Blömeke, Buchholtz, Suhl, & Kaiser, 2014) with more opportunities to learn mathematics education courses leading to more dynamic beliefs. The connection between programs' explicit or implicit belief goals and graduates' beliefs was not examined, raising the question of the role implicit or explicit expectations play in belief development.

Israeli guidelines for preparation of secondary mathematics teachers (Gutfreund & Rosenberg, 2012), referred to as "Gutfreund guidelines" in what follows, do not specifically address beliefs, however they include content goals characterizing mathematics as a process of knowledge development, which are aligned to dynamic beliefs about mathematics (Grigutsch & Törner, 1998). Pedagogical goals address higher order cognitive skills; also aligned with dynamic beliefs, and, additionally, a belief that mathematical knowledge is complex, rather than simple (M. Schommer, 1990). Developing epistemological beliefs of mathematics as a complex body of knowledge and a dynamic process of inquiry is, therefore, an implicit goal of the Gutfreund guidelines.

## Research Goal

The previously unexplored connection between belief expectations and students' end-of-program beliefs provided a rationale for studying the epistemological beliefs about mathematics held by Israeli mathematics education students at the beginning and end of the program of studies and analyzing these beliefs in terms of their alignment to the Gutfreund guidelines (2012).

## Methodology

This case-study was conducted within the framework of a regulated B.Ed. program mathematics education at an Israeli college of education; graduates are certified to teach Israeli secondary mathematics.

### Sample

Twenty-five students began the mathematics education program in the 2014-15 academic year. Data was collected before students began the course of studies. A second set of data was collected 3.75 years later at conclusion of the program. Twenty-two of the 25 students completed the program. All students who completed the program agreed to participate in the study. The initial data of the students who did not complete the program was excluded.

### Data Collection

Various methods have been employed to collect data on beliefs of pre-service mathematics teachers, including interviews and classroom observation (e.g., Ball, 1990) and Likert-type surveys assessing level of agreement with statements reflecting a pre-determined set of mathematics-related beliefs (e.g., Tatto et al., 2008). Interviews and observations provide an in-depth picture of beliefs, but they are time intensive in terms of both data collection and data analysis. Likert surveys are an important tool for gathering and analyzing large data sets, but they cannot access beliefs that are not included in the survey (Grigutsch & Törner, 1998) and may yield "false-positive" agreement with some beliefs (Philipp, 2006).

We employed concept maps (Novak & Gowin, 1984), which visually represent abstract knowledge and understanding, to collect students' beliefs about knowing mathematics. Primarily used to assess knowledge and understanding of content, concept maps have also been used to capture meta-cognitive views about thinking (Ritchhart, Turner, & Hadar, 2008). We adopted Ritchhart's methodology to collect students' epistemological beliefs: they were asked to reflect on what it means to know mathematics; to generate a list of words and phrases that came to mind; to arrange their ideas in a hierarchy of importance/centrality to the notion "knowing mathematics"; to connect related ideas with lines and to briefly describe the connections. Students created concept maps before beginning the course of studies and again 3.75 years later at the completion of the program course-work.

## Data Analysis

We used a two-step process to analyze the items (words and phrases) on the two sets of concept maps. First-stage qualitative analysis used a constant comparative paradigm; students' responses were read and reread to discover commonalities and recurring themes (Strauss & Corbin, 1990). This inductive process uncovered a structured system of categories describing different ways of knowing mathematics. Student maps included many items. When a single item seemed to relate to more than one way of knowing, it was categorized under each of the appropriate categories. Each item on a map was assigned a rank from 1 to *n* indicating its distance from the center of the map, with items closest to the center assigned a rank of one. The items were coded by category and rank.

The coded maps were used to define "beginning of program" and "end of program" matrices. Each category was assigned to a variable and each map was assigned to two rows in the appropriate matrix; each item on a map corresponded to two matrix entries-- the first denoting its category and the second, its rank. The ranking was used to assign a weight to each item; On a map with *n* ranks, rank *n* items (those items furthest from the center) were assigned a weight of $\frac{1}{n}$, rank *n*-1 items were assigned a rank of $\frac{2}{n}$, items closest to the center (rank one) received a weight of one.

For each map, the sum of the weights of the items in the category was computed, labeled as the [*category name*]-belief score. A [*category-name*] average weight was computed for each map by dividing the belief score by the number of map items in the category. Ratios of each belief score to the sum of all belief scores were computed both for the complete set of categories and for various subsets. Subset ratios will be described in the findings. The belief scores, average weights and belief ratios are dependent variables of the maps. For each student, differences between beginning-of-program and end-of-program values were computed, defining dependent variables of the students in the program.

## Findings

Students related to knowing mathematics in complex and varied ways. Two main ways of knowing mathematics, *i.e.,* epistemological beliefs, emerged from the categorical analysis of the maps: knowledge of *mathematical content* comprised of topics (such as algebra) or skills (such as addition); and *attitudes* toward mathematics. Students' attitudes were expressed in terms of cognitive, behavioral and affective components, *e.g.,* perseverance (behavioral), satisfaction (affective), and success (cognitive). The categorical structure is shown in Figure 1.

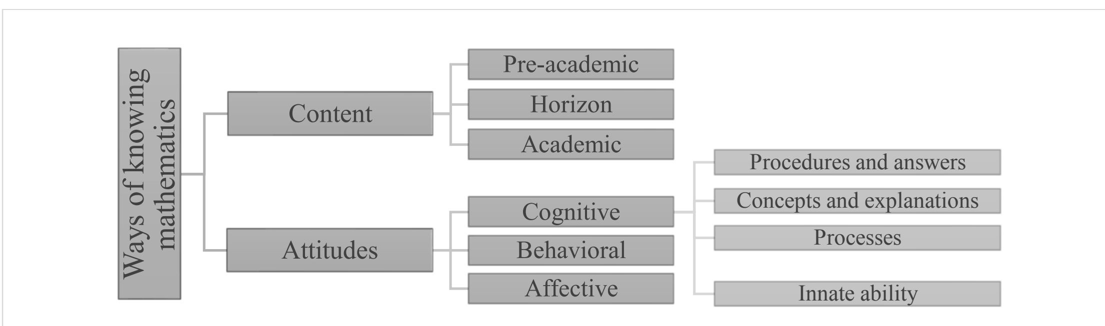

*Figure 1. Categorical structure of beliefs*

In the initial stage of quantitative analysis, four belief scores were computed corresponding to the content category (*content*) and the three components of the attitude category (*affective, behavioral, cognitive*.) The ratio of each score to the sum of the four scores was then computed. Mean ratios at the beginning and end of the program are shown in Table 1.

*Table 1. Differences in belief ratios*

| | Belief Ratios | | | |
|---|---|---|---|---|
| | Content | Affective | Behavioral | Cognitive |

| | | | | |
|---|---|---|---|---|
| Beginning of Studies | $\mu = 0.355$<br>$\sigma = 0.245$ | $\mu = 0.033$<br>$\sigma = 0.060$ | $\mu = 0.118$<br>$\sigma = 0.171$ | $\mu = 0.494$<br>$\sigma = 0.217$ |
| End of Studies | $\mu = 0.149$<br>$\sigma = 0.189$ | $\mu = 0.044$<br>$\sigma = 0.096$ | $\mu = 0.099$<br>$\sigma = 0.140$ | $\mu = 0.708$<br>$\sigma = 0.195$ |

Students at both the beginning and end of the program related to knowing mathematics as attitudes towards the subject more strongly than knowing specific mathematical skills and topics. Due to the small sample size and wide variation between students, effect size and statistical significance do not provide meaningful data. None-the-less, the results suggest that trend was stronger at the end of the program; the content ratio at the beginning of the program was 0.355 ($\sigma = 0.245$) and the content ratio at the end of the program was 0.149 ($\sigma = 0.189$). Same-student comparisons confirm this finding; the content ratio of 77% (*n*=17) of the students decreased over the course of studies.

**Mathematical Content**

Mathematical content was included on most maps: 86% (*n*=19) of the beginning-of-program maps and 64% (*n*=14) of the end-of-program maps. There were three categories of mathematical content: *pre-academic content* such as geometry, solving equations and order of operations; *horizon content*, which in Israel bridges secondary and post-secondary mathematics, such as three-dimensional geometry and vectors; and *academic content* such as cyclic groups and infinity. (Note: In Israel, high school encounters with infinity, such as horizontal asymptotes, are algorithmic and are not associated to the symbol or concept of infinity.) Four students included horizon content and four students included academic content. One of the four included both horizon and academic content. For only one student did the number of academic items exceed the number of pre-academic items. This finding suggests that program graduates do not relate to academic mathematics, *i.e.,* the mathematics of mathematicians (Beswick, 2011).

Students did not connect different areas of mathematics on their maps, suggesting that at both the beginning and end of the program students' viewed mathematics content as a disjoint set of skills and topics rather than as a connected system (e.g., Beswick, 2005), *i.e.,* they had a simple knowledge belief about the structure of mathematics (M. Schommer, 1990).

The mean weight of the content items changed over the course of studies. The mean weight was 0.68 ($\sigma = 0.32$) on the initial maps and 0.32 ($\sigma = 0.26$) on the final maps. Items closest to the center of a map have a weight of one, therefore the results suggest that content became less central to students' views about knowing mathematics over the course of studies. Same-student comparisons confirm this finding; for 82% (*n*=18) of the students, the mean content weight of the second map was less than the mean content weight of the first. These findings suggest that the strength of students' belief in simple mathematical knowledge decreased over the course of studies.

**Attitudes toward mathematics**

Students' attitudes toward mathematics included cognitive, affective and behavioral components (Figure 1). Statistical analysis indicated that and behavioral components of attitudes became less central to students' epistemological beliefs about mathematics over the course of studies; the centrality of cognitive beliefs was stable.

**Cognitive Beliefs**

Four distinct sub-types of cognitive beliefs emerged from the data: three categories of cognitive processes associated to knowing mathematics and one relating to who knows mathematics. The three sub-types of cognitive processes are listed below:

- *Procedures and answers:* Mathematical knowledge consists of procedures; it is absolute. Knowledge is demonstrated by implementing mathematical procedures and achieving correct outcomes. “Correct” presentation is (sometimes) included.
- *Concepts and explanations*: Mathematical knowledge consists of understanding the concepts underlying procedures. It is absolute. Knowledge is demonstrated by an ability to explain or understand explanations of procedures and concepts.
- *Processes*: Mathematical knowledge is based on concepts which can be intuited, and discovered (or rediscovered). New knowledge can be constructed from existing knowledge. Knowledge is demonstrated by connecting concepts, relating mathematics to real life, asking and answering questions about mathematics, and creating (or recreating) new ways to solve problems.

The fourth sub-type cognitive belief, labeled *innate-ability*, describes a belief that knowing mathematics requires a certain type of intelligence (C. Dweck, 2006; C. S. Dweck, Chiu, & Hong, 1995). Thirty-six percent of the students (*n*=8) began the program holding a belief that knowing mathematics requires “intelligence” or a “mathematical head.” No students expressed this belief at the end of the program, indicating that these future teachers had, indeed, internalized the idea that intrinsic ability is not a pre-requisite for learning mathematics.

Fostering dynamic beliefs is implicit in the guidelines for Israeli mathematics teacher preparation (Gutfreund & Rosenberg, 2012). We therefore separately analyzed map items in the three categories of cognitive processes that emerged from our data, computing procedures-and-answers, concept-and-explanations and processes beliefs scores as well as the ratio of each of these belief scores to the sum of the three scores. Differences between beginning- and end-of-studies mean ratios are shown in Figure 2.

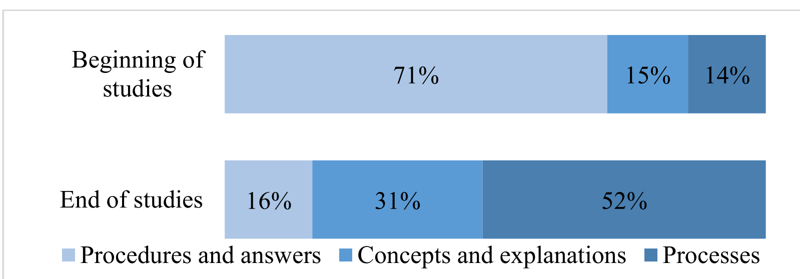

*Figure 2. Cognitive process ratios*

Cognitive beliefs expressed by beginning students were overwhelmingly focused on procedures and answers. By the end of the program, students’ cognitive beliefs had shifted to process; 52% of their beliefs expressed mathematics-as-processes. The mean weights for items in each of the three categories of cognitive processes support this finding. On the initial maps, the mean weight of procedures-and-answers items was 0.775 ( $\mu = 0.166$ ); on the final maps the mean weight was 0.480 ( $\mu = 0.316$ ). Same-student comparison showed that the mean weight of procedures-and-answers beliefs decreased for 77% (*n*=17) of the students. In contrast, the mean weight across all students of process beliefs increased from 0.338 ( $\mu = 0.388$ ) to 0.829 ( $\mu = 0.152$ ) and the mean weight of process beliefs increased for 77% (*n*=17) of the students. These findings indicate that over the course of studies students’ views shifted from mathematics as procedures to mathematics as processes.

## Discussion

This study analyzed pre-service secondary mathematics teachers' beliefs about knowing and learning mathematics at the beginning and end of their studies, as expressed through concept maps. Our findings document how their epistemological beliefs about mathematics changed over the course of studies, evolving to align with beliefs that support the cognitive objectives detailed in the Israeli guidelines for the preparation of secondary mathematics teachers (Gutfreund & Rosenberg, 2012). Prior research indicates that education impacts beliefs about the structure and stability of knowledge (Marlene Schommer, 1998), therefore the overall picture that emerged supports the idea that the program of studies impacted student beliefs about the complexity of mathematical knowledge and the cognitive components of mathematics. Other factors, such as age, may also have impacted beliefs.

Our results indicate that a view of knowing mathematics as knowing isolated content (simple knowledge) decreased over the course of studies. This has positive implications for these students' abilities to access and apply higher order cognitive strategies (Cano, 2005) and self-regulate their learning (Muis, 2007). The Gutfreund guidelines (2012) highlight these abilities as main components of mathematical literacy, deemed an essential component of teacher preparation. Our findings indicate that end-of-program beliefs align with the goals for mathematical literacy expressed in the guidelines.

Gutfreund guidelines (2012) for content knowledge of mathematics include understanding mathematics as a creative process rather than a finished, polished product; guidelines for pedagogical knowledge guidelines include supporting learning of both low and high order cognitive processes and stress equity of opportunities to learn mathematics vis a vis gender and differing abilities. These goals are aligned with dynamic, process-oriented beliefs about mathematics (e.g., Blömeke & Delaney, 2012; Briley et al., 2009). Our findings document that students' beliefs changed dramatically from an almost exclusive focus on mathematics as procedures and outcomes to a nuanced set of beliefs where mathematics includes procedures, concepts and dynamic processes.

The connection between the structure of mathematics teacher preparation programs and graduates' beliefs have shown that differences in opportunities to learn mathematics education courses impact graduates' beliefs. Our findings indicating post-program alignment with (implicit) belief goals present another avenue of exploration: the connection between program goals and epistemological beliefs. As a first step belief-alignment to the Gutfreund guidelines (2012) of other Israeli mathematics teacher preparation programs should be assessed. Belief-alignment in other countries should also be evaluated, including comparing alignment when belief goals are explicitly stated and alignment when they are implied.

## Conclusion

This case study showed that the epistemological beliefs of students completing a three-year undergraduate program in mathematics education are consistent with goals in the guidelines for the preparation of Israeli secondary mathematics teachers (Gutfreund & Rosenberg, 2012) and are aligned with belief expectations implicit in the goals.

The attention paid to the epistemological beliefs of graduates of mathematics education programs (e.g., Blömeke & Delaney, 2012) should be expanded to other undergraduate STEM programs. Connections between acquisition and application of higher cognitive strategies and epistemological beliefs (Hofer & Sinatra, 2010) suggest a role for beliefs in setting and meeting STEM goals of complex problem solving and lifelong learning (Fairweather, 2008).

# Exploring the secondary teaching of functions in relation to the learning of abstract algebra

Nicholas H. Wasserman
Teachers College, Columbia University

*Secondary mathematics teachers regularly take advanced mathematics courses, but many regard them as unrelated to their work as teachers. In accord with a novel instructional approach (Wasserman et al., 2017), we designed materials for an abstract algebra course that connect to the teaching of functions in secondary schools. In this paper, we describe findings from a small-scale teaching experiment employing design research, which provides evidence that particular tasks were productive for accomplishing some of the mathematical and pedagogical aims.*

*Keywords:* Functions, abstract algebra, secondary teacher education

Prospective secondary mathematics teachers (at least in the United States) are frequently required to take a large number of mathematics courses, including advanced courses such as abstract algebra and real analysis, to obtain certification to teach secondary mathematics. This is ostensibly with good reason – much of the content in secondary school is connected to and can be informed by ideas studied in these advanced mathematics courses (e.g., CBMS, 2012). Yet secondary teachers regularly report that completing such courses provides little professional value and does not influence their subsequent instruction (e.g., Zazkis & Leikin, 2010). This raises the challenging problem of designing tasks and modules in advanced mathematics courses that make meaningful connections to secondary mathematics teachers' future professional work.

In this paper, we explore the findings from a small-scale teaching experiment with two students in a secondary mathematics teacher education program. These students engaged with materials designed in accord with a novel instructional model for teaching advanced mathematics courses to secondary teachers (Wasserman et al., 2017). In particular, this paper looks specifically at their engagement with and reflections on abstract algebra content in relation to the teaching of functions in secondary school.

## Literature and Theoretical Perspective

### Advanced Mathematics Courses in relation to Secondary Teaching

Given the strong connection between ideas studied in advanced mathematics courses and the content of school mathematics, one would expect such courses to have an influence on secondary teaching. Yet findings from various studies appear to indicate the opposite. Monk (1994) examined the relationship between the number of university mathematics courses that a teacher completed and the learning outcomes of their students. The key finding was that courses beyond a fifth course – i.e., an advanced mathematics course – had little to no effect on the learning outcomes of that teacher's students. Zazkis and Leikin (2010) found that, according to practicing secondary teachers' self-reports, knowledge of advanced mathematics was rarely used and had little direct influence on their classroom practices. Other studies have reported similar results (e.g. Goulding et al., 2003; Rhoads, 2014; Wasserman et al., 2015).

This disconnect brings up the challenge of how to leverage the content of advanced mathematics in ways that are relevant to secondary teachers. Distinguishing between connections to the content of secondary mathematics and connections to the teaching of secondary mathematics, Wasserman (2016) analyzed school mathematics standards (CCSS-M, 2010) to identify four areas – arithmetic properties, inverses, structure of sets, and solving equations – where knowledge of abstract algebra might influence school mathematics' instruction. In general, the connections explored by Wasserman (2016) were specific to abstract algebra. That is, they were regarding *abstract-algebra-specific-content*, such as a group. We highlight this as a means to distinguish such content from other content that would also be related to the study of abstract algebra, but not necessarily unique to the study of abstract algebra, such as a function. We consider this to be *non-abstract-algebra-specific-content*. These sorts of connections have been given less attention in the literature.

**A Novel Instructional Model**

From Wasserman et al.'s (2017) point of view, the belief that completing a course in advanced mathematics will improve prospective or practicing teachers' (PPTs) ability to teach secondary mathematics has been based on a traditional view of transfer from the cognitive psychology literature (e.g., Perkins & Salomon, 2002). More specifically, there is an assumption that as a byproduct of learning advanced mathematical content, PPTs will better understand secondary mathematics content and will consequently respond differently to instructional situations in the future – a tenuously presumed "trickle down" effect (Figure 1a). Given the notorious difficulties in achieving this type of transfer, it is less surprising that PPTs' experiences in abstract algebra (or other advanced mathematics) often does not influence their teaching.

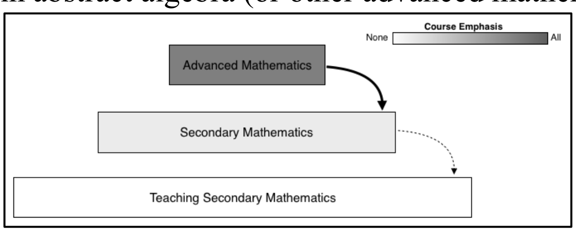

*Figure 1a. Implicit instructional model for advanced mathematics courses designed for teachers*

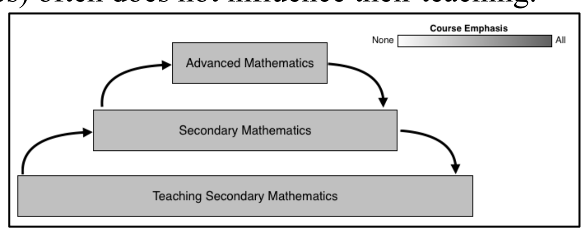

*Figure 1b. Our instructional model for advanced mathematics courses designed for teachers*

In Figure 1b, we present Wasserman et al.'s (2017) alternative instructional model for teaching advanced mathematics (including abstract algebra) in ways that can inform a PPT's pedagogical practice. This model is based on the premise that knowledge that PPTs learn should be inherently practice-based and applicable to the actual activity of teaching (e.g., Ball, Thames, & Phelps, 2008). Our model is composed of two parts: building up from and stepping down to practice. To *build up from (teaching) practice,* the abstract algebra content is preceded by a practical school-teaching situation. The building-up portion provides a context that sets the stage for the study of abstract algebra in ways that are both relevant to teachers' practices as well as well-suited to being learned in abstract algebra, which also aims to ease the challenges associated with transfer (e.g., Barnett & Ceci, 2002). The second part, *stepping down to (teaching) practice*, then uses the mathematical ideas from abstract algebra as a means to reconsider the secondary mathematics and relevant pedagogical situations. Stepping down to practice explicitly clarifies the intended mathematical and pedagogical aims of the abstract algebra content. In between building up from and stepping down to practice, the abstract algebra topics are covered by the instructor in ways true to its advanced nature with formal and rigorous treatment.

## Methodology

In accord with Wasserman et al.'s (2017) instructional model, our research team designed five modules that were intended to connect content typically covered in an abstract algebra course – including binary operations, groups, isomorphisms, subgroups, and rings and fields – to various teaching situations. The modules included some of the *abstract-algebra-specific-content* connections identified by Wasserman (2016). For the purposes of this paper, however, we elaborate only on one module, the Functions Module, which leveraged the abstract algebra content of binary operations and isomorphisms as a means to converse, broadly, about functions and to reflect on the secondary teaching of functions. That is, the connection in this module was not about binary operations and isomorphisms per se, but instead used them as instantiations of and an opportunity to discuss functions – an example of a *non-abstract-algebra-specific-content* connection. Figure 2 gives an overview of this module.

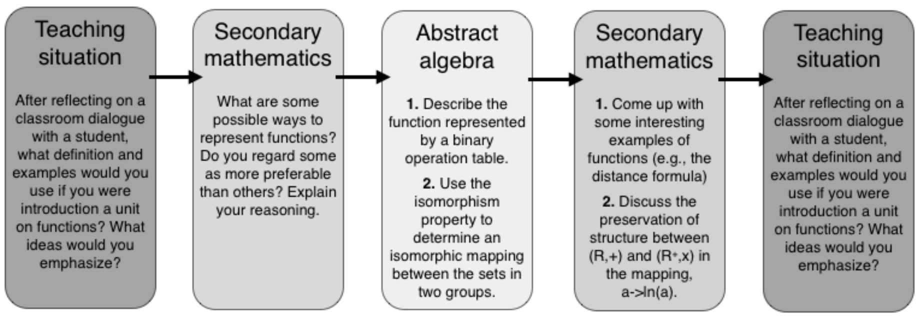

*Figure 2.* Overview of the Functions Module

Using design research (e.g., Cobb, et al., 2003) within a teaching experiment, the study engaged participants with some specific mathematical ideas and secondary mathematics teaching situations. Researcher-hypotheses were tested against participants' ways of thinking during the sessions. Two students (PPTs) enrolled in a program in secondary mathematics teacher education agreed to participate. One was a pre-service teacher, the other an in-service teacher with five years of experience (but not currently teaching). We collected and analyzed two sources of data: (i) a (transcribed) video-recording of PPTs engaging in the materials; and (ii) an (transcribed) audio-recording of a post-teaching-experiment semi-structured interview.

In our analysis, we compared what actually transpired during the teaching experiment to our hypothesized responses. First, we considered responses to the teaching situation. We characterized important aspects of PPTs' initial responses to the teaching situation, and their responses at the end of the module, and identified differences. Second, we considered whether these differences were in accord with our hypotheses, and, if not, whether they were meaningful instructional changes. Third, for each of these instructional differences, we then analyzed PPTs engagement with all facets of the module and their post-interviews to identify instances where their thinking appeared to shift in relation to the difference identified, and then to consider why this may have been the case. In this paper, we report on one instructional difference identified in the Functions Module that was in accord with our hypotheses, and discuss the aspects of the module that appeared to be most-closely associated with why PPTs responded differently.

## Results

We organize the presentation of results from our analysis in terms of their support for two particular claims: 1) PPTs indicated their future teaching of functions would include novel mathematical examples and more non-mathematical examples, not just numerical ones; and 2) PPTs' struggle to view a binary operation table through a functional lens progressed through four stages and was productive for acquiring a deeper understanding of function, and was influential on their reported approaches to teaching the function concept to secondary students.

**Claim 1**

The first claim is that PPTs indicated their future secondary mathematics instruction would include novel mathematical examples and more non-mathematical examples of functions, not just numerical ones. As mentioned, this instructional change indicated by PPTs was essentially in accord with researcher hypotheses. We consider three sources of data in support of this claim: i) their initial reaction to the teaching situation; ii) their reflection back on the teaching situation at the end of the module; and iii) their interview responses after the module.

During PPTs initial discussions about a teaching situation (which is omitted here for the sake of space), they responded to the question: "If you were introducing a unit on functions, what definition and examples would you use? What ideas would you emphasize? Explain your reasoning." The definition they had mentioned already was that every input has a unique output. Their initial examples were pictorial mappings that demonstrated the idea of uniqueness with an example, $\{(1,1),(2,2),(3,3)\}$, and non-example, $\{(1,1),(2,2),(3,3),(3,2)\}$. Further examples included tables and graphs, and used a step function to reinforce uniqueness – that it was a function, but if you had two closed circles (at the same *x*-value) it would not be. They also included various other types of functions (linear, quadratic), using their equations to talk about inputs having unique outputs. The key point is that their initial examples of functions were numerical (i.e., in $R \times R$) – which was in accord with our hypotheses – and they used different representations of these kinds of functions to exemplify the issue of uniqueness.

After engaging with the material in the module, the PPTs reflected back on their responses. In contrast to functions with numerical inputs and outputs, their discussion focused almost exclusively on incorporating more abstract examples, especially real-world examples (e.g., people to birthdays, piano keys to notes). These examples emphasized the "mapping between two sets of objects" part of function in addition to the "uniqueness" part.

*Interviewer*: Uh, talk about, maybe some of the things you might do, uh, definitions and examples you might use or see with students.

*A01*: So, the birthday?

*B03*: Yeah, and I liked, I liked the piano, or anything that's, you know, not so mathy, I guess."

*Interviewer*: The birthday, piano, real world, so why that?

*A01*: I just think they help them connect, like, what the idea of a function is.

*B03*: Yeah, and sometimes I feel that in math, you have to do…

*A01*: Only numbers.

*B03*: Yeah, like add, subtract, multiply, and divide, yeah, numbers, and…where was I going with this? I don't know. There's this idea a function is outside of just add, subtract, multiply, and divide… it helps identify the idea that the function is just some mapping we describe by however we want.

During the interview after the module, we probed further into some of their thinking. Here, they mentioned part of the rationale for doing so was: "Just to give [students] other examples of things that are functions besides what we traditionally talk about in an algebra classroom." They also indicated, "I have other examples of things that are functions now that I didn't have before…And maybe some of these are too complicated to show them, but it would cause me to maybe stop and think about…maybe there's another mathematical thing that I could show them outside of the traditional $y = x + 3$… that is a function that's not normally something we would talk about as a function." One such example they considered including was the quadratic formula, i.e., the function, $(a,b,c) \to \left(\frac{-b+\sqrt{b^2-4ac}}{2a}, \frac{-b-\sqrt{b^2-4ac}}{2a}\right)$, which was one they had come up with previously during the module when asked to identify interesting examples of functions in secondary mathematics.

**Claim 2**

The Functions Module was designed to leverage two aspects of abstract algebra as a means the motivate discussions about function. The first was viewing a binary operation table through a functional lens; the second was leveraging isomorphisms to discuss an abstract example of a function mapping. As it turned out, the first was especially important for PPTs' reflections on secondary teaching – the second, less so.

During the post-interview, the PPTs singularly identified the binary operation table task – which is discussed in more detail below – as being particularly influential. Also, however, we briefly trace two other facets of the module that made their way into PPTs' responses: i) their mention of the "piano" example was connected to the function that was included in the module as a precursor to the isomorphism activity (but was not the isomorphic mapping itself); and ii) their "quadratic formula" example was one they identified during the module. Notably, for (ii), their initial reaction was that the quadratic function would *not* be a function because each $(a, b, c)$ does not map to a unique output – there are two; later, they acknowledged it would be if the output set were pairs. This reiterates the idea that the objects being mapped to or from – and not just the idea of uniqueness – is important in determining whether something is a function, an aspect PPTs emphasized more readily in their teaching responses at the end of the module.

The primary activity in the module they identified as productive was the binary operation table task – where they were given the additive (mod 12) binary operation table and asked to "Describe the function (i.e., mapping) that this binary operation table represents." It was their (unexpected) struggle on this activity that appeared to have been especially productive for developing a deeper sense of function.

*Interviewer:* …So what were the main ideas that you got going through the abstract algebra content? …

*B03:* A deeper understanding of the function being something besides what I traditionally always thought about a mathematical function to be…

*A01:* I think that was the one that I had the hardest time—like the binary operation…

*B03:* And that one was really hard to think about cause it took us forever…it took us forever for us to figure out what the domain was.

*A01:* …it was a good place for us to get stuck.

*B03:* That's where I feel we, at least for me, I turned the corner about thinking about a function outside of just some linear situation… The fact that your domain can actually be an ordered pair…

We view their discussion here as indicative of a relationship between the binary operations task, which forced them to wrestle with and broaden their conception of function, and the real world and novel mathematical examples they mentioned including at the end of the module.

Since PPTs engagement in the binary operation task was profound, we looked further into reasons for why this may have been the case. In doing so, we identified four conceptual shifts that the PPTs went through as they came to view the additive (mod 12) binary operation as a function. During what we refer to as Stage 1, the PPTs had an *equation-view* of function. Their initial reactions to the task were:

*A01:* So, you're just, like, saying that $0 + 0 = 0$?

*Teacher-researcher:* Mmhm.

*A01:* Ok. …

*B03:* So, we just say, like, it's taking all the integers $0$ to $11$, and then…this is what we're mapping to?

*A01:* I don't know, I'm so confused… I'm so confused. I don't if this is the input, or…

*B03:* Are both of these inputs?

*A01:* … wouldn't these be outputs?... Unless it's like $x + y = z$. I don't know.

We point out that their initial, admittedly confused, attempts to view this as a function were by defining equations: $0 + 0 = 0$ and $x + y = z$. Now, these equations describe individual facts as well as more general truths about the binary operation table at hand. However, this equation-view was, ultimately, unproductive. For the next several minutes, the participants struggled to determine the domain – they cycled back and forth between thinking it was and was not "0 to 11." Their difficulties with the domain made their efforts to list actual elements in the mapping nearly impossible. The shift to Stage 2, a *mapping-view* of function, was facilitated by prompts to describe the mapping informally and to determine specific elements in the domain and range.

*B03:* It takes two of them… So it takes, it takes…if we do $A \times A$[1], we get all the ordered pairs, and then the added pairs get added together…like the two pieces of the pairs get added together to get that, but I don't know how we would write that.

*A01:* Ohhh.

*Teacher-researcher:* So… You don't have to be technical at this point. Just show me… Not just describe it, but show me things that map to things…

*A01:* $0 + 0$ maps to $0$, $1 + 0$ maps to 1. It…

*B03:* Go all the way up to, like, $11 + 1$, and $11 + 1$ maps to $0$.

*Teacher-researcher:* So what're you mapping? So what's the domain and what's the range?

*A01:* This [e.g., $0 + 0$] is our domain right? Cause this is being mapped to this [e.g., $0$].

Although this may seem a trivial difference, we argue that viewing the binary operation table as $(0 + 0) \to 0$ and *not* $0 + 0 = 0$ was an important conceptual shift: it fostered their ability to identify, or at least get closer to identifying, elements in the domain and the range. The next shift, to Stage 3, a *multivariable-view* of function, was facilitated by the teacher stating that "the '+' is actually fairly irrelevant…" Their response was, "So we can just list the ordered pairs?... So now our domain is all these ordered pairs… And our range is over here." In other words, this shift allowed them to recognize the mapping as $(0, 0) \to 0$, which is more clearly indicative of the multivariable domain input and which removes the "+" from the domain. Last, the shift to Stage 4, a *dependent-view* of function, was facilitated by a student-teacher interaction.

*Teacher-researcher:* Ok. So the general set, the domain is what?...

*B03:* So $A \times A$ is the domain, and $A$ is the range.

*Teacher-researcher:* … And so probably the easiest way to describe this is as a function is to say our function is taking things of the form here, it's taking two inputs, and it's mapping it to what? So if I have these inputs $A$ and $B$, it's mapping it to…?

*B03:* $A + B$.

This last shift, guided by the instructor, was important, in that it allowed writing the mapping not as $(a, b) \to c$, but rather as $(a, b) \to (a + b)(mod\ 12)$. In other words, it established the element in the range set as being dependent on the input variables ("+" as part of the output, not input), which led easily to the participants recognizing the equation form of the function as: $f(a, b) = (a + b)(mod\ 12)$. These four stages appear to be conceptual shifts in PPTs' thinking on the binary operations task that facilitated their coming to a deeper understanding of function.

---

[1] We note their use of the Cartesian product was likely prompted by the definition given, which was: A function $\phi$ mapping set $A$ to set $B$ is a relation between $A$ and $B$ (i.e., $\phi \subseteq A \times B$) such that each $x \in A$ is related to exactly one element in $B$.

## Discussion and Conclusion

This study explored how PPTs engaged in and reflected on materials designed to connect the secondary teaching of functions to content in abstract algebra (binary operations and isomorphisms). The purpose was to explore materials with some non-abstract-algebra-specific-content connections that might be used in an abstract algebra course with (or for) secondary teachers. We discuss three points with regard to the primary claims from the findings.

First, the binary operation table task (much more so than the elaboration on isomorphisms) was productive for deepening PPTs' notions of function. It was during this activity that PPTs struggled, productively, to view a familiar operation through a functional lens. The four-stage process they went through lends some insights into the conceptual challenges they faced. Notably, these mirror, or perhaps elucidate, some shifts that secondary students also go through in their transition to understanding even more basic functions. Functional relationships are regularly introduced through an *equation-view* with two variables, e.g., $y = x + 3$. These then need to be understood as a *mapping*, $x \rightarrow y$, in particular between pairs of *numbers* (the multivariable stage was, essentially, about identifying objects in the domain and range), for which the *dependent* relationship between the two variables provides a more useful characterization of the mapping, $x \rightarrow x + 3$. This mapping, then, can be given the more formal and typical equation notation of a function: $f(x) = x + 3$. According to their own reports, engaging in this process with a more abstract example helped the PPTs recognize the broader ubiquity of functions, such as the quadratic formula mapping from 3-space to 2-space, the derivative relationship as a mapping between functions, etc.

Second, we present similarities and differences between the types of functions the PPTs indicated they might use as examples after the module – more abstract real-world examples (e.g., piano keys to notes) and novel secondary mathematics examples (e.g., quadratic formula). Both of these are more abstract, by which we mean that the sets being mapped to or from are typically not just a set of numbers, but rather a set of objects, letters, coordinate pairs, etc. However, there are some differences between real-world examples and novel secondary mathematics examples. First, real-world examples are already regularly introduced in secondary classrooms – but oftentimes only to be quickly discarded and forgotten. Given that PPTs' discussions valued looking at different representations of functions, including visual ones, this makes sense: real-world examples are harder to represent in multiple ways via tables, equations, graphs, etc. Now, "graphing" such real-world functions might in fact be an interesting exercise. However, in contrast, novel secondary mathematics examples such as the quadratic formula provide a similar sense of abstractness, but also may have the advantage of having other easily-identifiable representations to discuss (e.g., explicit formulas, graphs, etc.).

Third, we make a dual point about the PPTs' reflections on their teaching. On the one hand, the kinds of examples they ultimately discussed incorporating into their own teaching were in accord with the aims of the module. Indeed, one of the goals was that teachers should select examples that exemplify more nuances with the idea of function, which such abstract examples helped accomplish. On the other hand, many of the ideas came directly from the module materials or from their engagement with the module materials. Indeed, they even mentioned potentially having secondary students look at the (mod 12) binary operation task. We have seen this tendency before, of PPTs "transporting" materials from a teacher education setting, in the exact form they experienced them, to their teaching (Wasserman et al., under review). It exposes a tension in teacher education, and suggests that teacher educators may need to be more explicit about how general ideas (not just materials) might be adapted for and applied to teaching.

Convergent and Divergent Student Experiences in a Problem-Based Developmental Mathematics Class

Martha B. Makowski
The University of Alabama

*In recent years low success rates in traditionally taught pre-college mathematics classes has led to new courses that use group work and problem solving to teach the required content. Early results examining student outcomes are promising, but say little about students' classroom experiences. This study uses interviews from six students and one instructor in a single class to explore differences between student experiences and the intentions of the instructor. Although several students expressed positive perceptions of the class, tensions arose between students who wanted to learn efficiently versus the classroom expectation that students stay together in their groups. Practices such as copying and dictation arose, at least partially, as coping mechanisms for students caught between these conflicting values. Future work should examine alternative grouping methods and ways of using early indicators of need to provide additional support.*

*Keywords:* Community college, developmental mathematics, group work, problem solving

Community colleges, although initially conceptualized as a place to prepare students for advanced study, now serve an incredible range of missions and students (Dougherty & Townsend, 2006). Students enter these schools at dramatically different stages of life, ranging from recent high school graduates with plans to earn a PhD, to adults returning to school after many years in the workforce or at home raising families (Cohen, Brawer, & Kisker, 2013). As a result, the mathematics background of these students is wide: spanning from seeing the material the first time, to having taken advanced coursework. Nowhere within community colleges is this truer than in pre-college, or *developmental*, mathematics classes, where instructors must meet the challenge of addressing the needs of this unique and complex population in a single classroom.

For many community college students, achieving their educational plans requires completing a developmental mathematics class, which are intended to provide the knowledge and skills necessary for success in credit-bearing college-level classes. However, low success rates (Attewell, Lavin, Domina, & Levey, 2006; Bailey, 2009) mean that developmental courses often play a gate-keeping function, a fact that is particularly concerning given that African Americans (Attewell et al., 2006) and individuals from lower-socio economic backgrounds (Hagedorn, Siadat, Fogel, Nora, & Pascarella, 1999) disproportionately enroll in developmental classes.

In recent years, developmental mathematics educators have moved to address the high failure rates by implementing mathematics curricula that use real-world problems and group work to help make the curriculum more accessible, echoing the reform efforts from the 1980s and 1990s in K-12 mathematics (National Council of Teachers of Mathematics [NCTM], 1989, 2000). In addition, these classes, often called *Mathematical Literacy*, are intended to support students in learning how to see mathematics in their daily lives. Studies of K-12 classrooms have shown that in problem solving and group work contexts, some students may resist the instructional norms (Lubienski, 2000). In addition, group work, although promoting opportunities for learning, can also lead to power struggles within groups (Esmonde & Langer-Osuna, 2013) and lack of opportunity to learn for some students (Baxter, Woodward, & Olson, 2001).

The most famous of the *Mathematical Literacy* classes are the Carnegie Pathways (Carnegie, n.d.a, n.d.b), with research from early implementations of these Pathways yielding tentatively positive results (e.g., Sowers & Yamada, 2015; Yamada, Bohannon, & Grunow, 2016; Yamada & Bryk, 2016; Norman, 2017). However, this work focuses on student success rather than on students' experiences with the curriculum. Given the large instructional shift, the uniqueness of the developmental population, and the diverse mathematics backgrounds of the students, it is important to understand how students experience these classes and what the individual instructor intended for students, paying particular attention to how these perceptions differed between students with different reactions to the class. This study sets out to do exactly this, asking:

1. How do perspectives on specific aspects of the course differ among students who have a positive, neutral, or negative reaction to the course?
2. How do students' experiences with the course compare with the intentions of the course instructor/developer?

## Methods

All data were collected from students in a single *Mathematical Literacy* classroom at Fields Community College (FCC; all names are pseudonyms), taught by an instructor who had participated in the development of the course. The course was not a Carnegie Pathway. Data draw from interviews with the instructor and students conducted outside of class and classroom audio recordings of the interviewed students' groups during the Spring 2015 semester.

### Sample

This study focuses on six of 22 students from a single *Mathematical Literacy* classroom who consented to participate in a single interview outside of class and contained more than 8 (of 24 possible) hours of audio of them in their groups. All students in the observed classroom were invited to take part in data collection. Everyone who indicated interest was interviewed. Table 1 provides basic demographics and the mathematics backgrounds of the interviewed students.

*Table 1. Interviewee demographics, mathematics backgrounds, and class outcomes*

| Name | Demographics | Mathematics background | Expected grade |
|---|---|---|---|
| Carley | White female<br>19 years old | Started developmental at lowest level; Trigonometry in high school | |
| Carrie | Asian female<br>20 years old | First developmental class<br>AP statistics in high school | |
| Craig | White male<br>25 years old | First developmental class<br>Trigonometry in high school | |
| Dave | White male<br>20 years old | First developmental class<br>Statistics in high school | |
| Emilia | Black female<br>19 years old | First developmental class<br>Trigonometry in high school | |
| Tyrone | Black male<br>48 years old | Started developmental at lowest level; GED | |

### Data Collection

Most student interviews occurred during the eighth or ninth week of the semester. Audio data were collected throughout the semester, but I focus on the data collected in week seven.

Focusing on this subset of classroom data provides alignment between the observation data and the experiences students shared during their interviews. In addition, during week seven all 22 students were still actively attending class, meaning the class contained its full range of diversity, both mathematically and demographically. The instructor interview occurred the last week of instruction.

**Analysis: Student Interviews**

To examine the similarities and differences in students' perceptions of *Mathematical Literacy*, depending on the type of experience a student had in the class, three main stages of analysis took place. I discuss each stage in more detail in the following sections. The majority of the coding was done by two researchers trained in mathematics education.

**Stage 1: Classifying student experiences.** Students' experiences were classified as positive, neutral, or negative using their response to the interview question "would you recommend *Mathematical Literacy* to others who were considering taking the class?"

**Stage 2: Coding for emerging themes.** Interviews were coded for emerging themes related to their perceptions of the class and classroom phenomena using multiple rounds of open coding (Creswell, 2014; Emerson, Fretz, & Shaw, 2011). This study focuses on data related to three main, mutually exclusive codes: *Group Work*, *Problem Solving*, and the *Instructor*. *Group Work* referred to students' discussions of working in groups, relationships with group members, or reflections on working in groups. *Problem Solving* related to students' discussions about the problem-rich curriculum and experiences engaging in mathematics. The *Instructor* code related to students' reflections on the instructor, their relationship with her, and their experiences working with her individually or with their group. Within each of these three main codes, mutually exclusive sub-codes were developed.

Elements of the classroom are inherently closely related, which occasionally made mutually exclusive coding difficult. For example, sometimes students spoke about their group interactions with the instructor. Broadly, this discussion fell into both the *Group Work* and *Instructor* codes. In instances like this, the default code was always *Instructor*.

**Stage 3: Contrasting student experiences.** For each student, the final list of codes from Stage 2 were tabulated for each individual. Using these tabulations, I identified patterns using the mixed-methods-analysis technique of matrices (Miles & Huberman, 2013), which organizes data along two or more dimensions, one of which is ordinal, to identify patterns between cases. Each matrix cell contains project data and the entire matrix can be used to draw inferences and detect patterns. For this project, I apply matrices with a convergent-divergent purpose in mind, using students' experience type (i.e., positive, neutral, or negative) as the ordinal dimension and final codes along the other, looking for patterns in how students spoke within codes.

As part of this analysis, I draw on interview segments, combined with examples from the classroom audio, to explore similarities and differences in how students with positive, neutral, or negative perspectives spoke about the classroom. I include these classroom examples not to causally link the perceptions students shared to a particular classroom event, but rather to illustrate examples of the classroom phenomena students identified.

**Analysis: Instructor Interview**

The initial round of coding of the instructor interview relied on the same three main codes as students (i.e., *Mathematics Curriculum*, *Group Work*, and *Instructor*), with appropriate adjustments made for the fact that the subject of discussion had switched from perceptions of the classroom to intentions for the classroom. Only the components of the interview that related to the instructor's experiences of these three things were considered.

I wrote these results to represent the intended curriculum with respect to each of the three codes. After analyses of the student interviews were complete, I returned to the instructor's interview, rereading it with a lens toward the student interview sub-codes. The analysis of the instructor's intentions was then refined to reflect the student sub-codes, noting places where the instructor's responses did not have comparable student codes.

## Results

The research questions of this study examine how students with different experiences in *Mathematical Literacy* vary in their perspectives of the class and the classroom phenomena, contrasting these with instructor intentions. I start with the classifications of student experiences and then present the results from the instructor, followed by the students. In this brief report, I focus on the results from the main code of *Group Work* (this code had the most material). Results for *Problem Solving* and *Instructor* will be included in the full report and presentation.

### Student Recommendations

Student recommendations fell into one of three categories: positive, neutral, or negative. Students who recommended the class tended to provide an overwhelming positive response. For example, Craig started answering the question with "I would now….especially if they were like me." Those coded as negative tended to qualify their answers, saying that the class might be appropriate for some students, but not for them personally. For example, Tyrone recommended the class for students "if they're up for a challenge," but would not recommend it for "people like me." Dave did not indicate his personal feelings, thus, his response was coded as neutral. Table 2 presents the recommendations of the students crossed with their anticipated grades.

Table 2. *Students' recommendations for the class and their expected grades*.

| | Recommendation | | |
|---|---|---|---|
| Expected grade | Yes | Neutral | No |
| A | Craig, Carrie | Dave | |
| B | | | |
| C | Carley | | |
| Did not complete class | | | Emilia, Tyrone |

### Convergent and Divergent Perspectives on Mathematical Literacy

To explore the instructor's intentions and how students with different experiences in *Mathematical Literacy* vary in their perspectives of the class and the classroom phenomena, I organize the remaining results with (a) the instructor's perspective and (b) results related to the patterns within the student codes.

**Group work: Instructor's perspective.** Group work was an important part of the course design, for Ms. Ann, the instructor, who, together with her colleagues at FCC, decided that in order to get students to do the mathematics the way they desired, "lecture classes aren't just going to be able to work. They need to be having these conversations [about math] in class." Thus, the choice to implement group work was driven by the curriculum objectives.

During her interview, Ms. Ann explicitly discussed how she created groups, explaining that she liked to spread her top- and low-performing students evenly between groups, but within this also considered “personalities and attendance” to create groups that provided a productive environment for all her students. She tried to include at least one “strong” member in each group. Thus, the instructor explicitly considered the range of abilities within the groups so as to provide as many students as possible with access to others who were fairly comfortable with the material.

An underlying assumption of much of Ms. Ann’s discussions related to group work was creating conditions where students worked together and discussed many instances of reaching out to students to help manage group relationships and keep students working together.

Ms. Ann acknowledged that group work allowed some students to minimize the amount of work they contributed, but explained that the class grading structure meant that most of these students would not pass the class without some degree of personal understanding of the content. She also noted that the group project rubrics allowed students to grade each other, but she observed that “the students are not always willing to throw each other under the bus,” which she found frustrating because it limited her ability to hold students individually accountable.

***Group Work*: Students’ perspectives.** *Group Work* sub-codes fell into six categories: (a) *Group Dynamics*, (b) *Togetherness*, (c) *Checking In*, (d) *Copying*, and (e) *Accountability*. I discuss the main findings for each of these sub-codes below.

***a. Group Dynamics*.** Many of the students with more positive experiences explicitly noted that groups usually contained students with diverse mathematics levels. Dave commented that sometimes groups have “someone who knows a lot about something with someone who doesn’t know anything about it” and Carrie observed, “everyone is at a different levels [*sic*] and they all kind of contribute their own things.” These remarks suggest that students, although perhaps not explicitly aware of the mathematical backgrounds of their group mates, recognized that a range of background knowledge existed within their groups.

***b. Togetherness*.** Although a few students talked about the benefits of togetherness, the majority of the students’ talk related to *Togetherness* related to divisions within groups.

Emilia and Tyrone, students who would not recommend *Mathematical Literacy*, both noted they usually found themselves behind. Tyrone commented, “sometimes I might be behind. I’m always behind. And then I look, ‘hey where you at?’ I’m just like man, ‘you all just go ahead—I’ll catch up.’” For both, a lack of togetherness resulted in being left behind. For example, a diagrams of Emilia’s group for a day near the time of her interview (Figure 1) shows she lagged behind that day and rarely spoke. When she did speak, she was usually talking to the instructor about problems her group mates had already discussed. Although not shown here, similar lag patterns were observed for many of the students who did not complete the class. This suggests that an early lack of togetherness in groups might signal the need for additional intervention.

The four other interviewed students did not mention feeling left behind. However, Carley and Craig gave examples of the ways they strove to bring groups together, while Carrie and Dave distanced themselves from this responsibility. For example, Dave noted that “it’s really difficult to get things done when you’re in a bad or…not a good group…I mean once you’ve got a good motion going then there’s no reason really you should have to stop.” It should be noted that Carrie and Dave were in groups with Emilia and Tyrone respectively around the times of their interviews. As noted earlier, Emilia rarely spoke with her group, despite Carrie saying in her interview that usually everyone had someone to work with. Audio recording of Dave and Tyrone’s group demonstrates that Tyrone was helped in his group, but not usually by Dave.

The lack of togetherness the students note and that is illustrated in Figure 1 show that togetherness was an issue. Dave and Carrie touched on reasons why this might be the case, noting that slowing down could be disruptive or distract from completing assignments quickly.

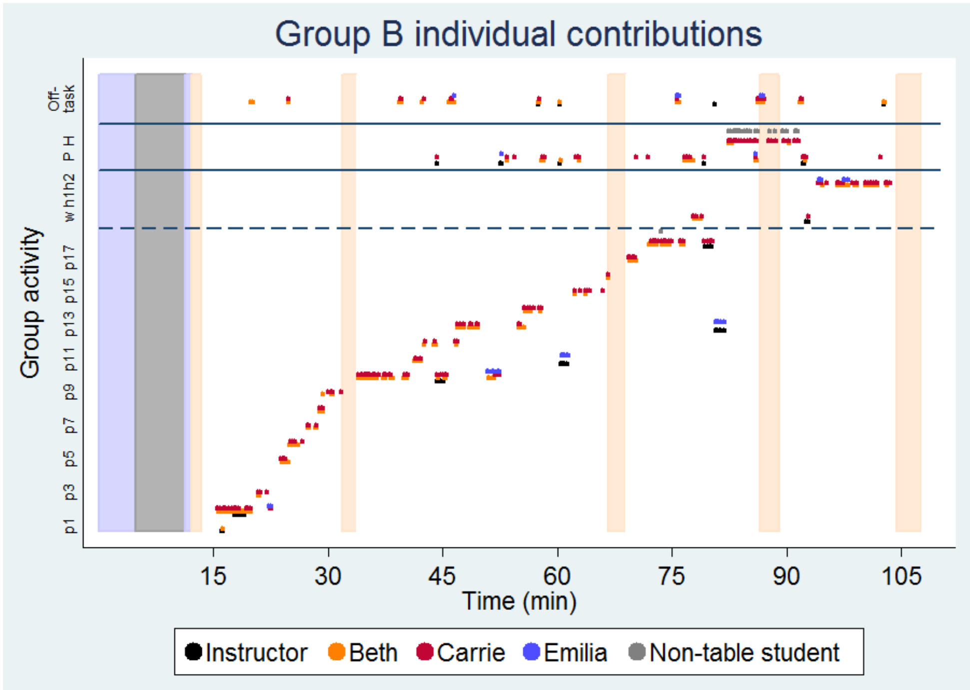

*Figure 1. Individual contributions in group B. Each dot indicates when an individual started a new speaking turn. Recording of individuals started when the instructor opened the classroom up for group work (here, around minute 15). The light blue regions indicate when the instructor was returning assignments and checking in with students. The grey regions are when the students were engaged in a quiz or an activity related to the study. The light orange regions are when the instructor was lecturing. White regions are when the class working in groups. The Group activity labels mean, in ascending order: problems 1 through 17 (skipping even numbers on the labels), written reflection task (w), group homework assignments 1 and 2 (h1, h2), group planning discussions (P), helping other groups (H), and off-task talk.*

***c. Checking In.*** All six students talked about asking others for help or being asked by group members if they needed assistance and described the help they received from their group mates as useful. However, Emilia and Tyrone both mentioned times when they had needed help but encountered barriers to receiving aid. Emilia expressed feelings of stress when others checked on her, noting that in one group "they would like stop occasionally to see if I need help but it just, it makes me feel like 'Oh my god! I need to step it up.'" Tyrone discussed a group member who "really knows her shit, but I don't even speak to her." When pressed about the relationship, he indicated that he thought "she just don't like me." In both cases, the students who would not recommend the class did not trust that their group would provide the help they needed or wanted.

***d. Copying.*** All the students acknowledged copying occurred within the groups, but clear divisions existed. Both Tyrone and Emilia, who negatively recommended the class, said they copied. Emilia said her group at the time "just tell me to copy down the answer," suggesting group-sanctioned copying to quickly address Emilia's questions or catch her up to the rest of the group occurred. Tyrone admitted to initiating the copying "so I can go back and look at it and do it like that….I always, like, go back and look at it so I can understand it." For Tyrone, copying was a strategy for learning, allowing him access to the content he could not cover in class. For Tyrone and Emilia copying was a coping strategy for the lack of togetherness in their groups.

The four other students admitted copying occurred but did not admit to themselves doing so. Three of these students said that they had let others copy, but none mentioned encouraging the practice. Instead, they distanced themselves. For example, Carley, in talking about a woman who often copied, said "I'll let her copy, but it's…just going to hurt you in the long run." Thus, while the students universally acknowledged copying, the roles they played in the practice varied.

***e. Accountability.*** Distribution of the workload and a lack of control were themes common among the students with more positive recommendations, identifying that the workload on group assignments was not always even and they lacked control over group assignments. Most of these students described conflicting feelings about trying to regulate or report their peers. In contrast, Tyrone and Emilia, the students who negatively recommended the class, said little about their experiences with group-graded assignments. Emilia did not mention group-graded assignments at all. Tyrone, rather than talking about the fact that the quality of the work was sometimes out of his hands, noted that group grades could hide the fact that not everyone in the group understood.

The contrast in experiences might be at least partially understood by a classroom instance during which Carrie and Emilia's group negotiated a graded group assignment. Emilia was responsible, by a class policy, for writing up the group answers. During the group conversation about the problem, Emilia functioned primarily as a scribe, with her group members effectively dictating answers. Thus, Emilia's group members managed the work to produce an acceptable product *efficiently*, meaning that Emilia lost the opportunity to reflect with and learn from her group, even when positioned by classroom rules to act as a critical person in the discussion.

Note that the scribe work Emilia did in this example differs from the copying discussed earlier. Here, Emilia was completing an assignment where each person in the group received the same grade, regardless of who did the assignment. In contrast, when copying, the students were doing so for work graded for completeness, so only the student who copied stood to lose.

## Discussion and Conclusions

The results presented here demonstrate some of the consequences of forming groups with diverse mathematics backgrounds and demonstrates how these conditions mean classroom goals can come into conflict. During her interview, the instructor suggested that she *relied* on a diversity of mathematics knowledge within groups to provide the best opportunity for students to learn effectively from the curriculum. Although students recognized that groups often contained a large range of knowledge levels, not all students felt they received the support they needed, while those in a position to help did not always believe supporting others was a productive use of time. Through this lens, the decision to not always support their group mates can be viewed as a rational choice, even if this is not particularly kind or fair. Many of the classroom practices that students discussed were consequences of, or coping mechanisms for, addressing the range of needs within the groups. An uneven workload on assignments was a consequence of having high-knowledge students not trusting their slower moving group mates to do the work. Copying was, for at least some students, a coping mechanism to help them quickly acquire access to the course materials when they could not participate fully in the discussion during class.

The resulting lack of togetherness in some groups did not meet the instructor's intentions and could be an indicator, if it occurs early in the semester, that a student needs additional support. Although the instructor did notice and work to address the lack of togetherness within groups, these measures were not always enough. Future iterations of *Mathematical Literacy* should experiment with group structures that prioritize knowledge levels differently. In addition, an early lack of togetherness in mathematically diverse groups might be an early and actionable indicator a student requires additional support. While this study shows that not all students had positive experiences in *Mathematical Literacy*, some did. Refinements and reflections on ways to better meet the needs of students could do a lot for future *Mathematical Literacy* students.

*Hypothesis testing is a key concept included in many introductory statistics courses. Yet, due to common misunderstandings of both scientists and students, the use of hypothesis testing to interpret experimental data has received criticism. With statistics education on the rise, as well as an increasing number of students enrolling in introductory statistics courses each year, there is a need for research that investigates students' understanding of hypothesis testing. This paper describes results obtained from a larger study designed to investigate introductory statistics students' understanding of one population hypothesis testing. In particular, we present on one student's understanding of the concepts involved in hypothesis testing, Steve, who provided us the best spectrum of different levels of knowledge according to APOS Theory, our guiding theoretical framework. Based on this data, we suggest implications for teaching.*

*Keywords:* Hypothesis Testing, Introductory Statistics, APOS Theory

## Introduction

The use of statistics is crucial for numerous fields, such as business, medicine, education, and psychology. Due to its importance, according to the *Guidelines for Assessment and Instruction in Statistics Education (GAISE) College Report*, more students are studying statistics, and at an increasingly younger age (GAISE College Report ASA Revision Committee, 2016). As a result, the *GAISE College Report* calls for nine goals for students in introductory statistics courses. One of these nine goals is that "Students should demonstrate an understanding of, and ability to use, basic ideas of statistical inference, both hypothesis tests and interval estimation, in a variety of settings" (p. 8).

Hypothesis testing is conducted in order to analyze a claim about a population parameter, based on sample statistics. It involves formulating opposing statements—the null hypothesis and alternative hypothesis—about the population parameter of interest. The goal of hypothesis testing is to determine whether or not to support the original claim, based on whether we reject the null hypothesis. To do so, a sample statistic is measured or observed and converted to a standardized value called the test statistic. The test statistic is then used to calculate the probability, called the *p*-value, of obtaining a test statistic at least as extreme, under the assumption that the null hypothesis is true. If the *p*-value is too low, then we reject the null hypothesis. Once a decision is made, a conclusion can be formed about the claim.

With statistics education reform on the rise, as well as an increasing number of students enrolling in introductory statistics courses each year, there is a need for research that investigates students' understanding of hypothesis testing, a concept taught in almost every introductory statistics course (GAISE College Report ASA Revision Committee, 2016; Krishnan & Idris, 2015). While previous research in this area has focused on students' misconceptions pertaining to hypothesis testing, our study sought to turn attention to what students understand and how they come to understand it. We focus our attention on the following research question:

*How do students reason about the concepts involved in one population hypothesis testing while working two problems involving real-world situations?*

In this paper, we focus on answering this question for one particular student, Steve, who elaborated the most in his interview, and thus, provided us with the richest data.

## Literature Review

Research has revealed that although students are able to perform the procedures surrounding hypothesis testing, they lack an understanding of the concepts and their use (Smith, 2008). Providing a survey of research on students' understanding of statistical concepts, Batanero et al. (1994) stated that hypothesis testing "is probably the most misunderstood, confused and abused of all statistical topics" (p. 541). Students appear to experience a "symbol shock" (Schuyten, 1990), which provides an obstacle for students interpreting particular questions (Dolor & Noll, 2015; Liu & Thompson, 2005; Vallecillos, 2000). Vallecillos (2000) found that students have trouble with not only the symbols, but also with the formal language and meaning behind the concepts involved in hypothesis testing, including words such as "null" and "alternative" when referring to the hypotheses. Students interviewed were not able to accurately describe what these terms mean and how they impact the decision to either fail to reject or reject the null hypothesis (Vallecillos, 2000). Williams (1997) made a similar observation. She found that, due to the tedious process behind hypothesis testing, students were not able to connect the statistical concepts back to the context of the problem. She further stated that, "the biggest hurdle is reaching a statistical conclusion, and the real meaning of the original question may be forgotten in the process" (p. 591).

Students' difficulty with understanding hypothesis testing can oftentimes be attributed to how it is taught. Textbooks and instructors frequently give a specific step-by-step script to follow when performing hypothesis testing, which does not provide students the opportunity to see the process as a whole. Link (2002) described this as a six-part procedure, which leads many students to look for keywords and phrases as guides when solving hypothesis testing problems. He found evidence that students were able to correctly substitute values into a formula selected from a formula sheet, but they did not have an understanding of the logic behind the overall procedure of hypothesis testing.

## Method

The focus of our larger study is on university students who are enrolled in an introductory statistics course at a large public institution in the southeastern United States. For this particular institution, students were required to spend three academic hours per week in a computer lab, completing assignments through Pearson's *MyStatLab.* Data collection took place during Fall 2014 and Spring 2015. All students enrolled in six sections of an introductory statistics course (approximately 240 students) were invited to participate in a problem solving session and semi-structured interview pertaining to hypothesis testing. Twelve students volunteered to participate. During the problem solving session, each participant worked alone on two hypothesis test questions, similar to problems they had already seen. They were encouraged to use Excel when needed, since the use of it was required as part of the class. The first question asked the student to conduct and interpret a hypothesis test for a single population proportion. The second question asked the student to conduct and interpret a hypothesis test for a single population mean. The questions were as follows:

1. In a recent poll of 750 randomly selected adults, 588 said that it is morally wrong to not report all income on tax returns. Use a 0.05 significance level to test the claim that 70% of adults say that it is morally wrong to not report all income on tax returns. Use the *P*-value method. Use the normal distribution as an approximation of the binomial distribution.
2. Assume that a simple random sample has been selected from a normally distributed population and test the given claim. In a manual on how to have a number one song, it is stated that a song must be no longer than 210 seconds. A simple random sample of 40 current hit songs results in a mean length of 231.8 seconds and a standard deviation of 53.5 seconds. Use a 0.05 significance level to test the claim that the sample is from a population of songs with a mean greater than 210 seconds.

Immediately following the problem solving session, the students participated in a semi-structured interview that was video-recorded. There were ten interviews, eight with one participant each and two with two participants each. During the interviews, participants were asked to elaborate on their solutions and thought processes. Conducting the interviews was divided among five members of the research team, who all followed the same protocol. The data (interview transcriptions, written work, and Excel files) were analyzed and coded according to the levels of conceptions in APOS Theory (described below). The research team deliberated until an agreement was made regarding the codes.

### APOS Theory

Action–Process–Object–Schema (APOS) Theory is a constructivist framework for describing how an individual might develop his or her understanding of a mathematical concept (Arnon et al., 2014). It emphasizes the construction of cognitive structures called Actions, Processes, and Objects, which make up a Schema. These structures are constructed through reflective abstraction, particularly through the mental mechanisms of interiorization, reversal, coordination, encapsulation, and generalization. The construction of these structures signify levels in the learning of a mathematical concept. An Action is a transformation of Objects in response to external cues. The primary characterization of an Action is the external cue, which could be keywords or a memorized procedure. Reflection on a repeated Action can lead to its interiorization to a Process. While an Action is an external transformation of Objects, a Process is an internal transformation of Objects that enables an individual to think about the transformation without actually performing it. Once a Process is conceived as a totality and the individual can perform transformations on it, the Process is said to have been encapsulated into an Object. While a component of APOS Theory is the development of a genetic decomposition, i.e., description of how an individual might develop an understanding of a mathematical concept, our genetic decomposition is omitted in this paper due to space limitations.

## Results

While performing a hypothesis test, it is necessary for an individual to formulate the hypotheses about a population parameter, evaluate the test statistic, find the *p*-value, compare the *p*-value to the significance level, form a decision about the null hypothesis, and form a conclusion about the claim. Through these objectives, students construct mental structures called **hypotheses**, **test statistic**, **p-value**, **decision**, and **conclusion**, each of which can be conceived as an Action, Process, or Object. In this section, we provide examples of how the mental structures of **hypotheses**, **test statistic**, **p-value**, and **decision** emerged in the reasoning of one particular student, Steve. As we will show, these constructions emerged as Processes or Objects in Steve's reasoning. We use bold font when referring to the primary mental structures that make up our genetic decomposition, to distinguish them from other uses of these terms. For simplicity, we do not use a different font to distinguish between the different levels corresponding to a concept. Note that we are not seeking to classify Steve in terms of his understanding, but instead, present evidence we found of his reasoning. Due to space limitations, we omit discussing **conclusion**.

**Hypotheses**

The mental structure, **hypotheses**, can be conceived as a transformation—an Action or Process—that acts on the claim of the hypothesis test and returns the null and alternative hypotheses. As an Object, additional transformations can be performed on **hypotheses**. Steve exhibited both a Process conception and Object conception of hypotheses.

To illustrate Steve's reasoning of **hypotheses** as a Process, the following excerpt is considered from Question 1 of the instrument.

> Um, well, when you're doing null and alternative you always focus on the claim they give you. Um, so 70%, and just to make things easier, uh we do the null is equal to .7, and then the alternative would be whatever you're asking, in this case you're asking, is it 70%. So you use not equal to 70%.

Steve acknowledged, in general terms, that the claim is used to formulate the hypotheses. We consider this to be evidence of a Process conception of hypotheses.

To illustrate Steve's reasoning of **hypotheses** as an Object, the following excerpt is considered from Question 2 of the instrument.

> OK. I just did the same thing I did with proportion, and I said the null is equal to um 210, in this case, and uh the alternative is greater than 210. But the only reason I said that is because um in this bottom line of the question says, test the claim that the sample is from a population um with a mean greater than 210.

Steve used the phrase, "in this case," to indicate that in his mind he distinguished his procedure for Question 2 from his procedure for Question 1. Despite the fact that the questions on the instrument pertained to two different contexts, Steve said, "I just did the same thing I did with proportion." In order to be able to describe his procedures as the same, while also distinguishing between them in the different situations in which they arose, he had to have compared them, which is evidence of an Object conception of hypotheses.

**Test Statistic**

The mental structure, **test statistic**, can be conceived as a transformation—an Action or Process—that acts on various population parameters and sample statistics and returns a standardized value, namely the test statistic, which is the number of standard deviations a sample statistic is away from the distribution's center, or expected value. As an Object, additional transformations can be performed on **test statistic**. Steve exhibited both a Process conception and Object conception of test statistic.

To illustrate Steve's reasoning of **test statistic** as both a Process and an Object, the following excerpt is taken from Steve's discussion of Question 1, in which he described what accounted for an extreme value of the test statistic.

> But going back on it, it makes sense, you know, if you've got a *p*-hat that, that's very very different from your, from your *p*, you know, 78 is a whole 8% off of uh the 70%. And also your test statistic is very large. I'm not totally sure what a test stat is, but it reminds me of *z*-scores, and I remember when you have a *z*-score that gets above 3, it starts to get pretty, pretty crazy. So 5 is huge, which is also the reason that you're getting a bunch of zeros or very close to 1.

Steve appeared to have encapsulated into an Object the Process of calculating a *z*-score for proportions, in order to consider how it resulted in an extreme value of the test statistic. He explained that a large value of the test statistic resulted from having a value of the sample statistic that is very different from the value of the population parameter in the null hypothesis. APOS Theory acknowledges, in general, that it is necessary to de-encapsulate an Object back into a Process, which appears to be the case with Steve. That is, he de-encapsulated his test statistic Object back into a Process to consider the difference between $\hat{p}$ and $p$. We should note that based on Steve's statement, "I'm not totally sure what a test stat is, but it reminds me of *z*-scores," he appeared to have constructed isolated Processes for each test statistic, which he needed to further coordinate in order to construct a single test statistic Process.

***P*-value**

The mental structure, **p-value**, can be conceived as a transformation—an Action or Process—that acts on the test statistic and returns a probability—a number between 0 and 1. As an Object, additional transformations can be performed on **p-value**. Steve exhibited both a Process conception and Object conception of p-value.

To illustrate Steve's reasoning of **p-value** as both a Process and an Object, we consider the following excerpt from Steve's discussion of the *p*-value for Question 1, in which he explained various procedures for calculating the *p*-value, depending on the situation.

> *Steve:* Well, whenever you're finding a *p*-value you're doing a .DIST function, and when you're doing proportions, it's NORM, and when you're doing means, it's T. So in this case we used NORM.S.DIST cause I think the other formula is silly. But uh since it's a two-tailed test I couldn't just stop there. I had to 1 minus that and then double it.
> *Interviewer:* OK, OK. And you did the 1 minus, why?
> *Steve:* Um because if you don't do 1 minus, it ends up being something very very close to 1. So a bunch of .9999…, and you can't double that. Whenever I got stumbled, I was like, oh wait, do I, uh, do I double the 1 minus or it by itself. Well, you can't go over 1. It has to be between 0 and 1.

Steve explained, in general, that an Excel .DIST function is used to calculate a *p*-value, and he said the result "has to be between 0 and 1." Steve's description in general terms of the transformation on the test statistic that resulted in the *p*-value and recognition of the p-value as a probability is evidence of a Process conception of *p*-value. Furthermore, Steve described situations in which you would use NORM.S.DIST versus T.DIST. Although Steve was not completely correct in stating that you always use T.DIST in the context of means, he clearly compared different procedures for calculating the *p*-value and considered situations in which these procedures would arise. Thus, we consider this to be evidence of an Object conception of *p*-value.

**Decision**

In hypothesis testing, we make a decision about whether or not to reject the null hypothesis by comparing the *p*-value to the significance level, which, in this course, was a predefined upper bound for the *p*-value. In particular, if the *p*-value is less than or equal to the significance level, we reject the null hypothesis. The mental structure, **decision**, can be conceived as a transformation—an Action or Process—that compares the *p*-value to the significance level and returns the decision about whether to reject the null hypothesis. In particular, **decision** compares the *p*-value and significance level as areas or probabilities. As an Object, additional transformations can be performed on **decision**. Steve exhibited a Process conception of decision.

To illustrate Steve's reasoning of **decision** Process, we first consider the following excerpt from Steve where he demonstrated that he compared the *p*-value and significance level as areas.

> Oh wait! Wasn't the *p*-value supposed to be from the edge? So wasn't the *p*-value supposed to be like this … [*draws on paper*] … the stuff on the outside? I remember now. It was um . . . I don't see how that relates to those, but I know it relates to the significance level 'cause your .05 is going to be outside of that.

Steve explained how he was able to graphically represent the *p*-value (see Figure 1). Finding that the *p*-value is less than the significance level, he drew the region whose area is the *p*-value inside the region whose area is the significance level, evidence that he compared the *p*-value and significance level as areas. To clarify, when Steve said, ".05 is going to be outside of that," we interpret it to mean that the rejection region is not strictly contained in the region whose area is the *p*-value. In addition to considering this to be evidence of a component of a **decision** Process, we also consider this as further evidence of a **p-value** Object.

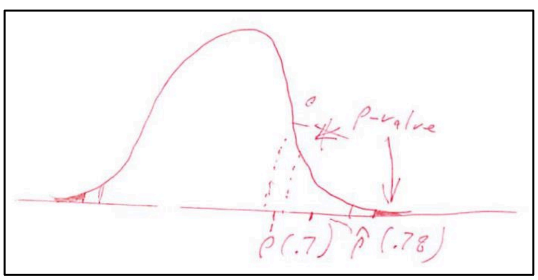

*Figure 1: Steve's graph of the p-value for Question 1.*

The previous excerpt established that Steve was able to compare the *p*-value and significance levels as areas, which we consider to be a necessary characterization of a **decision** Process. To further illustrate Steve's reasoning, we consider the following excerpt about whether or not to reject the null hypothesis for Question 1. Note that part of this excerpt was discussed previously in the section on test statistic.

> *Interviewer:* OK, so, and how did you arrive at your conclusion? What did you arrive at?
> *Steve:* I just remembered anytime the *p*-value is less than the, uh, significance level you reject the null, uh, I think [*laughs*]. But going back on it, it makes sense, you know, if

> you've got a $p$-hat that, that's very very different from your, from your $p$, you know, 78 is a whole 8% off of uh the 70%. And also your test statistic is very large. I'm not totally sure what a test stat is, but it reminds me of $z$-scores, and I remember when you have a $z$-score that gets above 3, it starts to get pretty, pretty crazy. So 5 is huge, which is also the reason that you're getting a bunch of zeros or very close to 1 […] So it's interesting, we always go all the way out to the $p$-value, but you can pretty much tell from your test statistic if it's correct or not.

Initially, Steve rejected the null hypothesis based on a memorized rule, suggestive of a **decision** Action. However, he reflected on this Action and related an extreme test statistic to a small $p$-value. As a result, Steve explained that depending on the magnitude of the test statistic, you could potentially form a decision about the null hypothesis without comparing the $p$-value to the significance level. The ability to describe the result of a transformation without needing to perform all of its steps is evidence of a Process conception.

## Discussion and Concluding Remarks

Since the number of students enrolling in introductory statistics courses each year is continually increasing, it is important to explore students' reasoning of hypothesis testing (GAISE College Report ASA Revision Committee, 2016; Krishnan & Idris, 2015). This report, part of a larger study, focused on examples of how the mental structures of **hypotheses**, **test statistic**, **p-value**, and **decision** emerged in the reasoning of one particular student, Steve. Steve's constructions of the mental structures emerged as Processes or Objects in his reasoning. Steve exhibited a Process conception of hypotheses by acknowledging that, in general, the claim is used to formulate the hypotheses. In another situation, Steve exhibited an Object conception of hypotheses by being able to compare procedures for formulating hypotheses between two different problems. Steve illustrated test statistic as both a Process and an Object by describing what accounts for an extreme value of the test statistic in a situation. Steve exhibited an Object conception of $p$-value by being able to explain and compare various procedures for calculating the $p$-value, depending on the situation. Lastly, we found evidence that Steve illustrated a Process conception of decision by being able to describe the results of his decision without going through the steps of comparing the $p$-value to the significance level. In this case, he related a large test statistic to a small $p$-value.

Our results suggest that concepts involved in hypothesis testing are related through the construction of higher order transformations, operating on Processes that have been encapsulated into an Object. It has been widely recognized in APOS Theory literature that encapsulation of a Process into an Object is difficult to achieve, a possible explanation for why hypothesis testing is such a challenging topic for students. However, we found evidence of these constructions of higher order transformations in Steve's rich descriptions of the concepts.

With textbooks and instructors frequently introducing the topic by giving a step-by-step script to follow, what Link (2002) describes as a six-part procedure, construction of higher order transformations becomes even more difficult as this instruction leads students to look for keywords and phrases as guides when solving hypothesis testing problems. Based on the results, it is important when teaching to develop questions for students that motivate them to think and explain beyond a procedural approach. Creating activities with guiding questions will encourage students to think such as Steve, and to develop deeper knowledge of hypothesis testing.

Framework for Students' Understanding of Mathematical Norms and Normalization

Kevin Lee Watson
Virginia Tech

*Mathematical norms and normalization of vectors are important concepts used throughout the mathematical and physical sciences; however, very little research has been done on students' understanding of these concepts. To remedy this lacuna, this report presents a framework that can be used to model, explain, and predict the ways students reason about and solve problems involving norms and normalization.*

*Keywords:* norms, normalization, student understanding, vectors, linear algebra

Normalization of particular vectors from various vector spaces (e.g., $\mathbb{R}^n$, $\mathbb{C}^n$, function spaces) is mathematically important in various contexts. Some examples include directional derivatives in multivariable calculus, states of quantum mechanical systems in Physics, and the development of orthonormal bases through the Gram-Schmidt process in Linear Algebra and Numerical Analysis. Despite the wide applicability of normalization within mathematics and science, students' understanding of norms and normalization seems not to have been studied. Research that has examined students' understanding of absolute value have come close to the topics (e.g., Almog & Ilany, 2012; Sierpinska, Bobos, & Pruncut, 2011), but have not directly addressed them. This lack of research into students' understanding of norms and normalization must be remedied.

In this report, I present a framework for students' understanding about mathematical norms and normalization. This framework aims to address the following research questions: (a) What are the various components involved in understanding mathematical norms and normalization, and how are they interconnected? and (b) How does a students' understanding of those components impact their thinking and solution strategies when working on problems involving norms and normalization?

I first explain the theoretical lens of the Emergent Perspective that I adopt within this report, and why the development of models of student thinking and understanding are important. Next, I describe the methods for the study and framework development. An explanation of the framework is given afterwards, with a focus on how the various components fit together and interact with one another. I then use data from two students to illustrate how the framework can be used to model, explain, and predict students' reasoning about normalization problems. Lastly, I discuss how the results illustrate elements of understanding norms and normalization that were particularly powerful for students in their reasoning about normalization problems, and the implications these have for teaching and future research.

## Theoretical Lens

The Emergent Perspective (Cobb & Yackel, 1996) coordinates psychological constructivism (von Glasersfeld, 1984, 1995) and social interactionism (Bauersfeld, Krummheuer, & Voigt, 1988) into a version of social constructivism that views mathematical learning as both individual construction and enculturation into the mathematical community. As an elaboration on the Emergent Perspective, Rasmussen, Wawro, and Zandieh (2015) added the importance of understanding the conceptions individual students bring to bear in their mathematical work. The main goal of this research is to gain a better understanding of students' conceptions about norms and normalization, and create a framework for modeling, explaining, and predicting students' reasoning about these concepts.

## Methods and Framework Development

The framework developed and used herein was inspired and influenced by Zandieh's (2000) framework for student understanding of derivatives and Lockwood's (2013) model of students' combinatorial thinking. Similar to the work of Lockwood (2013), I used a *conceptual analysis* (von Glasersfeld, 1995) or "a detailed description of what is involved in knowing a particular (mathematical) concept" (Lockwood, 2013, p. 252) to create this framework of students' understanding of norms and normalization. This conceptual analysis involved an iterative process of moving among my own theoretical thinking about the constructs involved in understanding norms and normalization, relevant literature, and the student interview data.

Although research examining students' understanding of norms and normalization is scarce, research on students' understanding of absolute value is relevant, as the absolute value is an example of a norm. Important findings include: the power in understanding multiple ways to define the absolute value (e.g., delete the negative sign, $|x| = \sqrt{x^2}$) in solving different problems (Wilhelmi, Godino, & Lacasta, 2007); and the power of understanding absolute value as the magnitude of a number or its distance from zero (Almog & Ilany, 2012; Sierpinska, Bobos, & Pruncut, 2011). These ideas impacted the development of the framework, and may be important for students' understanding of norms and normalization, as I illustrate later.

The data used in the development of the framework consists of hour-long, video-recorded, semi-structured interviews with individual students at two different collection sites: nine junior-level quantum mechanics students from a university in the northwestern United States; and two junior-level linear algebra students and two sophomore-level multivariable calculus students from a university in the southeastern United States. Students at the first site were asked questions about several linear algebra concepts including normalization, while students at the second site were only asked questions about norms and normalization. Although interviews from both sites informed the framework development, the data used within this report to illustrate the utility of the framework come from the second collection site.

In analyzing the student data, I first watched the sections of the interview in which students explained their understanding of normalization and normalized vectors from $\mathbb{R}^2$ and $\mathbb{C}^2$, writing a summary of each student's thoughts afterwards. Next, the transcript or video of the interview was coded (Maxwell, 2013) for each student, with some codes influenced by the state of the framework at the time of coding. Lastly, I examined the framework to see how well it could be used to model and make sense of each student's thinking and reasoning about norms and normalization, making modifications as necessary. The framework, as it stands in the next section, has gone through several revisions and refinements based on this analysis, as well as feedback received through poster presentations at two conferences (Watson, 2017a, 2017b).

## Framework for Students' Understanding of Normalization

Figure 1 presents a visual representation of the framework. I contend that understanding normalization essentially involves three major components, namely the norm of a vector, procedures for normalizing a vector, and what a normalized vector is (as conveyed by the three large ellipses in Figure 1). I expand on the contents of these ellipses in the following subsections. The lack of directional arrows in the figure is deliberate, as any component could inform how a student thinks about any of the other components, although when normalizing a vector, students

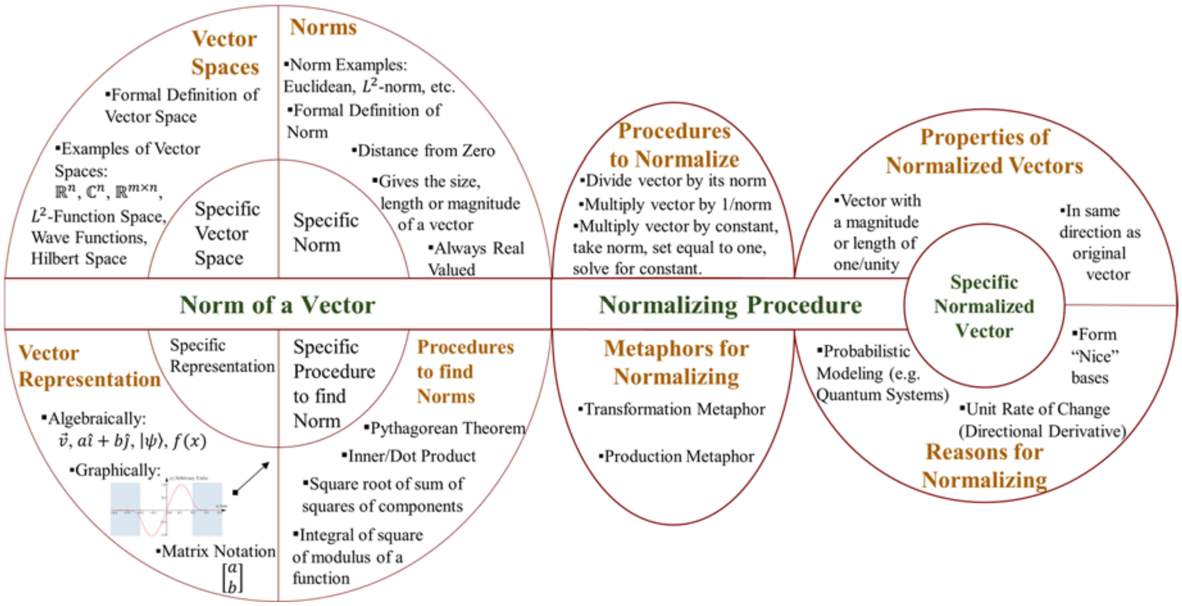

*Figure 1: Framework for students' understanding of norms and normalization*

generally find the norm, perform a normalizing procedure, and end with a normalized vector (i.e., left to right in the figure). Finally, students' understandings of norms and normalization do not necessarily include all of these components and connections; as such, when using the framework to model a student's understanding, components and connections presented in Figure 1 could be scarcer or even missing for a particular student's model.

**Norm of a Vector**

I have found four elements that can influence or determine how a student finds the norm of a vector, namely the vector space the vector is an element of, the representation chosen for the vector, the particular norm function to be used, and the procedure chosen for finding that norm (these four aspects are represented by the inner ellipse on the left of Figure 1). Additionally, a student's broader or more general understanding of vector spaces, representations of vectors, norms, and different procedures for finding norms, discussed in further detail below, can also inform and influence how the student finds the norm of a specific vector

A student's understanding of vector spaces could include examples of several vector spaces, such as $\mathbb{R}^n$, $\mathbb{C}^n$, or $L^2$-function space, although many students only have experience with vectors in $\mathbb{R}^n$. Mathematically sophisticated students may also be able to draw on their understanding of the formal definition of vector space. Altogether these can influence how a student thinks about a specific vector, which can inform their normalization of it.

A student's understanding of vector representations could include examples of algebraic notations (e.g., letter with special marking, functions, Dirac Notation), graphical notations (e.g., graphs of functions, points on a Cartesian coordinate system, directional arrows), and matrix notation (i.e., column or row vectors), with each representation choice affecting how a student thinks about finding the norm of a vector. Furthermore, a student's understanding of why we use representations, and their ability to select the best or most useful representation for a given task—which is part of Meta-Representational Competence (diSessa, Hammer, Sherin, & Kolpakowski, 1991; diSessa, 2004; Wawro, Watson, & Christensen, 2017)—could also impact a student's thinking about norms and normalization.

For many undergraduate students, the only norm they are explicitly aware of is the Euclidean Norm on $\mathbb{R}^n$, as most have only heard the term "norm" in conjunction with real vectors. However, mathematically sophisticated students may also know examples of other norms, the formal definition of norm, and important properties of norms (e.g., always real valued). Any of these ideas about norms can shape how a student finds the norm of or normalizes a vector.

There is also great variety in how students approach finding the norm of a vector for a given norm. For instance, a few ways students can find the Euclidean norm of a vector in $\mathbb{R}^2$ are to take the square root of the sum of the squares of the components, take the square root of the dot product of the vector with itself, or graph the vector and use the Pythagorean Theorem to find the length. While all of these are correct, each procedure can influence how students think about the norm, and their understanding of multiple procedures and connections between them could be drawn upon at any time.

**Normalizing Procedure**

There are several different ways a student can normalize a vector, such as dividing the vector by its norm, multiplying the vector by the reciprocal of its norm, or multiplying the vector by an unknown constant *before* finding the norm, setting it equal to one, and solving for this normalization constant. Moreover, there seem to be essentially two metaphorical expressions (Zandieh, Ellis, Rasmussen, 2017) students call upon when normalizing a vector which influence how they think about, and even notate, the normalized vector. The *transformation/morphing metaphor* views normalizing as a procedure that transforms or morphs the original vector into the normalized one, as when a student talks about "shrinking" the original vector down to a length of one. The *production metaphor*, on the other hand, views normalizing as a procedure that produces a vector that is in the "same direction" as the original vector, but has a length of one.

**Normalized Vector**

A student's understanding of normalized vectors includes ideas about properties of normalized vectors and reasons why normalization is important. The properties could include normalized vectors having a norm, length, or magnitude of one, and being in the same direction as the original vector. Reasons for normalization students have in their understanding could include probabilistic modeling (such as in quantum mechanics), looking at unit rates of change (such as with directional derivatives in multivariable calculus), or even simply a rule or procedure that must be carried out as a part of some algorithm.

## Using the Framework to Model Students' Understanding of Norms and Normalization

I now demonstrate how the framework can be used to model students' understanding using data from two students, Luke and Spencer. Luke was a physics/mathematics double major who came from an advanced linear algebra course, and Spencer was a computer engineering major who came from an introductory multivariable calculus course at the time they were interviewed. The interview consisted of having them solve three problems related to norms and normalization (an absolute value problem $|x - 7| = 3$; normalizing a vector in $\mathbb{R}^2$; normalizing a vector in $\mathbb{C}^2$ with components $3$ and $3i$), and explain their own understanding of absolute value, norms, and normalization in general.

Although Spencer did briefly mention that the absolute value can tell you how far away a number is from zero, he struggled to make use of this fact in solving problems, and did not see how absolute value could be related to mathematical norms. In fact, Spencer always described a process for normalizing vectors when asked about norms, and essentially seeing “norm” and “normalize” as the same idea:

*I*nterviewer: Do you see a difference between norm and normalization, or are those just, like, so related that...?

*Spencer*: I mean, I see 'em pretty related. Um, I don't really see a difference between them, honestly.

Furthermore, what Spencer understood by normalization seemed particularly narrow, as evidenced in his work on normalizing the vector $\boldsymbol{v} = \begin{bmatrix} 2 \\ 5 \end{bmatrix}$. Before even starting the problem, he changed the vector $\boldsymbol{v}$ to the form $2\hat{\imath} + 5\hat{\jmath}$, and proceeded by finding the square root of the sum of the components, $\sqrt{2^2 + 5^2}$, to get $\sqrt{29}$. He then explained that he would need to divide by $\sqrt{29}$ to get one, and proceeded to divide each component by $\sqrt{29}$ to arrive at his solution of $\frac{2}{\sqrt{29}}\hat{\imath} + \frac{5}{\sqrt{29}}\hat{\jmath} = 1$. I then asked him what normalization means to him, and why he chose that particular procedure:

*Spencer*: Normalize to me is basically making, like, getting the, getting this one, basically. … Like, so, when you use the distance formula, obviously, like, this is the distance formula [pointing at the square root of the sum of the squares]. But, um, you want, like, the distance to be [pause]. You want it to be one. … Um, like, but other than that, I never, I've never actually asked why?

*Interviewer*: Why did you choose that procedure to normalize?

*Spencer*: It's really the only one that I know. And it's the most recent one in my head. We just went over it, I think, last week. So, that's, that's the most recent one. And, I think that's the only one that I know as of now. I think that's it.

Spencer did seem to realize that the distance formula is an integral part of normalization, but the discussion above continues to affirm that Spencer did not have a strong understanding of norm, and rather understood norm and normalization as being one in the same, namely a procedure he was taught to carry out. In fact, when he tried to make sense of normalization graphically, he plotted the original vector and normalized vector as points on a Cartesian plane, but was never confidently able to describe the relationship between the two points, or what it meant for the normalized vector to have a magnitude of one.

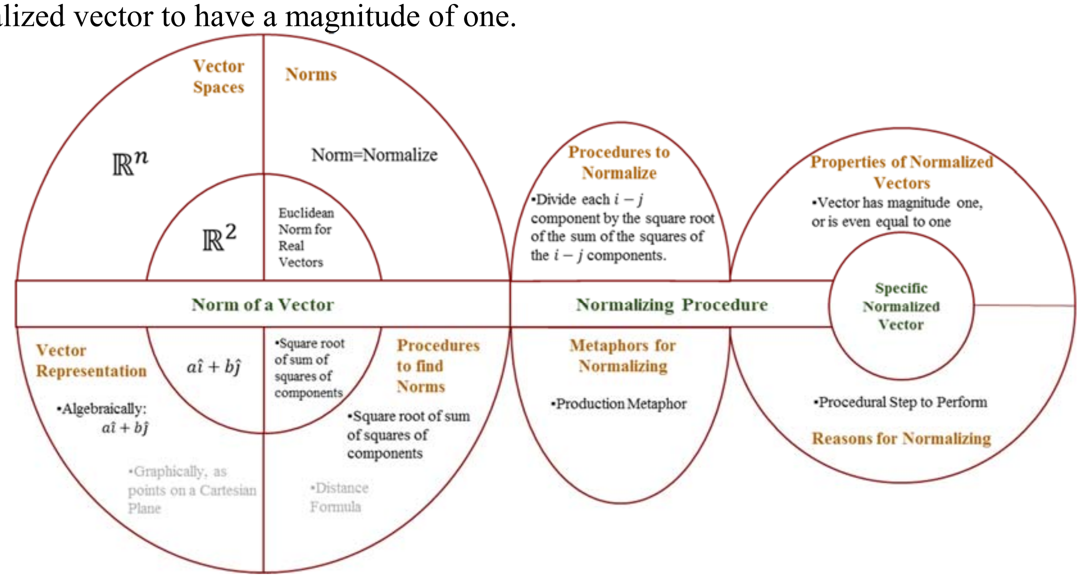

*Figure 2: Model of Spencer’s understanding of normalization*

Based on the above discussions with Spencer, I present a model of his understanding of normalization in Figure 2, which uses the framework as an organizational tool. This model can help us make sense of Spencer's understanding, but also gives us power to predict how he might approach normalizing vectors from unfamiliar vector spaces. More specifically, we would predict that Spencer would rely on the only procedure he knows for normalization, and probably encounter moments of uncertainty and confusion in the process.

As predicted by the model, when Spencer was asked to normalize the vector $\begin{bmatrix} 3 \\ 3i \end{bmatrix}$, he again attempted to write the vector as $3\hat{\imath} + 3i\hat{\jmath}$, which alone bothered Spencer, having the imaginary $i$ and the normalized basis vector $\hat{\imath}$ in such close proximity. He then used his method of finding the square root of the sum of the squares of the components, and arrived at a value of zero.

*Spencer*: So, um, [pause]. I don't think it can be normalized? 'Cause I got zero.

*Interviewer*: OK, what do you mean by...?

*Spencer*: … you can't really divide anything by zero. … I just don't think it can be normalized at that point.

Spencer's approach to solve this problem could be modeled by replacing the $\mathbb{R}^2$ in the model above with $\mathbb{C}^2$, with all other components essentially the same. As soon as he got zero, however, his procedure broke down, leading him to declare the vector as something that cannot be normalized. Spencer was not able to draw on any generalized understandings of norms or normalized vectors to help him rethink his procedure for normalization. Still, by the end of the interview Spencer realized his understanding of normalization was limited, and he even mentioned the possible existence of other types of normalization.

To see a stronger understanding of norms and normalization, I present my model for Luke's understanding in Figure 3, and highlight important aspects of it. First, Luke had a strong understanding of absolute value as representing a number's distance from zero, and

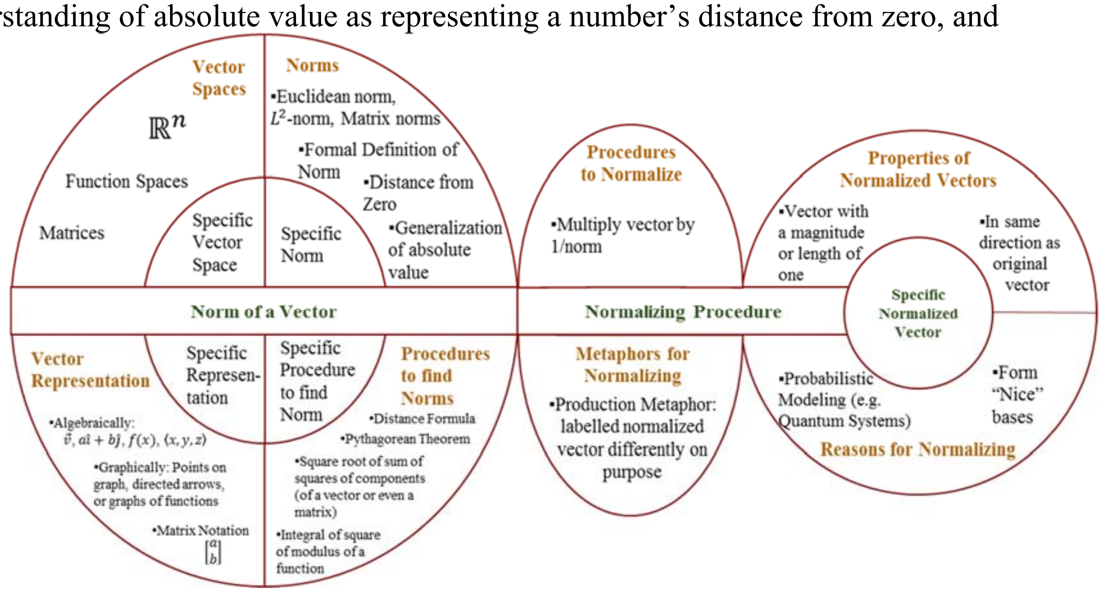

*Figure 3: Model of Luke's understanding of normalization*

understood norms as a generalization of this idea, namely giving the distance a vector is from the zero vector. Second, this distance from zero conceptualization was not limited to $\mathbb{R}^n$, as Luke was able to describe what the norm would be for several vector spaces, and how this could be thought of as giving a distance from zero. As an example, consider his description of a possible norm for the vector space of matrices:

*Luke*: So, if you have a matrix ... that would be, like, you know, you could define the norm where it's, like, just the square of the sum of all of 'em [the entries of the matrix]. Or, whatever you wanted to do. And that would be the distance from the zero matrix in the same sort of way, because, the zero matrix would be all zeros.

Third, Luke was confidently able to use and move among multiple vector representations and procedures for finding norms. And fourth, Luke understood the result of normalization, and why it is important for the creation of orthonormal bases, as well as probabilistic modeling in quantum mechanics.

Based on Luke's model, we would predict Luke to successfully draw upon his strong understanding to make sense of normalizing vectors from vector spaces that he was not familiar with. This was evidenced in his work to normalize the vector $\begin{bmatrix} 3 \\ 3i \end{bmatrix}$. Luke was somewhat unsure of how to proceed with normalizing this vector, and his first attempt was similar to Spencer's above, arriving at a norm of zero. However, unlike Spencer, Luke was able to draw on his understanding of norms, and immediately recognized this could not be correct:

*Luke*: So, I did something wrong, 'cause that's not the zero vector.

*Interviewer*: So, why did you think you did something wrong?

*Luke*: Well, the way a norm is defined, says that like, the norm of a vector can only be zero if that vector is zero. And, these entries are not zero. [I: OK]. So, there's something wrong with how I've been doing this. And, I bet, if I just took the modulus of each one first, then it would work.

Even more striking is the fact that Luke was able to propose a modification (taking the modulus of both components first) that was viable and mathematically sound, and he went on to correctly normalize this complex vector.

## Discussion and Conclusion

Luke's understanding of norm representing a distance from zero was particularly powerful for making sense of norms in multiple vector spaces, even vector spaces that were unfamiliar to him. This coincides with Sierpinska et al. (2011) who explained the power in understanding absolute value as a distance from zero:

> Definitions based on the notion of distance are important in applications and in mathematical theory, in particular in generalizations of absolute value to norms in higher dimensions and general vector spaces, and in generalizations of limits and continuity in topology. (p. 280)

This also relates to my own findings on the importance of understanding norms for a strong understanding of normalization, including its importance for multiple contexts within science and mathematics (Watson, 2017a, 2017b).

In this report I have presented a framework for students' understanding of mathematical norms and normalization. This framework has identified the components that go into understanding mathematical norms, normalization, and normalized vectors. Furthermore, I have shown how students' solution methods for mathematical problems involving these concepts can be thought about, made sense of, explained, and even predicted by using the framework to model students' understanding. It is hoped that this framework will be helpful for future research into students' understanding of norms and normalization, as well as their understanding of related concepts such as metrics and metric spaces within real analysis and topology. Furthermore, this framework could be used by instructors to think about ways they might best help their students develop robust understandings of norms and normalization within a variety of courses where these concepts are used, such as helping students conceptualize norm as a distance from zero.

# Mind the 's' in Individual-With-Contexts: Two Undergraduate Women Boosting Self-Efficacy in Mathematics

Fady El Chidiac
University of California, Berkeley

Melissa Carlson
University of California, Berkeley

Sakthi Ponnuswamy
University of California, Berkeley

*Investigations of students' identities are shedding light on the processes that generate differential learning. In this paper, we expand the construct of dispositions to account for what individuals carry through their bodies and beliefs across contexts. While bringing back the attention to individualized dispositions, we avoid the trap of innateness. After we create a three-layered framework of dispositions to explain why and how two undergraduate women, Bettie and Melissa, develop differential confidence in mathematics through a semester-long number theory class. We learn that individualized dispositions can change throughout time, and desensitize or make individuals vulnerable to gendered, racialized, and sexualized stigma.*

*Keywords:* Self-efficacy, Equity, IBL, Situated Learning, Dispositions.

The scholarship on identity, specifically in Mathematics education, has demonstrated the mutual construction of individual identities, preferably called positionings, and the contexts within which these identities emerge (Cobb & Bowers, 1999; Greeno, 1998; Hand & Gresalfi, 2015; Lave & Wenger, 1991; Martin, 2000; Nasir, 2002). The revised concept of *dispositions* is particularly illuminating. Following a situated approach, Cobb and Gresalfi (Gresalfi, 2009; Gresalfi & Cobb, 2006) define dispositions as ways of engaging with an activity organized by sets of ideas, perspectives and values. In an IBL activity, dispositions can include: "working together or individually," "providing developed or succinct explanations to a groupmate," "offering critical comments to others," "using the textbook (when and how)," "preferring to study with others or alone" and others. Contexts and individuals determine which dispositions emerge and become patterns of engagement. For instance, a student may actively participate in a group and be a passive listener in another type of group or class (Hand & Gresalfi, 2015). In this paper, we expand the construct of dispositions and create a framework to explain why and how two undergraduate women in a number theory class, Bettie and Melissa, developed differential confidence in mathematics.

Bettie and Melissa self-reported a low self-efficacy at the start of their number theory class. During exit interviews at the end of the semester, Bettie reported a robust increase in self-efficacy while Melissa reported only a relative confidence in her mathematical ability. Their number theory course used predominantly small-group work; after the third week students stayed in the same groups. Bettie and Melissa were the only women in their five-member groups.

As we conducted a situated approach analysis of Bettie's and Melissa's group work, we observed how group dispositions explained the differential roles they took in groups and classroom dispositions. Particularly, a classroom norm to not look at textbook solutions, shaped the construction of their differential self-efficacies. In addition to classroom and group dispositions, Bettie and Melissa activated dispositions that were produced in historic contexts or outside the studied classroom. Melissa enacted a collaborative disposition and Bettie a solitary reflective disposition. The collaborative disposition rendered Melissa vulnerable to groupmates' unresponsiveness, while the latter left Bettie immunized.

The reported analysis shows three interlaced layers of dispositions: classroom, group and individualized dispositions. These offered different learning opportunities to Bettie and Melissa, and fostered different mathematical identities (see Figure 1).

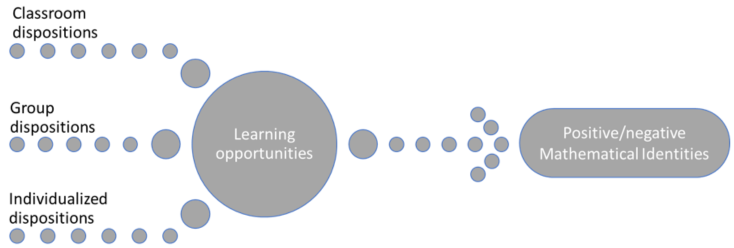

Figure 1: Three layers of dispositions construct learning opportunities that shape mathematical identities.

*Classroom dispositions* are constructed through interactions between an authority, either institution or instructors, and students. Social and socio-mathematical norms (Yackel, Rasmussen, & King, 2000), as enacted in a classroom, are the best examples of classroom dispositions. When students work in small-groups, *group dispositions* are constructed. For example, if group members assign a high mathematical authority and social influence to a group member, group dynamics may easily turn into a tutoring disposition. Esmonde (2009) showed that mechanisms of group dispositions are independent from, but may connect to, classroom dispositions. The new construct to a situated approach introduced herein is *individualized dispositions*, by which we conceive the interconnectedness of individual-with-context**s**.

When we think of individuals as embedded within a context, we must account for the ways individuals navigate through and connect multiple contexts simultaneously or consecutively. We propose two mechanisms by which dispositions transfer from one individual-with-context to the same individual in a different context. First, dispositions can transfer across contexts through the individual's body. Performativity theorists (Butler, 2010; Kramsch, 2010) have shown that repetitive enactment of dispositions leave embodied marks in individuals. To use an external resource, Erickson (2004) observed that linguistic and gestural behaviors common to an environment, e.g. home or church, may become reflexes that individuals carry to the educational environment. Second, dispositions may translate into beliefs or narratives that individuals can carry into other contexts. Boaler and Greeno (2000) documented students, who enacted classroom dispositions aligned with traditional teaching. They believed that mathematics lack creativity, which influenced their decisions of major choice in college. Sfard and Prusak (2005) documented narratives produced during family meetings about the mathematical ability of East-European immigrants to Israel. The narrative identities transferred to classroom behaviors: students from these communities were renown of persevering at solving challenging math problems. We shall call the transferred dispositions *individualized dispositions,* since transfers occur through the individual's body or beliefs.

The selection of relevant concomitant and historic individual-with-contexts is challenging. Relevant transferred dispositions must be triggered by current individual-with-context. Thus, we find mediated and unmediated interviews to be an optimal data collection method to investigate individualized dispositions. Further discussion is in the methods section.

## Methods

### Activity and Participants

Data reported was collected from a semester-long number theory class at a Northern California University. The class met for one hour ten minutes twice a week. Professor Hoffmann, the instructor, used group work as the predominant form of teaching in class for the first time in his career. He gave students worksheets of theorems and problems to solve in class with their groups. Students could find the proofs of theorems in the assigned textbooks, but Hoffmann encouraged them to "use [their] brains not the textbooks" to solve the problems. A weekly homework, consisted of writing the solutions to selected problems from the worksheets, was assigned to be submitted individually and graded. Students took a midterm and final exams.

The class included students from diverse ethnic backgrounds and mixed gender, 10 women and 13 men, the majority of whom were majoring in Mathematics for teaching. The African-American ethnicity was not represented in this class. Students composed their groups at their will and stayed in the same group by the third week of class. There were total of 5 groups of 4 or 5 members each. One group did not participate in the research.

Melissa and Bettie were selected for focal study, because both worked with four men in their groups and reported low self-efficacy at the start of the class. Melissa was majoring in Mathematics for teaching and Bettie in Mathematics for liberal arts. Melissa's group (GM) and Bettie's group (GB) had three vocal members and one predominantly silent member. GM's members were Robert (Math for teaching major, vocal), Tom (Math for advanced studies, vocal), Emil (Math for liberal arts, vocal), Tito (Math for teaching, silent). GB's members were Ted (Math for teaching, vocal), Jeremy (Math for advanced studies, vocal), John (Applied Math, vocal) and Boutros (Math for teaching, silent).

### Data Sources

Starting from the second week of class, four group's group work, including GM and GB, were *videotaped*. Students took *early and exit surveys* and submitted *individual memos* after every group session. They participated in an *early individual interview*, where they were asked about their motivations for majoring in mathematics, feelings about the mathematics discipline, history with mathematics classes in high school and college, experience with group work in classes, and first impressions about current group members. They also participated in *individual interviews by the end of the semester*, where they were asked about their understanding of number theory, confidence in the material, the changes throughout the semester in their learning methods and behavior in group work, and the roles their groupmates tended to play.

Students participated in SCNI interviews (Stimulated Construction of Narratives about Interactions; see El Chidiac, 2017) every other week. In the SCNI interviews, participants watched a video of their recent group session and commented on their social interactions. The SCNI interviews were conducted individually and within twenty four hours of the end of class. The SCNI sessions of GM and GB took place within five hours of the end of the class. GM participated in one and GB two out of the four SCNI interviews. Emil (GM) and John (GB) did not participate in any interview.

## Results

### Developing Two Types of Self-Efficacy

At the beginning and throughout the semester Melissa showed low levels of confidence in relation to her peers. She stated in the early interview on 9/17 that “every single person I've met has understood more than I have which is really you know, makes me feel very insecure about my decision to be a math major when everybody's you know - smarter than you.” During the exit interview Melissa showed a shift in her perception.

> Melissa: So, then I started contributing more […] cause at first I felt like I was not the smart one of the group, and I'm not. But, I also felt, feel now that I'm at least at a level playing fieldish, more at a level playing field of like, brain capacity [laughs] I guess, and um knowledge in general. Um, because I don't know sometimes I shock myself when you know, I get something and then like Robert doesn't get it or Tom doesn't get it and I'm just like why don't why don't you understand, it's this, come on now. You know. Um. But that makes, that makes me feel more confident in myself and it makes me want to participate more cause then you know, I'm not actually like helping them, but I'm helping them in my not understanding. (Interview 12/02)

Melissa developed a relative type of self-efficacy. She constructed a confidence not on her own mathematical ability, but based on noticing her groupmates were not as smart as she previously believed. Even at the end of the semester, Melissa felt she did not fully understand the material (“I'm helping them in my not understanding”). She started the class with an individualized disposition from her prior proof course, in which she “struggled” (Interview 9/17). She reiterated this perceived inability later in the semester, “I'm just really bad at writing proofs” (SCNI 11/05). We note that in both interviews, Melissa revealed an individualized disposition about her mathematical ability, namely *evaluating one's own mathematical ability in contrast to one's perception of others' abilities*.

Like Melissa, Bettie started the class feeling she was not smart enough. In the early interview on 9/22, she stated, “I feel like I'm not super um I don't know I guess smart so it takes me a while to understand things I have to see it done a couple times and like I have to do it a couple times to like completely fully understand it.” Unlike Melissa, Bettie's perception of her non-smartness depended on her slow learning processes and not her comparison to other people's abilities.

Like Melissa, Bettie expressed a struggle with proofs in previous classes. But unlike Melissa, she was satisfied of her learning in this number theory class. In the exit interview on 12/02, she stated, “for me I feel like theory in general is just like learning proofs and . I don't know . it's just been really difficult for me. But . uhh out of all the proof classes I've taken this is probably the most that I've . like . learned . I guess you can say. Cause a lot of the time I kinda just got by. and I feel like this one I'm actually understanding like . why.”

When asked about their learning methods, both Melissa and Bettie stated at the start of the class that they learn by memorizing. On 9/22 Bettie said she used to learn by “keep doing it, repeating it, just memorizing.” When asked how she prepared for the midterm, Melissa said she “wrote up cheat sheets,” looked through her notes and homework and “tried to memorize it all.” By the end of the semester, Melissa reported no change of learning methods (“I pretty much learn the same,” Interview 12/02). However, Bettie emphatically affirmed a move away from learning by memorizing towards learning by understanding. On the exit interview (12/02), answering whether she endured a change in her ways of learning, she responded as follows.

Bettie: "yeah definitely. I kinda just . not really change it but it made me realize what . my style of learning is . kinda thing. I would just study and I didn't really know what was beneficial and what wasn't. now I realize I need to read, obviously . I have to read through the book. I have to . like do the homework . like slo::owly at my own pace and like do it myself. and . um . that's like the only way I'm gonna retain anything or like know what I'm doing. Because before I would just like do the homework. but I wouldn't really . like know what I was […] I was just like copying and pasting . finding answer online . and writing it out and like hoping it was the right answer. but now that . I'm actually like reading the book, working with friends, like doing the homework, actually doing the homework myself, I just feel like this is just what I need to start doing."

Bettie and Melissa differentially boosted their mathematical self-efficacy: Bettie improved her learning methods, while Melissa only repaired her perception of groupmates' mathematical abilities. This differential improvement of self-efficacy was reflected in their exam achievements as well (Table 1). Given the self-reported significance of group learning and use of textbooks, we shall investigate them next. [For lack of space, we leave the study of textbook usage to the extended paper]

Table 1: Melissa's and Bettie's grades on the midterm and final exams

| | *Melissa's grade* | *Bettie's grade* |
|---|---|---|
| *Midterm exam* | 45% | 53% |
| *Final Exam* | 20% | 61% |

### Learning During Group Work

We watched the videos of GM and GB group sessions and coded the instances when Bettie and Melissa offered explanations (Figure 2), contributed mathematical ideas (Figure 3) and sought explanations (Figure 4) by group sessions over the semester. Melissa increased her participation in the group work after 10/15. This evidence corroborates her comment (above), her increase of confidence made her "want to participate more" (see quote above). Bettie's pattern of participation in group work remained low throughout the semester. Overall, Melissa participated more in group work than Bettie. However, the latter surprisingly showed more learning gain than the former. Why was Melissa's participation in group work not conducive to learning?

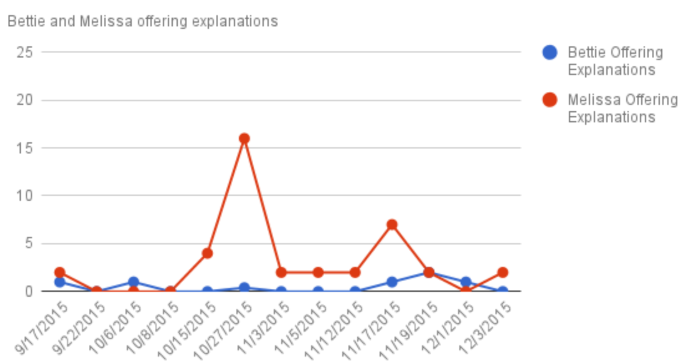

Figure 2: Instances of offering explanations for Melissa and Bettie over the semester.

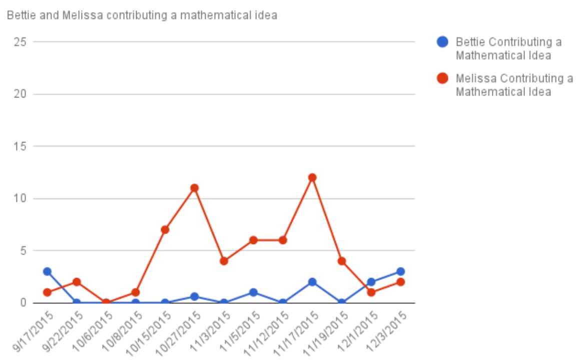

Figure 3: Instances of contributing mathematical ideas, for Melissa and Bettie over the semester

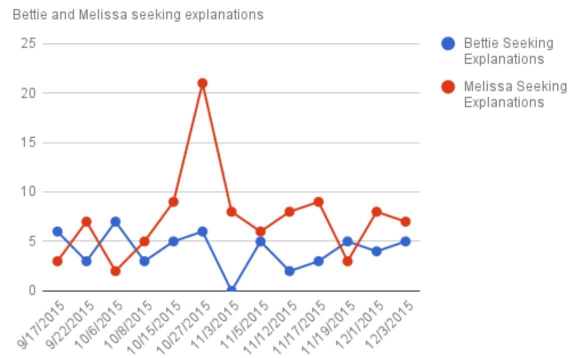

Figure 4: Instances of seeking explanations, for Melissa and Bettie over the semester

To answer this question, we looked at the individual interviews. During the early interview (9/17), Melissa was asked how she felt about the current group. She responded, "yeah I feel very focused um not necessarily like I know what's going on but I feel like I'm not thinking about anything else but what's in front of me on the worksheet and like trying to help […] more more than trying to figure out what's going on I'm trying to help my friends who know better like give them my ideas of what I might be thinking to help them put put it together because once they put it together then they can explain to me what's going on." Later in the same interview, as she was describing the role of her groupmates, she commented, "And so they [Tom, Robert and Emil] are kind of like the three main brains I feel like um and they all just bounce ideas off each other and I try to like this if they stop talking I just kind of like ask a question to get their brains going again because I mean they know way more than I do. I feel like. and then they're also in modern right now. Emil's taking modern and Robert's in modern and I'm pretty sure Tom is taking modern, Tito's taking modern right now. I'm just like over here like I'm still in linear. so they know a little bit more about what's going on." During the SCNI on 9/24, Melissa reiterates, "I don't know where to go from here I hope someone [small laugh] gets something and like, I normally would ask a question to someone, you know to clarify something and usually that gets their brains going, but […] I tried that, and nobody really responded to me, besides Emil."

At the beginning of the semester, Melissa activated a group disposition of helping her groupmates find the solutions and deactivated the disposition of understanding the materials. She took up the role of stimulating the brains of her groupmates because she thought they are more resourceful than she. Nonetheless, the helping group disposition echoed a similar individualized disposition. During the early interview on 9/17, Melissa confessed, "I feel like it's kind of hard for me to relate to [the courses in college] since I'm not going to be using it while I'm teaching I mean I'll have it in the back of my head you know for that one kid that's going to ask me 'well why?'" For Melissa, learning is conditioned by how knowledge can help others.

As Melissa spent more time in group work and realized she could be resourceful, she faced a new challenge: unresponsiveness from her groupmates. During the SCNI interview on 11/05, Melissa paused the video and commented, "oh number two I understood and I'm kind of pissed because, I shout out my idea and no one really listened to me because in the end that's kind of almost exactly what we ended up proving. which kind of pisses me off because I wish someone would have realized, I wish I could have said it better so that they would have understood what I meant." She reiterates this struggle at the end of the same SCNI and the exit interview.

> Melissa: I would see that they weren't listening to me […] So I had an idea so I would a- like, act dumb, and kind of you know, ask them about, you know well what about this, what if like we do this or this or this kind of thing. Well like, what about that, to kind of lead them in the direction that I'm already on. […] they can't be told […] how to think. […] So, I just like, ask a question that maybe has them change their perspective to understand what I'm trying to say. (Interview 12/02)

Bettie also faced lack of recognition from groupmates. In the exit interview on 12/02, she stated in a colloquy style, "if it has to do with arithmetic I feel like I'm just . I feel like . I can do it. like I. Maybe they don't take me as like serious so when I have the answer they're like "whatever like it's probably wrong." but I usually do get the right answer and I feel like "hah" like "told you.""

Unlike Melissa, Bettie did not attend to her groupmates. In fact, during the early interview, she thought her group had only four, instead of five, members, of whom she knew only Jeremy by name. During group work, she mostly worked alone, reading from the textbook and writing on her notebook. During the SCNI interview on 10/15, she confessed, "when I hear people talking and I don't understand I just zone them out because it confuses me more so I just like keep do . I just keep looking on my own." Later on in the same interview, she reiterated and generalized her group disposition, "that's basically all I do [in group work]. like when I'm in class. I just listen to what [my groupmates] are saying and look at the book . cause if I don't understand it then . when they're like talking . I don't know. so I just zone people out . until I look at it myself because . otherwise it just confuses me more." During group work, Bettie took up a group disposition geared towards building her own understanding of the mathematics. In effect, her dominant participation role was "seeking explanations" (compare graphs in Figure 2, Figure 3 and Figure 4). In the interviews, Bettie reported an individualized disposition of seeking to understand mathematical concepts. When she was stuck on homework, Bettie affirmed during the early interview on 9/22, "I go online […] yeah I work alone […] most of the time […] I just like to read over because I like to understand things cause like it's really frustrating when I'm just like copying work I have to really just like understand what I'm doing and why I'm doing it so I kind of just like to work alone because it takes me a pretty long time to figure out a problem."

## Conclusion

Both women, Melissa and Bettie, were not recognized as reliable resources by their groupmates. However, this stigma was more detrimental to Melissa than Bettie. Due to Melissa's group and individualized helping dispositions, the developmental path of her mathematical identity led her to take on the role of helping others to find answers to problems. This path was blocked twice throughout the semester. Melissa could overcome the first barrier, i.e. her perception that her groupmates are more resourceful than she, but struggled with grabbing her groupmates' hearing. In contrast, the developmental path of Bettie's mathematical identity went through coping with her slow learning processes in group. She was oriented towards understanding the mathematics, the disposition of which made her immune to others' recognition of her abilities.

Throughout the analysis, we showed that individualized dispositions undergirded all observed group dispositions. Dispositions that students carry from other contexts into the classroom are more significant for identity development than it is commonly being thought of.

# First Results From a Validation Study of TAMI: Toolkit for Assessing Mathematics Instruction

Charles N. Hayward, Timothy Weston, and Sandra L. Laursen
University of Colorado Boulder

*Many researchers consider observation to be a 'gold standard' for measuring classroom practices since self-report surveys may be prone to bias. In this paper, we explore how the design of survey instruments and observation protocols affects the trustworthiness of the data collected. We describe our process of developing well-aligned observation and survey instruments in order to reduce sources of measurement error. We present results from a large-scale test of these instruments in 176 observations of 17 different math courses. Our results indicate that when survey instruments are designed to describe what happens in a course, rather than evaluate the quality of the instruction, and when those survey results are compared to observation protocols measuring teaching in the same way, self-report surveys are largely trustworthy.*

*Keywords:* Measurement, Instruction, Observation, Surveys

Describing and assessing instructional practices in science, technology, engineering, and mathematics (STEM) courses is a difficult undertaking. Various methods exist, each with their own advantages and disadvantages (American Association for the Advancement of Science, 2012). Two commonly used methods in RUME studies are classroom observation and instructor surveys. Observational data is collected by a neutral third party so it is sometimes considered more objective or 'accurate' than self-reported survey data, which may be prone to subjective bias (Ebert-May, Derting, Hodder, Momsen, Long, & Jardeleza, 2011).

However, observations have their own sources of measurement error. Observers often need significant amounts of training to ensure sufficient inter-rater reliability (IRR) – the degree to which different raters agree on their ratings of what they observe (Smith, Jones, Gilbert, & Wieman, 2013). Though IRR is usually used as a standard for judging quality of observation data through adherence to a particular protocol, IRR only captures whether observers apply the protocol consistently, and does not address other inherent sources of variability in observation data. Multiple observations of the same instructor are needed to make confident inferences about their teaching as a whole (Pianta & Hamre, 2009), since two or three class sessions may not represent the entire class (Hill, Charalambous, & Kraft, 2012). But if more observations are needed, this adds significantly to the time and cost of collecting observation data. This drives the need for validity comparisons (Hill, Charalambous, & Kraft, 2012): if researchers can confidently substitute a survey for observations, then they can increase the number of participants involved while decreasing the costs and time invested.

A number of studies have attempted to answer the question of whether survey data can be as trustworthy as observations, and they have come to different conclusions. Ebert-May et al. (2011) found that while most instructors said in surveys that they changed their courses to become more active and learner-centered, most were observed using traditional lectures and teacher-centered instruction. A similar study conducted in a K-12 context (Fung & Chow, 2002) found a mismatch between the teachers' conceptions of their teaching style and observed practices with teachers again overestimating the interactivity and student-centered characteristics of their teaching. However, college faculty members studied by Smith et. al (2014) were "generally self-aware" of how often they used methods related to lecturing and presentation.

If observations are considered more objective, mismatches are interpreted as 'inaccuracy' or 'bias' in self-report. However, it may be that mismatches are at least partially caused by a misalignment between survey and observation instruments. In this paper, we present results of our own validation study comparing an instructor survey and observation protocol. We first describe the framework and process we used to create two well-aligned instruments, and then present results from a large-scale study using them. We explore the questions:

1. What design choices affect alignment between surveys and observation protocols?
2. When using well-aligned instruments, in what ways does instructor self-report of instructional practices agree or disagree with observation data?

## Conceptual Framework: Types of Observation Protocols

Observation protocols are characterized along multiple dimensions (Hora & Ferrare, 2012). The two main dimensions are descriptive vs. evaluative and segmented vs. holistic. Descriptive protocols aim to simply capture or describe what is happening in a class, whereas evaluative protocols rate the quality of a class. Segmented protocols divide a class into short time segments, usually 2 or 5 minutes long, with coders recording features of the class during each period. Thus, the whole class is characterized by the sum and sequence of short segments. In contrast, holistic protocols aim to characterize the class as a whole. The observer may take notes during class then use the notes as evidence to rate the class across multiple criteria. Additionally, protocols may focus on the instructor or students, may or may not take subject matter into account, may require high or low inference by the observer, and may vary in the degree of structure.

These dimensions can be combined in many different ways, but the two main dimensions capture the largest differences between protocols. A descriptive protocol may measure how frequently a practice such as group work occurs using a segmented approach (e.g. group work occurred during 17 of 25 two-minute intervals) or a holistic approach (e.g. "about ¾ of class time"). Evaluative protocols may measure the quality of group work by asking how students engaged in group work or whether the group task was structured effectively. Again, that can be done in a segmented way (e.g., marking student engagement during each interval) or holistically (e.g., rating on a 0-4 scale whether "students were productive and engaged in group activities").

| | **Segmented** | **Holistic** |

*Figure 1. Framework for classifying observation protocols.*

In Figure 1, we characterize some common observation protocols used in STEM courses based on their main design features; individual items may fall into the other quadrants. For example, some items on the MCOP2 are more descriptive than evaluative. Segmented protocols tend to be very detailed and granular, whereas holistic protocols zoom out to capture a broader view. The choice of a protocol should match the goals for its use. For example, if the goal is to offer formative assessment for instructor growth, a descriptive protocol such as RIOT, which focuses on instructor/student interactions, offers a lower-stakes measure conducive to constructive discussion. In contrast, RTOP is more evaluative and may be viewed as judgmental rather than constructive.

Surveys items about instructional practices can also be classified as descriptive or evaluative. Surveys may ask instructors to describe and quantify their behaviors over a period of time (e.g. "How often did you lecture this semester?"), or ask them to reflect on and evaluate their own teaching based on criteria such as the quality of their interactions with students, the types of activities used in the course, or their perceived ability to explain difficult concepts.

## Methods

Now, we describe how we used this framework to design a descriptive instructor survey along with a well-aligned segmented, descriptive observation protocol. We then describe how we collected and compared data from both instruments in college math courses. The instruments are part of the Toolkit for Assessing Mathematics Instruction (TAMI) that we are developing.

### Development of the Survey Instrument

Our survey came out of prior work evaluating professional development workshops (Hayward, Kogan, & Laursen, 2016). Our goal was to assess initial changes in the use of particular instructional practices, not to evaluate how well instructors were using these practices, since these skills may take years to develop. So our questions asked instructor to report the frequency of use of different practices. We designed our survey to be administered shortly after the conclusion of a course and to use descriptive rather than evaluative items, asking "*what did you do*?" versus "*how well did you do it?*" For this project, we conducted think-aloud interviews to adjust the items and answer choices to better align with instructors' conceptualizations of their own practices.

On our final survey, instructors first report how frequently they use 11 different classroom practices commonly seen in college math courses including group work, whole class discussions, formal lecture, interactive lecture, and student presentations. Frequencies are measured with a 7-point scale with concrete descriptors from 'never,' to 'about once a month,' to 'every class.' Then, instructors report the duration of use for each of the practices they used: 'a few minutes,' '1/4 class,' '1/2 class,' '3/4 class,' or 'entire class.' Open-ended items ask instructors to describe patterns in practices or rare events (e.g. computer lab for the last 3 classes.) Finally, instructors supply text descriptions of 'lecture,' 'presentations,' and 'group work' in the courses.

### Development of Observation Protocol

**Background.** A 2011 paper by Ebert-May et al. is often used to argue that self-report is not 'accurate.' They compare biology instructors' self-reported practices to observations coded with the Reformed Teaching Observation Protocol (RTOP) (Sawada, et al., 2002). Many instructors reported using active learning strategies, but RTOP scores were more in line with lecture-based teaching. The authors concluded, as their title suggests, that 'what we say is not what we do.'

However, our own analysis of the RTOP instrument reveals that this protocol is not well aligned with the data collected through self-report. The RTOP is evaluative and holistic, whereas the self-reported survey items are more descriptive and behavior-oriented. We were curious how much of the discrepancy between observation and survey methods was due to a difference in what is being measured, rather than an 'inaccuracy' in self-report. In other words, were the answers really different, or were they comparing answers to two different questions?

**Design of our observation protocol**. Our existing survey functioned well for evaluation work, and internal consistency provided evidence that it was trustworthy (Hayward & Laursen, 2014). It is a descriptive, frequency-based behavioral survey, so we wanted a descriptive, segmented, behavior-oriented observation protocol to match. Measures in the TDOP (Hora & Ferrare, 2013) offered more detail than we needed, but the COPUS (Smith, Jones, Gilbert, & Wieman, 2013), a simpler modification of the TDOP intended for STEM courses, did not quite align with practices we saw in college mathematics courses, especially with its focus on clicker use.

We modified the COPUS by changing a few codes and adding others to better align it with practices we saw in mathematics classes and with survey items we previously developed through interviews with mathematics instructors. We incorporated the ICAP framework (Chi & Wylie, 2014) as a research-based measure of the nature of student engagement. We included some end-of-class holistic items that are evaluative and descriptive. Thus, while most of our protocol is segmented and descriptive, it also includes items from each of the other quadrants. The main portion aligns well with our survey items, but adding items from other quadrants allows us to analyze how misalignment may affect the comparison between survey and observational data.

### Sample

Our sample included 176 in-person class observations from 17 courses. Our average of 10.4 sessions per course is many more than is typical (1-3 observations per course), but was necessary to ensure that we obtained a truly representative sample (Weston, Hayward, & Laursen, 2017). The data included 4789 two-minute observations, or nearly 160 hours of observations carried out over two terms at three public universities in courses on algebra, calculus, geometry, statistics, and mathematical modeling. Class meetings were 50 minutes long, meeting three or four times per week, or 75 minutes long, meeting twice per week. All courses were on semester schedules.

### Reliability of Observations

In piloting our observational protocol we assessed inter-rater reliability (IRR). Overall IRR was high, with raters agreeing on 93% of their observations over each two-minute period and varying only modestly by the type of item. Modest variations were also found for how well raters agreed when rating activities for different teachers, from 91% to 96% depending on which teacher was observed. These results are on par with those of other published protocols.

### Analysis Methods

Comparing survey to observational results was complicated by differences in the frequency of measurement, with surveys given once at the end of each term, and observations taking place multiple times throughout the term. To make a fair comparison, we aggregated observations at the course level by taking averages across all classes observed. We also aggregated within similar types or formats of classes such as classes primarily devoted to lecture, group work or a mix between these formats. Aggregating this way makes a fair comparison to survey items that ask instructors to estimate the proportion of time spent in classes "*when you used this activity.*"

We made two types of comparisons. First was the comparison of the instructors' report of average amount of time within each class devoted to specific activities (such as lecture) compared with the average observed time devoted to this activity. Observational averages took values between 0 and 100%; survey values asked teachers to estimate rougher proportions of class time spent doing the activity (e.g., "entire class," "¾ of class"). For this analysis we used a fairly liberal criterion and considered bivariate points a match if the observational value fell between the two nearest boundaries for survey proportions – these 'match' ranges are represented as vertical green bars in Figures 2-4. For instance, if an instructor estimated he lectured ½ of the class, any observed value between the next nearest survey responses of 25% and 75% was considered a match. Lower and higher boundaries were set at 10% and 90% of class time. Analysis with the full data set will use correlation coefficients and other tests of congruence such as the Kappa coefficient.

Second, we created an interactivity index based on the number of questions teachers and students asked during lecture. To create a three-point scale aligned with our three categories, "formal," "some interaction," and "interactive," we counted frequencies for six question/answer types – 2 for students and 4 for instructors. Each item was scored as its tertile (1,2, or 3) of the frequency distributions. We averaged these scores, and again split into tertiles for the final index.

**Results**

We compared observation and survey data from all participants who were observed in-person, totaling 176 observations of 17 courses, although most comparisons used 13 or 14 courses depending upon which activities were reported. Results from this analysis are presented below. We are currently integrating data from 141 additional observations from 16 courses observed via video camera and results from the full analysis will be available by February.

We first examined the match between survey responses and observational data for lectures. The survey question about lecture asked: "*On average, when you used this method, did you use it: Entire class, ¾ class, ½ class, ¼ class, a few minutes.*" We asked about three types of lecture: formal (little or no question or answer), some interaction, and frequent interaction. We compared the dominant mode of lecture reported in surveys to the observed averages of time spent lecturing in classes (Figure 2). For the most part, instructor estimates were aligned with what we observed. Four out of 13 cases were considered misclassifications, for a "true" classification rate of 69%. However, two of these errors were very near the classification boundaries. One instructor drastically underestimated the amount of lecture used, relative to what was observed.

We also compared survey instructor ratings of their own lecture interactivity to observed interactivity in classes (Figure 3). The tertiles for the interactivity index were 1–2, 2–2.5, and 2.5-above. Again we saw moderately high congruence between how instructors rated the interactivity of their courses and observed interactivity. Three out of 14 teachers highly overestimated the interactivity in their classes, and one teacher slightly underestimated the interactivity of his/her teaching. Overall accuracy was 69%.

We also compared averages for instructors' reported use of group work (Figure 4). We found that most instructors were at the extremes – either they mixed a fairly small amount of group work with lecture or other activities, or devoted the whole class to working with groups, usually on one day of the week devoted to recitation. Two instructors slightly overestimated the amount of time their students spent working in groups, one slightly underestimated, and one made a large overestimation. Overall accuracy was 71%.

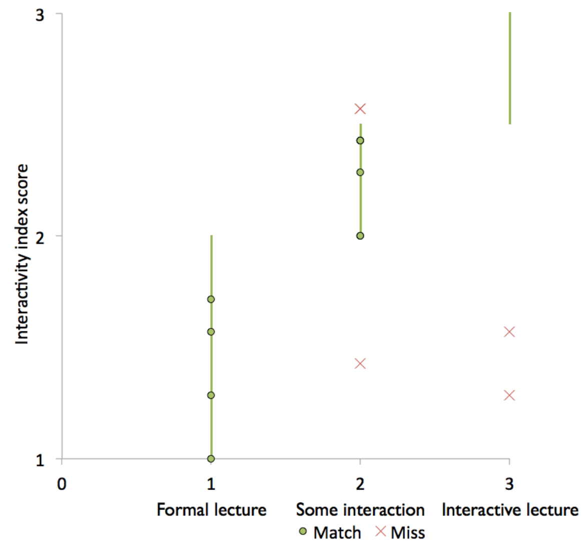

*Figure 3. Dominant lecture mode defined by survey and interactivity index from observations.*

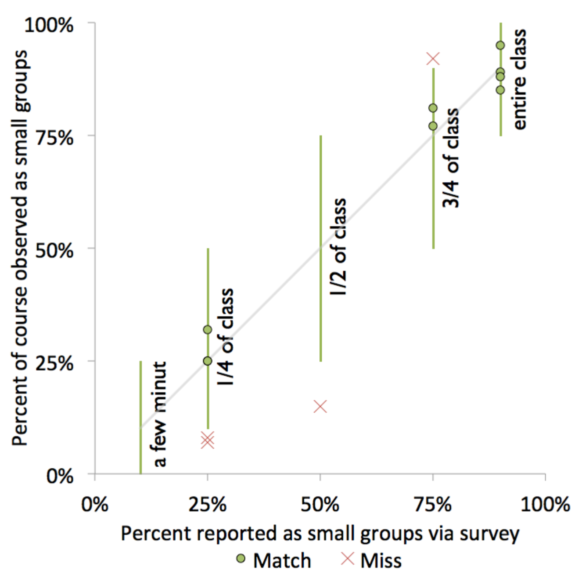

*Figure 4. Comparisons between survey and observations of group work.*

## Discussion

We made three validity comparisons with our initial data. Overall, it seems that when survey and observational measures are aligned, instructors' self-reported practices are aligned with observation data. For the two comparisons of proportions of time spent lecturing and in structured group work (Figures 2 and 4), most instructors seem to have an accurate idea of the proportion of class time spent on each activity. These descriptive comparisons are fairly straightforward, and instructors likely remember their basic lesson structure over the course of a term. Not surprisingly, some underestimate the amount of class time they spend lecturing, and overestimate the time students work in groups. However, most of these differences are relatively small and are related to extreme values; at the upper ends, instructors tended to underestimate and at the lower ends, they tended to overestimate. Only one participant had a large discrepancy, which may be due to differences in how our definition of “lecture” differed from the instructor’s.

Estimates of teacher-student interactivity (Figure 3) were also fairly accurate in terms of the number of matches. However, the discrepancies are large; those who reported the most interaction were some of the lowest-rated in observations. These results are interesting when interpreted through the design framework. Our interaction index is a norm-referenced measure. This means ratings are based on comparisons to other courses in the dataset rather than to an outside, objective standard. When we collapsed the three types of lecture on the survey (formal, some interaction, and interactive), self-reports aligned well with observations. However, when we used a more evaluative approach by comparing the type of lecture with our interaction index, discrepancies were large. So while instructor self-report was quite accurate with strictly descriptive measures (i.e. duration of lecture or group work), there were greater discrepancies with this more subjective, evaluative index. Past studies claiming that instructors were not ‘accurate’ in self-report relied heavily on evaluative measures, and our results suggest that using descriptive instruments instead of evaluative may help reduce these discrepancies.

Although observations are commonly thought to be objective, it is impossible to remove all forms of bias. We found that using segmented, descriptive items helps to reduce bias. However, protocol designers still must decide how to define items. Their perspectives bias what ‘counts’ for items. For example, when coding question and answers, we designed our protocol to only count when the instructor provided a real opportunity for students to respond. Many times, instructors asked rhetorical questions, or answered their own questions so quickly that students had no opportunity to respond. So we did not count these as questions. It is entirely possible that instructors frequently used these types of questions, but our coding would reflect very little interaction. The ‘error’ for those who drastically overestimated the interactivity of their lectures relative to our observations may originate in our definition of what counts as a question.

Despite multiple claims that self-report is not ‘accurate,’ the issue of trustworthiness is much more nuanced than how well it compares to observation data. Survey data may be prone to self-report bias, but there are also many sources of variation or error in observation data. These include observation protocol and survey design alignment, coding definitions of what ‘counts,’ and variability in day-to-day activities and representativeness of the observation sample compared to the whole course. Our results suggest that when survey and observation instruments are well designed and properly aligned, surveys may be a trustworthy, efficient, and less costly method of measuring teaching practices.

It remains an open question whether it is possible to use a survey to measure changes in teaching practice following professional development interventions. Issues of bias increase when instructors are expected to change their practices, and some may consciously or unconsciously overestimate the time spent on inquiry-based activities, and underestimate their time in teacher-centered lecture. Survey items must also be sufficiently sensitive to capture differences before and after the intervention. Future work should test the surveys in such intervention conditions.

**A Department-Level Protocol for Assessing Students' Developing Competence with Proof Construction and Validation**

Tabitha Mingus
Western Michigan University

Mariana Levin
Western Michigan University

***Abstract:*** *This methodological paper describes a protocol for assessing the development of students' competence with proof, created by the assessment committee within the Department of Mathematics at Western Michigan University. The assessment protocol we describe evolved over a period of 20 years and aims to collect information that is meaningful and actionable for improving mathematics instruction within the department. While there are several unique features of Western Michigan University that have created a context in which such work can be undertaken at the level of the department, we believe that this case will be of interest to mathematics departments seeking to find ways to measure their students' developing competence with proof.*

**Keywords:** Proof construction, Proof validation, Assessment

## Introduction

The role of mathematical reasoning and proof in the undergraduate major's mathematical training is crucial. Becoming skilled at constructing mathematical proofs requires the mastery and coordination of a number of different skills and the creative ability and mental dispositions to bring all those skills and the appropriate content knowledge to bear on a particular statement. These skills and abilities can be roughly divided into two categories – comprehension of an argument and construction of an argument, with validation of a purported proof involving skills from both categories.

Early work on proof construction and comprehension established different classification schemes students used to understand mathematical proofs and typologies to classify student generated proofs (Balacheff, 1988; Harel and Sowder, 1998). More recently, Mejia-Ramos et al. (2012) developed a multidimensional model of that revealed the complexity of proof comprehension. They present seven aspects of understanding a proof and then generated possible items that could enable teachers/researchers to assess students' understanding of these facets of proof comprehension. The Mejia-Ramos et al. model incorporated many of the aspects identified by the Selden and Selden (1995, 2003) in their work on student validation of purported proofs.

Successful construction of a proof requires the coordination of skills related to logic, proof structure and types of argumentation, content knowledge, and creativity. Atwood (2001) identified seven obstacles in writing proof – three related to beginning the process and four to completing the process. Thus far, much work on proof construction has focused on course level interventions to improve student abilities to construct proofs (e.g., Selden, Benkhalti, & Selden, 2014). In terms of work on assessing student proof attempts, Andrew (2009) describes a "Proof Error Evaluation Tool (PEET)" that would help instructors provide consistent feedback to students regarding typical errors. Andrew identified two main categories of difficulties students had in writing proofs – eight types of errors related to proof structure and six related to conceptual understanding. He suggests that the tool be used as a rubric for the instructor and as a way of making the assignment of writing a proof more transparent to the student by providing them with the PEET as a reference when writing proofs and when examining the feedback provided by the instructor. Some of the "errors" identified relate less to the validity of the student's argument and more to the superficial issues that influence the readability of the argument (e.g. legibility of the writing, the lack of a diagram to guide the reader, lack of succinctness in argument).

Despite the growing literature on the difficulties students face in constructing and validating arguments, a challenge in the literature remains creating a way to define and track the development of proof competence over longer periods of time and experience, such as over the course of one's undergraduate program of study (Stylianides, Stylianides & Weber, to appear). It is this challenge that the protocol we present in this paper aims to address.

**Development of a Protocol to Assess the Longitudinal Development of Proof Competence: The Case of Western Michigan University**

Western Michigan University Mathematics Department is a medium-sized department within a public university with Carnegie classification of High Research Activity. Assessment has long been a priority for the university and the department. Several years ago, in response to calls at the university level, all departments were asked to identify one student learning objective that they would focus on collecting data about and improving with respect to. The mathematics department coalesced around the learning objective

*"Students will have the ability to detect invalid arguments and construct different types of valid mathematical arguments at an appropriate level of sophistication."*

In constructing an assessment protocol around students' development of proof competence, guided by the literature on proof, the assessment committee chose to approach the task of tracking students' developing proof competence by focusing on these two, distinct, but related competences of proof construction and proof validation.

*Task Criteria*

The first step in putting our department-wide assessment protocol in place was to find candidate tasks. We had several criteria for the sort of tasks we needed to create. The tasks needed to be suitable for students at many levels (i.e. the content of the task should engage high school math and not content students would not have experience with until later in their programs). At the same time, the task needed to allow us to see growth in sophistication of both proof approach and growth in sophistication of ability to communicate mathematically. We were particularly interested in tasks that would submit to several different approaches. Finding tasks that worked well for our purposes took several iterations and pilots. In constructing items to assess our dual objectives of proof construction and validation, we used the data from our proof construction task to generate sample arguments that became the basis of our proof validation task.

*Implementation Cycle*

We collect data from all students in our program every semester. In the fall semesters, we administer a proof construction task and in the spring semester students work on a proof validation task. Our current protocol involves a two-year cycle of tasks. We knew that we did not want to give the *same* exact task every year because students would begin to know the task and be less generative in their methods. Our data collection efforts are aimed at students in our program (e.g., math majors). However, in many cases, a student may not declare a mathematics major until later in their undergraduate career. Thus, in order to collect data on math majors' proof development, we also sample our lower division courses broadly and collect data from all students enrolled in our courses. The timing of the assessments is also deliberate. We aim to conduct the fall assessments early in their program before having the influence of particular coursework. Thus, we aim to administer the fall assessment within the first weeks of the fall semester. We made a conscious decision to administer the spring assessment as late as possible in the spring semester to allow the maximal time for growth over the course of a single year.

*Assessing Performance: The Development of Proof Construction Rubric*

Generating the data on the proof construction and validation tasks led to the need to have a systematic way to score and interpret the data. The validation tasks are multiple choice (students evaluate several arguments that are given to them) and are thus easy to score and interpret. The proof construction task, however, presents many more issues with respect to scoring and interpretation. Discussions at the department level about what was valued in assigning codes to student work led to discussions about how to handle/interpret issues such as how students communicated their arguments (symbolic versus with words) or whether written work revealed that students had the kernel of the idea of a proof, but were not yet able to complete it. Engaging the faculty in looking at students' proof work was extremely generative in that it revealed interesting and significant differences among faculty in their expectations and interpretations of student work. Thus, the effort to articulate what was valued by faculty in students' proof work and to develop a common language for making consistent decisions about student-generated proof led directly into the generation of the proof rubric. After many iterations and sessions that involved testing the emerging rubric against student data collected in past iterations, as of Fall 2015 we had a working prototype of the protocol.

The rubric that the department is currently using can be found in the appendix. As an overview, we point out that the rubric can be thought of in three main sections. The first section of questions concern whether or not the proof was valid and whether or not it was communicated at a very high level. We consider an answer of yes to these two questions to be the "high bar" that should be reserved only for the papers that meet our top expectations. If the paper receives a yes to these two questions, the following questions on the rubric do not need to be answered. The next section of the rubric contains questions that pertain to establishing whether markers of minimal growth towards proof writing competence exist in the student work sample being scored. In contrast to the first section, we see this section as a kind of "low bar" that lets us see whether the student's proof attempt contained initial chains of argument or evidence of mathematical reasoning. The final section of the rubric pertains to specific challenges or hurdles to writing a valid proof that are common reasons why the proof sample did not rise to a "yes, yes" profile. These include questions related to whether the proof sample contained an algebra error, or whether students made unwarranted assumptions, or did not provide sufficient evidence for the claims they were making in the argument they were presenting.

*Faculty Involvement in Scoring*

Collecting longitudinal data on mathematics majors' developing proof competence is a large endeavor. Our aim was to create a data collection and analysis protocol that would be sustainable over the long term in the department and that would inform conversations about how to improve curriculum and pedagogy. Thus, a high amount of faculty involvement across the entire department is necessary for the ongoing success of the protocol. As we geared up to administer the assessment to our focal classes in Fall 2015, the assessment committee held faculty development sessions to train faculty on the interpretation and use of the common rubric. The faculty development sessions involved the use of sample student work generated in the pilot phase and scoring it using the rubric (then coming together and discussing discrepancies in interpretation). The assessment committee created open times for faculty to meet and discuss scoring with committee members. Such opportunities were important as qualitatively analyzing and coding student work is a practice that is not familiar to many mathematics faculty members (who may be more familiar with grading student work solely for correctness and assigning points).

*Assignment Protocol and Resolving Discrepancies in Scoring*

Early on in our assessment work, the task of scoring student work samples fell on the department assessment committee. As mentioned above, in order to move towards a more sustainable model, we have sought ways to fairly distribute the work of scoring. In our most recent iteration of the two-year cycle, we used the following assignment procedure for scoring the tasks. Lower level courses were assigned to be scored by one person (not the instructor). This is because we were aware that we were casting a wide net in collecting this data and that much of the student work generated would not be by students who ended up pursuing mathematics majors. For any course aimed specifically at mathematics majors, we decided to have two independent scorers (not the instructor). Our general practice was to have a member of the assessment committee be one of the two independent scorers for papers from upper level courses. Once assignments had been made of which faculty would be scoring (roughly an equal number distributed to each faculty member, with the committee having more responsibility), we sent faculty members a link to the scoring rubric in google forms. This allowed for a master spreadsheet of all proof scores to be generated automatically.

Having multiple people score the upper level student papers opened up the possibility that individuals will diverge in their scoring of the student work. For each person marking the paper, the assessment committee generated a spreadsheet (directly from google forms) that included the student's identifier, the person's name who marked the paper, and then entries for every element of the rubric (displayed in 1's for yes and 0's for no). Then, for each statement in the rubric, the assessment committee reviewed differences among the scores. Electronic copies of all exam papers by class were saved to a common workspace and the committee went directly to the pdfs of the student work in order to discuss the meaning of discrepant scores. When two committee members were involved in marking the paper, it was possible to have an immediate discussion that resulted in resolution of the discrepancy. If a scoring discrepancy involved a faculty member not on the committee and did not appear to be an obvious error, the committee assigned .5 to each score given instead of assigning a 1 or a 0.

*Reporting the Findings*

Currently, analyses presented to the faculty of student results on the assessment (usually presented the semester after data is collected) have included a cross sectional analysis of students' performance on particular competence within the rubric (e.g., "X% of students in Course Y or below were able to produce valid arguments on the assessment item.") Over time, we are interested in reporting patterns in longitudinal for students in our program.

*Discussion*

In the above sections, we have described in detail the protocol that we use to assess the development of students' competence in generating and validating proofs. There are a number of issues that are under ongoing discussion. While the development of proof protocol that we have put in place and are implementing is powerful, there are some limitations of the choices that we have made in developing our protocol. For example, one thing that we would like to learn more about is how students work to prove statements that are more closely related to the content that they are learning in their upper division coursework. By design, the statements that students engage with in our longitudinal assessment needed to be independent of the coursework that students take in our program. We are exploring the possibility of augmenting our protocol with course-embedded assessments that would be asked of students as part of their normal coursework but collected as part of the departmental profile of their developing proof competence. Other future directions include conducting follow-up interviews to establish alignment between scores on students' written work and what we assess as their understanding in an interview setting in which we can probe their thinking. With respect to faculty development, interview data may be useful for engaging faculty in analyzing student work. The topic of math faculty development around the pedagogical implications of what can be learned from student work (including the student work generated by our proof assessment protocol) is a topic for ongoing investigation.

## Appendix: Proof Construction Rubric

***Rubric Section 1***

**Question 1 -- Is the proof valid?** A valid proof should be free of algebraic errors, unjustified claims, missing cases, and the imposition of additional hypotheses. Students who use the fact that a^2-a+1 has no real roots must justify this claim.

**Question 2 -- Does the student sufficiently communicate their ideas (whether correct or incorrect)?** Is it easy to follow their line of thinking or interpret what they have done? For example, if a student wrote "I don't remember what a reciprocal is, but if I did, I would assume that there is a real number such that the sum of it and its reciprocal equals one," it would be coded "yes." If the student is only reiterating or clarifying the problem, then code as "No."

***Rubric Section 2***

This section should be marked only if the student did NOT write a valid proof ("No" on Question 1).

**Question 3 --- The student appears to understand that the problem is about a + 1/a compared to 1** The rest of their work, if any, can be at any level. A student who writes something like a * 1/a = 1 did not correctly interpret the problem.

**Question 4 -- The student engaged with the problem, doing some work (possibly incorrect) beyond just interpreting or rephrasing the statement** There is some evidence that the student engaged with the problem and persisted in their attempt. For example the student tried out specific numbers, sketched a graph, or did some algebraic fiddling (beyond rote steps like adding or simplifying fractions without a comparison to 1).

**Question 5 -- Some mathematical reasoning exists (possibly built from incorrect assumptions or definitions)**

**Question 6 -- The student used words to express at least one complete idea in support of their argument** If the student is only reiterating or clarifying the problem, then code as "No."

***Rubric Section 3***

This section should be marked only if the student correctly interpreted the problem ("Yes" on Question 3).

**Question 7 -- The student made an algebraic error, or their use of language or notation interferes with progress** These errors could range from a simple sign error to conceptual errors such as extending the zero product property to another integer.

**Question 8 -- The student ignored cases or imposed additional hypotheses (explicitly or implicitly)** For example, a student may successfully complete the proof under the assumption that a is strictly positive. Or a student may cover the case $a < 0$ and after this implicitly assume that a is nonnegative, for example stating that if $a < 1$ then $1/a > 1$. Also code proof by example(s) as "yes."

**Question 9 -- The student made claims that they did not attempt to justify** Examples of "yes": a student wrote "the equation $a^2 - a + 1 = 0$ clearly has no real solutions and so there cannot be any such real number" or arrived at the equation $a^2 - a + 1 = 0$ and then simply stated "therefore there cannot be any real number such that the sum of it and its reciprocal is 1." Attempting to justify a claim, but doing so incorrectly or incompletely, would be coded "no."

**Question 10 -- The student introduced a framework that *could* be used to write a successful proof** Manipulating the expression $a + 1/a$ (vs. the equation $a + 1/a = 1$) is exploratory work and not a framework. Introducing a multivariable scheme is unlikely to lead to a successful proof, so also rate this as "No." For a "yes", unresolved issues or gaps in the proof (including missing cases) could be resolved using skills that the student has either demonstrated already, or which are easily accessible to a calculus student (e.g., testing trivial cases). Simply testing the values $a = 1, 2, 3$, etc. would be coded "No."

Proof Norms in Introduction to Proof Textbooks

Joshua B. Fagan
Texas State University

Kathleen M. Melhuish
Texas State University

*We present a textual analysis of three of the most common introduction to proof (ITP) texts in an effort to explore proof norms as undergraduates are indoctrinated in mathematical practices. We focus on three areas that are emphasized in proof literature: warranting, proof frameworks, and informal instantiations. Each of these constructs have been connected to students' ability to construct, comprehend, or validate proofs. We carefully coded all the proofs and supplemental material across common sections in the textbooks. We found that the treatment of proof frameworks was inconsistent. We further found that textbook proofs rarely used explicit warranting and informal instantiations. We conclude by reflecting on the impact of inconsistent proof norms and unsubstantial focus on supportive proof components for students in ITP courses.*

*Keywords:* Proof, Proof Norms, Textbook Analysis, Warranting, Proof Frameworks

Proof is an essential aspect of the mathematical discipline (de Villiers, 1990; Hanna, 2000; Hersh, 2009; Rav, 1999), and as such proficiency in all areas of proof is important for students in undergraduate mathematics programs to gain. In order to meet this goal, university mathematics departments offer introduction to proof (ITP) courses to help students learn about the argumentative process of proof specific to mathematics. One of the main objectives of the ITP course is to improve the undergraduate student's ability to construct formal proofs. Despite this objective, numerous studies have documented the difficulties that students have in making the transition to advanced mathematics and in their ability to construct formal proofs (e.g. Moore, 1994; Selden & Selden, 2003; Weber & Alcock, 2004). In spite of this research and the hypothetical function of the ITP course, until recently little focus has been put on the nature of these classes.

In this study, we focus on the intended curriculum of ITP courses as reflected in textbooks. Curricular materials provide a significant factor in the learning and development of reasoning and proof (Konior, 1993; Stylianides, 2014). As such, the aim of this study is to understand both the implicit and explicit messages that ITP textbooks send to the reader about the nature of mathematical proof. Specifically, we analyzed three research-based aspects of proof: proof frameworks (Selden & Selden, 1995, 2003; Weber, 2009), explicit warranting (Alcock & Weber, 2005; Inglis & Mejiá-Ramos, 2008; Pedmonte, 2007; Toulmin, 2003), and diagrams as well as other informal reasoning (Samkoff, Lai & Weber, 2012; Weber & Alcock, 2004). We found that ITP proofs often lacked consistency in terms of frameworks and warranting, and generally overlooked diagrammatic and other informal reasoning.

## Theoretical Framing and Background

Underlying our work is the assumption that curricular materials reflect and impact the nature of a mathematics course. In general, we argue in alignment with Zhu and Fan (2006):

> ...textbooks are a key component of the intended curriculum, they also, to a certain degree, reflect the educational philosophy and pedagogical values of the textbook developers and the decision makers of textbook selection, and have substantial influence on teachers' teaching

and students' learning (p. 610).

While not a perfect substitute for the classroom, textbooks provide a substantial set of example proofs that students experience. Furthermore, writers of these texts are implicitly endorsing a set of norms for proofs in this setting. In this way, textbooks provide an artifact for exploring the norms for ITP-level proofs and a substantial resource impacting students' ultimate learning.

We also frame our work in terms of proof as a social construct. Research has established that what constitutes a valid proof varies based on context and even from individual to individual (e.g. Moore, 2016; Weber, 2008). In this way, we may expect that textbooks may reflect similar variation in proof norms. We focus on three areas of norms: proof frameworks, warranting, and diagrams and other informal reasoning.

**Proof Frameworks**

Selden and Selden (1995) introduced the construct of *proof framework* to capture the "top-level" structure of proof that comes directly from unpacking a statement. For example, if the mathematical statement to be proven is, "For all integers $x$, if $x$ is odd, then $x + 1$ is even integer" the *complete* proof framework for a direct proof of this this statement might look like the following:

*Proof:* Let $x$ be an integer. Suppose $x$ is odd…
…then $x + 1$ is an even integer. ■

Notice this is a direct proof. A contrapositive proof framework would unpack the contrapositive statement.

The literature reflects that ability to produce an accurate proof framework has a relationship to other activities such as constructing, validating, and comprehending proof (e.g. Mejiá-Ramos, Fuller, Weber, Rhoads, & Samkoff, 2012; Selden & Selden, 1995, 2003; Weber, 2009). Both Selden and Selden (1995) and Weber (2009) found that many students do not typically check proof frameworks and may lack awareness as the essential role of an appropriate proof framework in a proofs' validity.

**Warranting**

One of the most fundamental acts in mathematics, especially in proof and proving is that of warranting: justifying assertions (see Hanna 1991, 1995; Healy & Hoyles 2000). According to Toulmin (2003) arguments, and by extension proofs (see Alcock & Weber, 2005; Inglis & Mejiá-Ramos, 2008; Pedmonte, 2007), have a formal structure which is defined by the interplay of at least three fundamental constructs; that of *data*, *warrants*, and *claims*. In the tradition of Toulmin (2003), a claim is a statement or assertion of what is true, the data is the grounds by which the assertion of truth is made, and the warrant justifies the connection between the data and the claim by, for example, invoking a definition or rule. For instance, we can use Toulmin's scheme to analyze the following statement: "Since x is odd, then by the definition of odd, $x = 2n + 1$ for some $n \in \mathbb{Z}$." The claim being made in this instance is that "$x = 2n + 1$ for some $n \in \mathbb{Z}$," the data on which rests the truth of this assertion is "Since $x$ is odd," and the warrant that connects the data and claims is "by the definition of odd."

Warranting, explicitly connecting data and claim, is an important ability for students to learn. Alcock and Weber (2005) asserted that, "Failure to consider the warrants used in a proof will not only cause students to be unable to validate proofs reliably, but… can also prevent them from gaining conviction and understanding from proofs presented in their classrooms" (p. 133). Furthermore, Alcock and Weber claimed that instructors for proof-oriented course do not commonly discuss warrants and that textbooks are also infrequent in explicit language on the subject. Within proofs, warrants are often left implicit. The ability to infer these implicit warrants is an essential skill for understanding proofs in advanced mathematics and should be part of students' enculturation into proof based mathematics (Weber & Alcock, 2005).

### Diagrams and Other Informal Reasoning

Informal reasoning plays an important role in the learning and construction of proofs (Fischbein, 1983; Hanna, 1991), moreover, it is the multifarious interplay of these intuitions with the rigorous and abstract aspects of mathematical ideas that are the cornerstone of advanced mathematics (see Mariott, 2006). Informal reasoning may take many forms including that of exploring examples or diagrams.

Diagrams and other example based instantiations can aid students in understanding a statement, and gaining a level of conviction in a theorem and its proof (see Alcock & Weber, 2008, 2010; Samkoff, Lai, & Weber, 2012, Weber & Mejiá-Ramos, 2015). As moving from informal to formal reasoning is an important factor in the creation of mathematical ideas (Raman 2003; Weber & Alcock, 2004), we explored the degree to which textbooks leveraged informal instantiations including: using numbers to explore computational cases (e.g., substituting values as test cases), building example sets to explore set interactions (e.g. unions, intersection, Cartesian products), or testing the behavior of specific set members under a particular mapping.

## Methods

### Textbook Sample

In this study we analyzed three textbooks (see Table 1) which are among the most used textbooks for the standard ITP course in the United States. According to David and Zazkis (2017), these textbooks represent roughly 27%[1] of the market share for textbooks used by departments and instructors for the ITP course. All other standard ITP texts had less than a 4.2% market share.

*Table 1. Introduction to Proof Textbooks*

| Title | Publisher | Authors | Market Share | Year |
|---|---|---|---|---|
| Mathematical Proofs: A Transition to Advanced Mathematics (**Book A**) | Pearson Education | Chartrand, Polimeni, & Zhang | 11.3% | 2013 |
| A Transition to Advanced Mathematics (**Book B**) | Brooks/Cole | Smith, Eggen, & St. Andre | 10.6% | 2011 |
| Book of Proof (**Book C**) | Richard Hammack | Hammack | 4.9% | 2013 |

We selected the sections and chapters that aligned with content found in a typical Standard ITP course: formal logic, number and set theory, relations, functions, and cardinality of sets (David & Zazkis, 2017). We grouped the sections into *introductory material* which consisted of all sections prior to the three *content specific* sections of functions, relations, and cardinality of sets. For each of the pertinent sections and or chapters of the textbooks, we read the vast majority of proofs, as well as any explicit commentary that each book provided about the construction of said proofs. All told, we analyzed arguments for 345 mathematical statements, of which we identified 280 were proofs or at very least the outline of a proof. See table 2 for a breakdown of number of proofs by section in each text.

[1] David and Zazkis (2017) shared information on 154 universities use of textbooks, 12 of which used lecture notes only, meaning that 38 of the remaining 142 classes used one of these three texts.

*Table 2. Mathematical Statements and Proofs*

| | Book A | | Book B | | Book C | | Total | |
|---|---|---|---|---|---|---|---|---|
| Section | Statement | Proof | Statement | Proof | Statement | Proof | Statement | Proof |
| Intro. Material | 56 | 50 | 85 | 64 | 46 | 46 | 187 | 160 |
| Relations | 9 | 9 | 17 | 15 | 3 | 3 | 29 | 27 |
| Functions | 10 | 10 | 34 | 23 | 6 | 4 | 50 | 37 |
| Cardinality of Sets | 21 | 17 | 44 | 30 | 14 | 9 | 79 | 56 |
| Overall | 96 | 86 | 180 | 132 | 69 | 62 | **345** | **280** |

Each of the three textbooks were analyzed using thematic analysis (Braun & Clarke, 2006). The analysis began with open coding proofs from Book A within the categories of proof frameworks, warranting, and diagrams/informal reasoning. This set of codes of was condensed and categorized. The robustness was tested in the next text: Book B. These coding scheme was further expanded when new codes emerged from this text. For the purpose of consistency and in being faithful with the method of constant comparison, prior to coding Book C, we recoded Book A using the full set of codes. Once the second coding of Book A was completed and codes were refined and condensed, coding of Book C began, and it was at this point that saturation occurred and the coding cycle ceased as no new codes arose from coding Book C.

**Analytic Framework**

In this section we share the most relevant sections of our coding framework. Proof frameworks were coded as either complete, incomplete, or non-existent. All explicit warrants were identified based on their type: definition, theorem, or algebra. We identified two types of informal categories: diagrams (visual representations) and informal reasoning. See Table 3 for elaborations of the codes,

*Table 3*. Analytic Framework for Coding Proofs

| Category | Code: Description | Example |
|---|---|---|
| Proof Frameworks | **Complete:** A proof has both the antecedent and consequent of the original statement represented in accordance with the proof method being employed<br><br>**Incomplete:** A proof which only has one or the other of the antecedent or consequent represented in accordance with the proof method being employed.<br><br>**Non-Existent:** A proof which has neither the antecedent nor consequent represented. | For all integers x, if x is odd, then x + 1 is even integer.<br><br>*Proof:* Let $x = 2n + 1$ for some $n \in \mathbb{Z}$…<br>…then $x + 1$ is an even integer. ■<br><br>Code: Incomplete (the antecedent is not explicitly unpacked to: "Let *x* be an integer." |
| Warrants | **Definition**: The authors use a definition, property, axiom, or other fact *accepted* in the text as a warrant to connect some data and claim within a proof. | "By the distributive property we have that $3 \cdot (x + y) = (3 \cdot x) + (3 \cdot y)$…" |

| | | |
|---|---|---|
| | **Theorem**: The authors use a theorem, corollary, lemma, or other fact *proven* in the text as a warrant to connect some data and claim within a proof. | Code: Algebra (reference to the field property distributive) |
| | **Algebra:** The authors use an algebraic field axiom as a warrant to connect some data and claim within a proof. | |
| Informal | **Strategies**: Any instance where the authors present syntactic strategies for proof production. |  |
| | **Semantic**: Any instance where a proof or its supplementary material references a diagram or present other semantic explorations whether to simply clarify an idea or as a means to further the proof. | Code: Diagram (this figure was directly reference in a proof). |

## Results

### Proof Frameworks

We found that the three books varied in terms of how often they presented a complete proof framework (CFP). Book A and Book B provided CFP roughly 1/3 of the time while Book C provided CFP 68% of time (see table 4). Roughly a quarter of proofs from Book A and Book B did not include either the proof framework antecedent or conclusion. A student reading Book C is exposed to significantly more complete proof frameworks than a student reading Book A or Book B.

*Table 4. Complete Proof Frameworks and Non-Existent Proof Frameworks*

| Text | Complete | % Complete | Non-Existent | % Non-Existent |
|---|---|---|---|---|
| Book A | 32 | 37% | 22 | 26% |
| Book B | 50 | 38% | 27 | 20% |
| Book C | 42 | 68% | 2 | 3% |
| Overall | 124 | 44% | 51 | 18% |

Additionally, we found that complete frameworks were present more consistently in the introductory materials, as proof methods were being explicated, and then used less and less as we continued through each book (see Table 5). Conversely, non-existent frameworks were less frequent in the introductory material, but become more common as the texts progress. Finally, proof frameworks in the supplementary material were treated in a manner roughly parallel to how they were treated in the body of the proofs themselves.

*Table 5. Complete Proof Frameworks (Comp.) by Topic*

| | Book A | | Book B | | Book C | |
|---|---|---|---|---|---|---|
| Sections | Comp. | % Comp. | Comp. | % Comp. | Comp. | % Comp. |
| Intro. Material | 25 | 50% | 34 | 53% | 33 | 72% |
| Relations | 2 | 22% | 2 | 13% | 3 | 100% |

| | | | | | | |
|---|---|---|---|---|---|---|
| Functions | 3 | 33% | 2 | 9% | 3 | 75% |
| Cardinality | 2 | 12% | 12 | 40% | 3 | 33% |

**Warranting**

We found explicit warranting to be an uncommon occurrence in all three textbooks. In Table 6, we present the use of explicit warrants within the categories of definitions (DEF), theorems (THM), algebraic field axioms (ALG). We also provide the number of proofs and number of statements. Overall only 6% of statements included explicit warranting throughout all three texts, and a little more than a third of all proofs had *any* explicit warranting of any kind in them. Thus the reader of any of these texts is unlikely to regularly be exposed to explicit warrants. In all three texts, field axioms were implicitly warranted in all cases. Book C provided the most warrants often explicitly warranting with definitions.

*Table 6. Proofs with Warrants, Statements, and Total Warrants in ITP Texts*

| | Proofs with Warrants | Statements in Proofs | Warrants | | | | Total by Statement (%) |
|---|---|---|---|---|---|---|---|
| | | | DEF | THM | ALG | Total | |
| Book A | 18 | 808 | 5 | 19 | 0 | 24 | 3% |
| Book B | 47 | 885 | 21 | 38 | 0 | 59 | 7% |
| Book C | 37 | 633 | 51 | 20 | 0 | 71 | 11% |
| Total | 102 | 2326 | 77 | 77 | 0 | 154 | 6% |

When we expanded our analysis to the supplemental material, we found that Book B and Book C often included warrants in parenthetical comments. An additional 46[2] explicit warrants can be found in parenthetical comments. This reflects that warranting is (a) not meant to be part of the proof product; (b) but warranting is part of the proving process.

**Informal Reasoning and Diagrams**

We found diagrams and other semantic explorations to be the most sparsely represented construct of all coded entities. Conversely, the authors regularly offer insight akin to Weber's (2001) strategic knowledge as strategies were especially prevalent.  In Table 7 we present the use of strategies and semantic explorations as part of the argumentative process. The authors show a bias toward presenting strategies for how to produce a proof rather than the exploring instantiations to better understand the underlying premise being proven.

*Table 7. Use of Informal Reasoning and Diagrams*

| | Proofs | Strategies | Strategies (%) | Semantic | Semantic (%) |
|---|---|---|---|---|---|
| Book A | 86 | 40 | 47% | 6 | 5% |
| Book B | 132 | 72 | 55% | 8 | 6% |
| Book C | 62 | 10 | 16% | 3 | 5% |

[2] Three of these warrants were related to algebraic field axioms.

| | | | | | |
|---|---|---|---|---|---|
| Total | 280 | 122 | 44% | 15 | 5% |

## Discussion

Through our textbook analysis, we found proof frameworks, warranting, and informal reasoning occurred inconsistently and often infrequently in typical ITP textbooks. Proof frameworks were by far the most treated entity of the three as each text explicitly touched on the idea that there is an overarching logical shell implied by the mathematical statement to be proved and the chosen proof method. This was a point that was touched on early by each of the three texts, but was not used consistently throughout the texts. In general, the texts convey a message that a proof framework need not be explicit part of a proof. As we know students struggle to produce, identify, and understand the role of proof frameworks (Mejía-Ramos et al., 2012; Selden & Selden, 1995, 2003), leaving such a framework implicit may be further increasing the difficulty in seeing the importance of these structures.

Our analysis bore out Alcock and Weber's (2005) conjecture that textbooks do not treat warranting and its importance explicitly. None of the three texts explicitly addressed the role of warranting. Further, explicit warrants were a rarity. The textbooks reflected a norm for the ITP setting that field axiom claims never need warrants. Claims relying on definitions or theorems sometimes need explicit warrants. There is no reliable message to be found concerning the use of warranting within these texts. For the reader this means that coming to a deeper understanding of explicit warrants will be difficult, let alone coming to have an understanding about the importance of being able to infer warrants. This means that the impetus is on the instructors of ITP courses to introduce what a warrant is and the role that it plays in the argumentative process, but also to explore how they are used implicitly and the role the reader of a proof has in inferring the implied warrant (see Alcock & Weber, 2005, Weber, 2004).

Finally, informal reasoning, much like that of warranting, had no explicit conversation surrounding the subject in any of the three texts. None of the three texts present a clear picture of how informal reasoning may guide the production of formal proof and the place that informal ideas and representations such as diagrams play in a formal proof. The exception to this occurs in the cardinality section where maps are written informally. This more informal treatment is leaves us to wonder the lasting affect that seeing a large body of formal proofs, followed by some very informal proof on a particular subject will have on students' ability to understand and gain conviction in ideas surrounding cardinality in their future classes.

Our study implications are limited in the degree to which commonly used textbooks reflect the implemented curriculum. We see this exploration as highlighting that there is a clear under treatment of warrants and information exploration in common textbooks. We do not wish to claim this means there is an under treatment of these topics within classes. However, our textbook analysis paired with research on the typical nature of proof-based courses (e.g. Alcock & Weber, 2010; Lew, Fukawa-Connelly, Mejía-Ramos, & Weber, 2016), builds a strong argument for this being the case.

Furthermore, the textbook analysis unearthed inconsistent proof norms particularly around proof frameworks and warranting. If a set of typical textbooks designed to enculturate students in proof production contain fundamental inconsistencies, how can we expect our students to understand the importance of these constructs? As instructors and researchers, we must be aware of the messages our curricular materials may send.

*The purpose of this study is to examine the understandings of functions that students developed and tested while engaging with a Vending Machine applet. The applet was designed to purposefully problematize common misconceptions associated with the algebraic nature of typical function machines. Findings indicate that the applet disrupts students' algebraic view of function and supports their transformation of meaning schemes for the function concept.*

*Keywords:* Functions, Calculus, Teaching with Technology

The concept of function is central to the study of undergraduate mathematics, science, and engineering (e.g., Cooney, Beckmann, & Lloyd, 2010; Dubinsky & Harel, 1992; Leinhardt, Zaslavsky, & Stein, 1990). However, research has revealed persistent and common misconceptions among undergraduate students with respect to the definition of function (Vinner & Dreyfus, 1989), use of function notation (e.g., Oehrtman, Carlson, & Thompson, 2008), and connections between function representations (e.g., Brenner et al., 1997; Clement, 2001; Dreher & Kuntze, 2015; Stylianou, 2011). Hence, there is a need for the development and study of interventions to help address misconceptions such as these among undergraduate students so that they are set up for success in their future studies.

To this end, we designed and studied the implementation of an applet-based learning intervention focused on disrupting undergraduate students' understanding of the function concept. The purpose of this study is to examine the understandings of functions that students developed while engaging with a Vending Machine applet designed for students to test and develop their own definitions for function.

## Background Literature

Much of the research on student understanding of function has occurred in the context of college algebra, precalculus, or calculus classes. Through these studies there has been a careful identification of common understandings that students develop related to the concept of function. One common student understanding is that functions are defined by an algebraic formula (Breidenbach et al., 1992; Carlson, 1998; Clement, 2001; Sierpinska, 1992). This is not surprising since functions are typically introduced as specific function types, such as linear and quadratic functions, in the middle school and high school curriculum (Cooney et al., 2010). Thompson (1994b) found that not only do students view functions as algebraic formulas, they often view functions as two expressions separated by an equal sign. While an equation view of function is not inherently wrong, it is narrow and can lead to difficulties for students as they work with functions in different contexts and with different representations (Cooney et al., 2010).

Along with an algebraic view of functions as representations of particular objects (e.g., graphs, expressions) rather than a relationship between inputs and outputs, research has also shown that students often rely on the graph of an equation and the vertical line test to differentiate a function from a non-function (Breidenbach et al., 1992; Fernandez, 2005). This can lead to conceptual difficulties in determining functions from non-functions, including the tendency to apply procedures to determining functions from non-functions (Breidenbach et al., 1992; Fernandez, 2005). Students whose view of function is algebraic and who use procedural techniques to identify functions and non-functions struggle to comprehend a general mapping of input values to a set of output values (Carlson, 1998; Thompson,1994a). The consistency of problematic understandings of function found across studies of students speaks to the need for pedagogical practices to specifically disrupt and correct these ideas. This is especially important given that function is a unifying concept among many undergraduate mathematics courses. Students need to understand both what a function is (i.e., the definition of function) and how to identify one across contexts and representations (e.g., Carlson, 1998; Thompson, 1994a; Breidenbach et al.,1992). Yet, particular attention to students' understanding of the definition itself has not been widely researched.

## Theoretical Framework

As we consider undergraduate students' learning related to function, we adopt a theoretical lens of transformation theory (Mezirow, 2009). Transformation theory is consistent with constructivist assumptions, specifically that meaning resides within each person and is constructed through experiences (Confrey, 1990). Mezirow (2009) describes four forms of learning that lie at the heart of the theory: elaborating existing meaning schemes, learning new meaning schemes, transforming meaning schemes, and transforming meaning perspectives (p. 22). Meaning schemes are the specific expectations, knowledge, beliefs, attitudes or feelings that are used to interpret experiences (Cranton, 2006; Peters, 2014). In the context of this study, an undergraduate student might transform his/her meaning scheme for function by rejecting her prior conception of function as a graph that passes the vertical line test and adopt a broader view of function that includes numerical and algebraic representations.

Learning by transforming meaning schemes often begins with a *disorienting dilemma*. This stimulus requires one to question current understandings that have been formed from previous experiences (Mezirow, 2009). It is this type of learning experience that we are particularly interested in - both designing stimuli for it, and the ways that meaning schemes are transformed as a result. Given the evidence that undergraduates often have a view of function that is limited to algebraic expressions and their associated graphs (e.g., Carlson 1998; Even, 1990) and that such understandings typically result in a "vertical line test" related definition of function (e.g., Carlson, 1998), we designed an experience that would problematize these understandings, thereby creating a stimulus for transformation.

One strategy that has been suggested for resolving common misunderstandings related to function is the use of a function machine as a cognitive root. The idea of a *cognitive root* was introduced by Tall and colleagues as an "anchoring concept which the learner finds easy to comprehend, yet forms a basis on which a theory may be built" (Tall et al., 2000, p.497). As an example of a cognitive root for function concepts, Tall et al. suggest the use of a *function machine* (sometimes referred to as a function box). The machine metaphor Tall and colleagues describe is typically a "guess my rule" activity where the inputs and associated outputs are provided and students are challenged to determine what happened in the function machine (i.e., determine the function rule). While students are presented with a machine to embody the function concept, the rules used by the machine are algebraic in nature. In their studies using such machines proved quite promising as a cognitive root for function, yet some students still struggled with connecting representations and determining what is and is not a function (McGowan et al., 2000). Given the promise of a machine metaphor as a cognitive root for function coupled with our desire to present a disorienting dilemma for undergraduates, we set out to design an applet as a learning experience.

## Design of the Applet

The Vending Machine applet (version 2.0) was designed to trigger a disorienting dilemma in students' understanding of function. The applet contains no numerical or algebraic expressions, but instead was built on the metaphor of a vending machine. Our Vending Machine applet (https://ggbm.at/qxQQQ7GP) is a GeoGebra book consisting of four pages. The first two pages contain two soda vending machines each with buttons for: Red Cola, Diet Blue, Silver Mist, and Green Dew. When the user presses a button (input), one or more cans appear in the bottom of the machine (output). To remove the can(s) from the bottom of the machine, the user clicks the "take can" button. On each of the first two pages, one machine is labeled as a function and the other is labeled as not a function. The non-function machines each have at least one button that produces a random can when pressed (i.e., the resulting can is not predictable based upon the button that is pressed). The directions ask the user to explore Machines 1-4 on Pages 1 and 2 and make a conjecture about why Machines 1 and 3 are functions and Machines 2 and 4 are non-functions.

Pages 3 and 4 of the applet allow the user to test and adapt their conjecture through interacting with 10 additional vending machines, Machines A through J. The functionality of each machine was designed to address misconceptions from the literature on distinguishing functions and non-functions. Examining Table 1, you will notice that the understandings we are trying to disrupt are the notion of what represents an element in the range (Machines B, I, & J), students occasional use of the term "unique" when thinking about outputs (Machines B & I), and the notion that functions should be "predictable" (Machines A, C, I, & J) - meaning that if one knows the function rule and is given an output, it is possible to determine what input resulted in that output.

*Table 1. Machine output for each button pressed*

| | Button Pressed | | | |
|---|---|---|---|---|
| | Red Cola | Diet Blue | Silver Mist | Green Dew |
| Machine A | red can | blue can | silver can | random can |
| Machine B | two silver cans | green can | red can | blue can |
| Machine C | random can | random can | random can | random can |
| Machine D | silver can | green can | red can | blue can |
| Machine E | red can | silver can | silver can | green can |
| Machine F | blue can | silver can | green can | red can |
| Machine G | green can | green can | green can | green can |
| Machine H | red can | red can | silver can | silver can |
| Machine I | random pair | blue can | silver can | green can |
| Machine J | red can | blue & random can | silver can | green can |

## Method

The purpose of this study was to examine the understandings of functions that undergraduate students developed while engaging with the Vending Machine applet. We specifically address the following research questions: 1) How do students define function? and 2) How do students change their definition of function as a result of engaging with the Vending Machine applet?

### Data Collection

A total of 123 students at six post-secondary institutions, that ranged in size, location, and focus, participated in the study. These students were undergraduates who had completed Calculus I. Prior to their use of the applet, students were asked to write a definition of function in their own words based on their current understanding, i.e., a pre-definition. This was done toward the beginning of the course or before functions were discussed, and no explicit instruction or discussion of functions had yet occurred. This data was collected by the instructor and students subsequently engaged with the Vending Machine applet outside of class, recording their interaction via a screencast. During the following class session students were asked to define function once again, a post-definition. The data used for this particular paper are the students' pre-and post- definitions.

### Data Coding and Analysis

Given that our goal was to make sense of students meaning schemes within their written responses (i.e., text data) the use of content analysis (Creswell, 2007) as an analysis technique is appropriate. Specifically, we used *directed content analysis*. Directed content analysis uses existing theory or prior research to identify key concepts as initial coding categories for recognizing patterns in text responses (Hsieh & Shannon, 2005). For example, one set of initial codes were defined based on prior research that has identified student conceptions of functions as objects (e.g., expressions, graphs, tables of values) and relationships (e.g., mappings) (e.g., Dubinsky & Harel, 1992; Breidenbach et al., 1992). Through open coding, additional codes were defined as they emerged from the data. For example, students often included examples within their definitions so we created a set of codes to capture the nature of these examples (e.g., graph example, expression example).

Our completed codebook included 16 codes. To establish reliability in our coding a subset of 25 randomly selected definitions were coded independently by all six members of the research team and the number of agreements were divided by the number of assigned codes. The team had 93.1% agreement, so the codebook was considered reliable (Miles & Huberman, 1994). Once reliability was established, definitions were coded independently by six coders, with all definitions double-coded by pairs of coders. Pairs then compared codes and discussed and resolved differences (DeCuir-Gunby, Marshall, & McCulloch, 2011).

Prior to attending to aspects of the text individually, the pre- and post-definition were taken as a whole and coded in terms of their *accuracy* (i.e., correct, incorrect, or close to correct). Key elements of a correct definition were 1) the definition was not limited to a specific type of function (e.g. linear or quadratic), or to a particular representation (e.g., equation), and 2) the definition addressed the idea that functions map each input to one and only one output. Definitions coded as close to correct included those that indicated each input has one and only one output, but were not classified as correct because they were not general enough (e.g., the definition limited a function to a particular representation, such as an equation).

Next, each definition was coded regarding whether the definition indicated a function was a relationship (e.g., mapping), an object (e.g., equation, graph), or neither (see Table 2). We referred to this set of codes as *focus*, as they indicated how the students “saw” function. This coding was intended to be mutually exclusive, although some exceptions were found. Finally, definitions were coded according to whether or not they attended to output, as this was another aspect of the definition that we expected to be problematic based on the literature (Carlson, 1998; Even, 1993). After coding was completed, results for each code were summarized and analyzed for patterns and themes that provided insight to transformations of students’ meaning schemes related to the definition of function.

## Results

### Pre-definitions

Our results show that the vast majority of students initially incorrectly defined function and their definition focused on a function as an object (Table 2). Only 24 students (19.4%) defined function correctly or close to correct. Note that with respect to focus there is a fourth category, *both object and relationship.* This is because, although the categories of relationship, object, and neither were meant to be mutually exclusive, there were definitions that referred to a function as both a relationship and an object. For example, one student defined a function as “an expression that is representative of a relationship between two or more variables.” Referring to a function as an expression would generally be categorized as an object, but in this case the student also refers to a function as a relationship. Finally, there were initially 47 students (38.2%) who paid attention to output in their definitions. For example, “for each value of x, there can only be one and only one y” and “function is when there is a specific output given an input” were both coded as “attention to output”. Definitions that made mention of the vertical line test were also coded as paying attention to output.

*Table 2. Code occurrences n pre- and post- definitions*

| Code | Example | Pre (%) | Post (%) |
|---|---|---|---|
| | Accuracy | | |
| Correct | A function is a relation in which for every input there exists exactly one output. | 6 (4.8) | 8 (6.5) |
| Close to Correct | A function is a mathematical equation in which a single input only yields one result. | 18 (14.6) | 46 (37.4) |
| Incorrect | An expression that is representative of a relationship between 2 or more variables | 99 (80.5) | 69 (56.1) |
| | Focus | | |
| Relationship | A mapping from a domain to a codomain (or range) | 14 (11.4) | 18 (14.6) |
| Object | An equation with an x-input that gives a y output. | 86 (70.0) | 64 (52.0) |
| Both object & relationship | An expression that is representative of a relationship between two or more variables | 7 (5.7) | 10 (8.1) |
| Neither | f(x) → y; i) unique y value for every x; ii) one to one | 16 (13.0) | 31 (25.2) |

**Changes in definition**

In this section, we report results in terms of how students' definitions changed after interacting with the applet. In terms of accuracy, the majority of students (52.8%) persisted in an incorrect definition of function. However, considering students who moved from incorrect definitions to definitions that were either correct or close to correct, over one-fourth (27.6%) of students improved their definition of a function. Furthermore, only 4% of students regressed in their understanding of function, i.e., from correct or close to correct to incorrect, or from correct to close to correct.

To better understand the aspects of function that are still problematic in definitions we look at focus and attention to output. In terms of students' focus in their definitions of function, a total of 90 students (73.2%) did not change (Table 3). Furthermore, the majority of students (69.1%) started with a definition of function that was classified as an object, and most (52%) persisted in that view. In terms of students' attention to output, 45 of the 47 students who initially made special reference to the output of a function maintained a focus on output in their definitions after engaging with the applet. On the other hand, of the 76 students who did not make any special reference to output in their initial definitions, 60 (78.95%) of them did so after engaging with the applet. Overall, 85.3% of all students attended to output in their revised definition.

*Table 3. Occurrences of pre and post definition characteristics*

| | Post-Definition Characteristics | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Pre-Definition Characteristics | Incorrect | Close to correct | Correct | Object | Relationship | Both O & R | Neither | Attend to output | No attention to output |
| Incorrect | 65 (52.8) | 31 (25.2) | 3 (2.4) | | | | | | |
| Close to Correct | 3 (2.4) | 14 (11.4) | 1 (0.8) | | | | | | |
| Correct | 1 (0.8) | 1 (0.8) | 4 (3.3) | | | | | | |
| Object | | | | 64 (52.0) | 8 (6.5) | 1 (0.8) | 12 (9.8) | | |
| Relationship | | | | 1 (0.8) | 10 (8.1) | 0 (0.0) | 6 (4.9) | | |
| Both O & R | | | | 0 (0.0) | 1 (0.8) | 5 (4.1) | 1 (0.8) | | |
| Neither | | | | 3 (2.4) | 0 (0.8) | 0 (0.0) | 11 (7.9) | | |
| Attend to Output | | | | | | | | 45 (36.6) | 2 (1.6) |
| No attention to output | | | | | | | | 60 (48.7) | 16 (13.0) |

## Discussion

With the essential role function plays in college mathematics, it is imperative that students have an understanding of function beyond an algebraic understanding. To address this, we created an applet, building from Tall and colleagues (2000) suggestion of a function machine as a cognitive root. Our Vending Machine applet (version 2.0) was designed to provoke disorientating dilemmas related to students' understanding of function which promote reflection and ideally shift students' meaning schemes related to definition of function away from an algebraic view. Since little research has been conducted on undergraduates' definition of function since Vinner & Dreyfus (1989), one of the goals of the study was to examine the current definitions of a function from a large sample of undergraduate students from six universities. From examination of students' definitions before engaging with the applet, our results showed that only approximately 5% of students could correctly define a function. The majority of students in this study did not include in their definitions the two key elements that define a function: 1) it is applicable across different representations; and 2) functions map each input to one and only one output.

From examining changes in students' definitions, the Vending Machine applet seemed to support students in moving toward a correct definition of function, and promoted greater awareness of the importance of the output in relation to the definition of function. However, since 55.2% of the students' post-definitions were limited to a specific representation (i.e., graph, equation) the applet did not seem cause a dilemma for students to move away from their algebraic view of functions in their definitions. An examination of students' screencasts (see Martin, Soled, Lovett, & Dick., under review) showed that students did not experience the dilemmas we had designed for as they worked through the pages of the applet. The first two pages of the applet, that told students which machine was a function and not a function, seemed to cause students to only used what they learned from these machines when determining if the other ten machines were a function or non-function.

Even though the Vending Machine applet (version 2.0) seemed to help students move towards a correct definition of function, for many students the experience did not provoke a dilemma regarding function as an object (e.g., equation, graph). It is possible that the ways in which the students interacted with the applet might have prevented the dilemma from occurring. Thus, we felt the applet could be improved, and as such the applet has been revised. Version 3.0 now consists of four pages in a slightly different format and includes two new machines. The first three pages each contain two vending machines (similar to version 2.0) except the directions say "Which one is a function?" Our intent is that this version will allow students to deepen their understanding of function by applying their knowledge of the function concept to the vending machines instead of using their experiences with the first four machines in version 2.0 to determine whether the other machines are functions or non-functions.

## Conclusion

The results of this study suggest that the Vending Machine applet has the potential to be a powerful tool (cognitive root) for disrupting students' limited view of function and supporting their transformation of meaning schemes related to the concept of function. However, to determine whether or not these findings are generalizable, the use of the newest version of the applet (3.0) needs to be studied on a larger scale. Our plan is that through further study and revision, we will produce a transformative cognitive root that disorients students' algebraic view of function, remedies existing misconceptions, and on which conceptual understanding of function concept can be built.

# The Effect of Self-Efficacy on Student Performance in Calculus

Asli Mutlu
North Carolina State University
Heather Ba
University of North Carolina at Chapel Hill
Karen Allen Keene
North Carolina State University

*Self-efficacy is an important variable that has been used to study students' performance at all educational levels and in many content areas. In the report, we discuss the results of a quantitative study considering self-efficacy in college Calculus and its correlation to other variables available in a large scale study. Ultimately, our findings contradict existing findings regarding the effect of self-efficacy on class performance. We add to these results an interesting finding regarding the effect of self-efficacy on student's study habits: while time spent on course homework does not mediate the effect of self-efficacy, more time spent on course preparation by students with high self-efficacy tends to decrease their expected final course grade. Results contribute to math instructors' understanding of their teaching and may help with the construction of more effective instruction.*

*Key words:* Calculus, Self- Efficacy, Class Performance, Homework Hours Spent, Classroom Research.

## Introduction

Self-efficacy describes a person's perception of her own potential to master a specific task, and has been shown to have a powerful effect on achievement (Bandura, 1986; Bandura, 1997). Self-efficacy affects behavior by influencing one's choices and actions (Pajares, 1996). Bandura (1997) proposes four sources of self-efficacy: personal experience (referring to prior outcomes), vicarious experience (what one observes), social persuasions (feedback received from peers and others), and psychological state (ones mood), but personal experience and previous performance levels influence self-efficacy above all else (Chen & Zimmerman, 2007). In this research report, Bandura's theory of self-efficacy grounds and supports the work.

Within the context of mathematics, self-efficacy has been shown to be a better predictor of performance than measures of math anxiety or prior experience with math (Pajares & Miller, 1994; Pajares & Miller, 1995), and appears to be tantamount in importance to even intellectual ability (Pajares & Kranzler, 1995). High self-efficacy correlates positively with greater aspirations, greater commitments, and a greater ability to recover from setbacks; high math self-efficacy correlates with greater persistence on long and difficult problems, and greater accuracy of computation (Collins, 1982; Hoffman & Schraw, 2009). Hackett (1985) found a positive relationship between self-efficacy and ACT scores, which agrees with numerous studies showing a powerful link between high self-efficacy and high performance (Fast et al., 2010; Pajares & Miller, 1994; Pajares & Miller, 1995; Pajares & Kranzler, 1995); Peters, 2013). Meece, Wigfield, & Eccles (1990) found that high math self-efficacy corresponds to students valuing math more highly, and expecting to succeed. The study also found that students' performance expectations predict math anxiety, but that math anxiety only indirectly relates to subsequent performance. Performance expectations do, however, predict actual performance. Students who rate math performance as relatively important tend to have lower math anxiety than students who rate math performance as unimportant (Meece, Wigfield, & Eccles, 1990).

A positive relationship has been demonstrated between math self-efficacy and gender (men tend to have higher math self-efficacy) (Hackett, 1985). However, while Hackett (1985) found a positive relationship between gender and math achievement, other studies have found no such relationship (despite confirming that men tend to have higher math self-efficacy than women) (Meece, Wigfield, & Eccles, 1990; Peters, 2013). However, self-efficacy mediates the influence of gender on math performance (Pajares & Miller, 1994). Math self-efficacy has even been shown to mediate the effects of prior math experience on performance, itself the foremost source of self-efficacy (Pajares & Miller, 1994).

Our analysis utilizes the Mathematical Association of America's (MAA's) study of *Characteristics of Successful Programs in College Calculus* (NSF, DRL 0910240) data to revisit these issues by addressing the following two questions:

**Research Question 1**: Is the effect of student math ability on expected final grade moderated or mediated by student's self-efficacy, such that confidence in ability can overcome lower actual ability?

**Research Question 2**: Does a student's self-efficacy effect the amount of work he or she does to prepare for class, and does self-efficacy moderate the effect of class preparation on a student's expected final grade?

## Methods and Data

As mentioned before, we utilized the *Characteristics of Successful Programs in College Calculus* (CSPCC) data set and conducted factor analysis to construct a measure of self-efficacy by combining students' answers to several questions into a single variable. We then created mixed effects ordered logistic regression models with random intercepts using this measure and other data from the survey. The CSPCC data was collected and made available for reserachers by MAA based upon work supported by the National Science Foundation under grant DRL REESE #0910240 between 2009 and 2015.

The survey data concerns students' experience and performance in Calculus I. The entire survey consists of two parts, a pre-survey administered at the beginning of Calculus I, and a post-survey administered at the end of the Calculus I course. From this data set, we used the expected course grade from the post-survey as the dependent variable. From the pre-survey we use SAT and ACT math scores along with three separate questions that assess self-efficacy as independent variables. One additional independent variable was taken from the post survey: the amount of time spent on homework. As control variables, we used age, gender, mother's education, and father's education from the pre-survey.

The survey data included responses from 13,965 high school students who completed at least one of the surveys. Of these students, 10,506 are eliminated, because they only completed one of the surveys, and the questions we are using to complete the analysis come from both surveys. After using this list wise deletion criteria on just the dependent variable, the final sample of college student respondents is 3,459 from 14 universities. Of those 3,459, 10 did not report a final grade, reducing the sample to 3,449 (in the full sample 6,144 students did not report a final grade). Additionally, the two measures of student math ability, SAT and ACT math score, are also missing across some observations. We converted ACT math scores to SAT scores using the conversion method recommended by The College Board, so as to maximize the sample size of our model. After converting the ACT score, and eliminating observations where respondents did not report either score, the final sample is 2,973. The other independent variables were also missing in some responses. When included in a model together, the final overlapping sample size(*n)* is 2787. However, the exact *n* of each of our models changed depending on the variables included. Table 1 presents the summary statistics and missing observation counts across all of the variables used in our models.

Table 1: Summary and Missing Data Statistics

| | Mean | SD | Min | Max | Missing |
|---|---|---|---|---|---|
| Gender | .4531755 | .497892 | 0 | 1 | 24 |

### Linear Regression Results for Research Question 1

As mentioned above, previous research found self-efficacy to be a better predictor of mathematics achievement (Pajares & Kranzler, 1995). We reexamined this question and asked whether self-efficacy moderates or mediates the effect of ability on student performance in their Calculus I course. To assess the potential moderating effect, we first constructed a measure of self-efficacy. We used principal component factor analysis to construct a variable that combines three survey questions that evaluate a student's self-efficacy. Factor analysis is a statistical technique for data reduction. It reduces the data by generating linear combinations of "factors" that reconstruct a group of related variables (Hamilton 2013, Ch.11). More specifically, principal component analysis (PCA) conducts an eigen decomposition of the correlation matrix between the selected variables. The eigenvectors represent uncorrelated linear combinations of the variables that capture most of the variance across the variables. In other words, principal component analysis can reduce many variables down to a single variable that captures the most amount of covariance between the variables. We use the first factor loadings to construct a measure of self-efficacy.

The three survey questions that generated the data we use in the PCA are as follows and responses to these questions can range from 0 (strongly disagree) - 5 (strongly agree):

**Question 29 Know**: I believe I have the knowledge and abilities to succeed in this course.
**Question 29 Understand**: I understand the mathematics that I have studied.
**Question 29 Confident**: I am confident in my mathematics abilities.

A histogram of the constructed measure is presented in Figure 1

Figure 1: Histogram of Constructed Self Efficacy Variable

With this measure constructed, we interact self-efficacy with SAT math score and students' grade in the last high school math class they completed. Table 2 presents the results of the mixed effects ordered logistic regression models with random intercepts for respondent's university department. The interaction terms are not statistically significant, implying that there is not a strong consistent moderating effect of self-efficacy on course ability.

To analyze whether self-efficacy mediated the effect of their actual ability on their grade in Calculus I, such that actual ability causes self-efficacy, which in turn determines a student's grade, we start by examining whether all variables are statistically significant predictors of expected final grade when included on their own. The results of models (1), (2) and (4) shown in Table 3 show that the coefficients on all variables are positive and statistically significant. Secondly, we tested whether the coefficients on SAT math score or high school math grade lose significance when self-efficacy is included in the model, which would indicate a mediating effect of self-efficacy The results, presented in Table 3 are not consistent with the presence of a mediating effect. Both SAT math score and high school math grade remain statistically significant and positively signed when efficacy is included in the model (models (3) and (5) in Table 3).

## Linear Regression Results for Research Question 2

The work ethic of a student is an important determinant of her performance. However, the willingness of a student to invest her time and energy in preparing for the course (as a proxy for this, we used the Homework variable) is certainly impacted by self-efficacy. We included this important Homework variable in our analysis of student performance, and evaluated whether self-efficacy moderates the effect of homework hours invested on student performance, or whether homework hours mediates the effect of self-efficacy. Self-efficacy may determine the amount of time and energy a student decides to invest in her course. To assess the presence of a mediating effect of homework hours on self-efficacy, we first examined whether self-efficacy is correlated with the amount of homework hours students expend. We then evaluated whether homework hours and self perception of ability are statistically significant predictors of expected final grade when included on their own. Finally, we tested whether the effect of efficacy loses significance when homework hours is included in the same model. The results of these models, presented in Table 4, are not consistent with the proposition that homework hours mediate the effect of self-efficacy on student's achievement in Calculus I. In fact, the results imply the opposite direction of causality, but given that self-efficacy is evaluated prior to students completing the course, the causal relationship implied by the model is not plausible.

To evaluate the moderating effect of self-efficacy on homework hours, we create an interaction term between the two variables and again include it in a mixed effects multinomial ordered logit models with random intercepts for university. The results of the model are presented in Table 5.

The interaction term is negative and statistically significant. Examining the marginal effect of homework hours at different levels of self-efficacy produces some surprising results. When we examined the marginal effect of a five hour increase in homework hours at various levels of self-efficacy on a student's expected grade, in Figure 2, we observe that a one hour increase in the amount of time a student with low self-efficacy spends on his or her homework decreases the probability that she receives a D or an F. However, every additional hour of study time increases the probability that she earns a B by much more than it increases the probability that she earns an A. The effect of increased homework hours has a similar effect for students with average self-efficacy, in that the larger amount of study time increases slightly the probability that the student earns an A, and decreases the probability that the student earns a D or an F.

Interestingly, for students with high self-efficacy, every hour of study time decreases the probability that the student earns an A by about .008, but increases the probability that the student earns a B (by .005) or a C (by .003). Increased homework hours has no statistically significant effect on the probability that a student with high self-efficacy receives a C or lower. Implied in this relationship is that self-efficacy has the largest positive impact on grade when a student studies the least. Figure 1 presents the change in the predicted probability of receiving each grade for a one unit increase in self-efficacy at different amounts of homework hours. This figure demonstrates that high self-efficacy increases the probability that a student receives an A in the course, having completed on average zero hours of homework per week, by .162, increases the probability that the student receives a B by .148, and decreases the probability of an F by .004. However, the effect of self efficacy on the likelihood that a student earns an A decreases to .072 when the students spends 18 hours per week on homework. Therefore, high self-efficacy proves more impactful on a student's grade when he or she does not spend a substantial of time studying. For those students with high self-efficacy, putting in more prep time is an indication that they are more like to earn a B than A in the course.

(a) Marginal Effect of Homework Hours on Grade

(b) Marginal Effect of Self-Efficacy on Grade

Figure 2: Marginal Effects from Moderation Analysis for Research Question 2

**Conclusion**

In this study we were unable to confirm findings of past studies that suggest that self-efficacy is more important than actual ability. Mathematics ability and experience correlate with self-efficacy, but self-efficacy does not overtake the effect of experience and ability. Additionally, we inquired as to whether student's self perception mediates or moderates the impact of their study habits on their course grade. Ultimately, when considered in aggregate, the regression analyses presented in this paper seem to suggests the following conclusions. Students have a fairly accurate perception of their math ability. Those who are are not confident in their ability because their ability is not very strong put in more effort preparing for class, and benefit from increased time spend studying and completing homework. However, this increased effort most greatly increases the odds that they earn a B in the class. Those with very high ability, and who are confident in that ability, do not expect to earn a higher grade as a result of increased time spent on course preparation, but do expect to earn high grades. In fact, students with high math ability and high self-efficacy are most likely to expect to earn an A. For those students with average confidence, applying themselves and putting more time in on homework and class prep tends to increase the likelihood that they earn an above average grade. Finally, self-efficacy has the largest effect on a student's grade when the student did not spend a substantial amount of time preparing for class.

For mathematics instructors, the take home lessons from this study are simple and commonsensical. First, confidence is not a replacement for hardwork, experience, and preparation in mathematics achievement. Apart from especially gifted mathematics students, homework and study time boost exam performance for most students. Over time, sucessful experiences in mathematics courses compound and create a virtuous cycle whereby students become more confident and this confidence, in conjunction with a strong work ethic, in turn contributes to further good performance.

**Abstract**

*A new blended learning environment encompassing a wide variety of formative assessment was developed for a large undergraduate mathematics course to promote deep learning approach. In order to enhance reflection, the final exam was replaced by students' self-assessment. At the end of the course, a cluster analysis found four student clusters differing in their deep and surface learning approaches. Analysis of open feedback questions suggests that the contextual factor most commonly associated with deep learning approach was innovative assessment. Our findings lead us towards understanding how to foster deep learning approach in different kinds of learners.*

**Keywords**
Learning Approaches, Deep Learning, Blended Learning Environments, Self-Assessment

## Introduction

Student learning in higher education can be described by means of students' approaches to learning. These approaches are often divided to deep and surface learning approaches (Biggs, 2012). The adoption of these approaches is known to be connected with student characteristics but also with teaching methods and assessment (Baeten et al., 2010). In order to support deep approach to learning in a large mathematics course, we created a blended learning environment designed to offer a wide variety of feedback to the students and to promote reflection throughout the course. Based on our earlier findings on self-assessment in higher education (Tuohilampi, Rämö, Häsä, & Pekkarinen, 2017), we left out the course exam and replaced it with formative self-assessment. Moreover, the assessment methods were not separate components, but instead they were woven into the students' everyday activities in the course. This was achieved by innovative use of digital course components.

## Background of the Study

In our study, we seek to understand learning environments as diverse and complex structures that have the potential to alter students' learning strategies through reflection. Below, we briefly introduce the theory of learning approaches and the previous attempts to promote deep learning within different learning environments. We connect this background with the theory of blended learning environments, since in our learning environment the adoption of deep learning approach is promoted using both physical and digital elements.

**Approaches to Learning.** Approaches to learning consist of the combination of motivation and learning strategies of the student – very often these approaches are divided into deep and surface approaches (Biggs, 1987; Biggs, 2012; Entwistle 1991). A deep approach refers to a true intention to understand the content to be learned (Diseth 2003). It is linked with the idea of intrinsic motivation, "interest in ideas", and is allied to deeper pedagogical approaches that foster personal understanding (Entwistle 2000; Diseth 2003). Surface learning approach, on the other hand, is linked with using the least amount of effort to reach the minimal required outcomes (Biggs 1987; Garrison & Cleveland-Innes 2005). It can be said that the focus for surface approach learners is the completion of the task, not the growth with learning.

Deep learning approach has been valued more in the context of higher education (Garrison & Cleveland-Innes 2005). Sadler-Smith (1997) found a significant positive correlation between performance and deep learning in the context of higher education. Diseth (2003) observed the same connection; furthermore, he found that surface approach correlated negatively with performance in his study. However, deep and surface learning approaches are not to be seen as fundamental traits of students, as students have been observed to change their learning strategies with situational demands (Marton & Säljö 1976).

**Creating Learning Environments that Support Deep Learning Approach.** A large number of studies have investigated attempts to cultivate the deep learning approach within student-centred learning environments in higher education. However, the results of those studies are not consistent (Baeten et al. 2010). In their meta-analysis, Baeten and colleagues determined the factors needed to encourage deep learning approach; these were 1) contextual factors (teaching, assessment), 2) perceived contextual factors (how students perceive teaching and assessment) and 3) student factors (such as age and gender). The most successful strategies were determined within each of these factors. Those were found to be 1) innovative assessment and student-centred teaching, 2) satisfaction with the overall quality of the course and 3) intrinsic motivation. All these factors (contextual, perceptual and personal) need to be considered when designing a deep learning focused learning environment.

Innovative assessment methods prove to have a significant role in enhancing the adoption of deep learning approach within a learning environment. In their meta-analysis, Sluijsmans and colleagues found that self- and peer-assessment discouraged passive learning that was connected with surface approach (Sluijsmans et al., 1998); however, the use of these assessment methods was observed to require a lot of training. Increasing the variety of assessment in an active learning environment can increase the students' feeling of responsibility for their own learning and therefore enhance deep learning approach (Wilson & Fowler 2005). However, innovative assessment methods can also lead to adoption of more surface approaches when the terms of assessment do not require deep learning approaches (Gijbels & Dochy, 2006; Struyven et al., 2006). Learning environments can especially foster the adoption of deep learning approach if they encourage students to reflect on their own learning (Sobral, 2001; Waters & Johnston, 2004).

The research on the processes of deep learning within learning environments has focused on finding patterns inside the whole sample, which has been considered to be a weakness (Wilson & Fowler 2005; Baeten et al. 2010). In this study, we try to identify those subgroups of the student sample that are not able to benefit of the various feedback forms that we offer to foster reflection through our blended learning environment.

**Blended Learning Environments.** At its simplest, blended learning refers to providing digital learning materials in a physical classroom environment (Garrison & Kanuka 2004, 96–97; Singh 2003, 52–53). In this study we use a more complicated model to capture the diversity of support mechanisms of the reflection-centred learning environment. According to Manninen and colleagues (2007), blended learning environments can be seen to be composed of five dimensions that are separate yet overlapping: 1) physical environment (the space and buildings around learning situation), 2) social environment (the social interaction of learning situation), 3) digital environment (learning technology, ICT), 4) local environment (learning in the "real world", learning where the skills are needed), 5) didactic environment (learning as a centre for the learning environment). The learning environment that we developed reflects all the introduces elements (Figure 1).

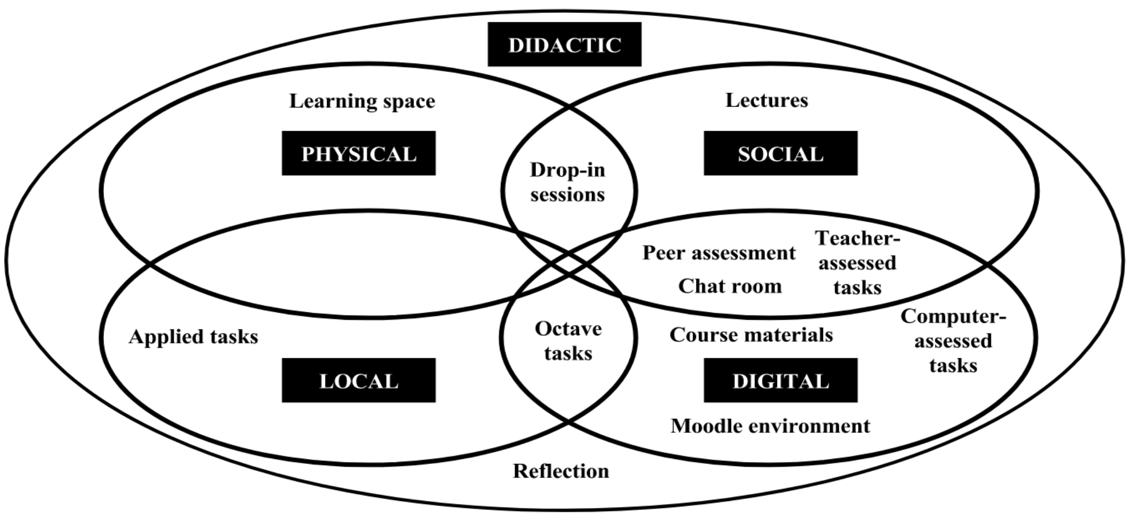
In our study, we seek to examine the connections between our learning environment and adoption of deep learning approach. However, unlike many course settings described in the literature (Baeten et al., 2010), ours is based exclusively on reflection. In our course, the whole culture of assessment is flipped, as we replace the traditional course exam with a variety of formative, digital assessment methods, such as self-assessment, that require a high amount of reflection. This led us to call our setting a "reflective-centred, blended learning environment". In the next section, we provide more details about the course setting.

**The Pilot Course with a Blended Reflective-centred Learning Environment**

The blended, reflective-centred learning environment investigated in this study was created for the course Linear algebra and matrices I. The course was taught in the Open University of the University of Helsinki during six weeks in May–June 2017. The course had 164 students, most of whom were degree students from the University of Helsinki, majoring in mathematics or a related discipline. Teaching in the learning environment was based on the Extreme Apprenticeship Model (Vihavainen, Paksula, & Luukkainen, 2011; Rämö, Oinonen and Vihavainen, 2016). It is a teaching model in which students take part in activities resembling those of experts. A central feature in the model is formative assessment.

All the digital features of the course were implemented in the digital learning platform Moodle. All course materials, such as lecture notes and problem sets were offered electronically, and all submissions were also handled electronically. Figure 1 shows the components of the learning environment divided into the five different dimensions indicated by Manninen and colleagues (2007).

Figure 1
*The reflection-centred learning environment divided into dimensions (Manninen et al. 2007).*



Each week, students were given a set of problems to solve. Some of the problems were digital tasks created with a system for automatic assessment called Stack (Sangwin 2013). For these tasks, instant automatic feedback was offered. Others were manual tasks completed with pen and paper and then scanned for submission. For a subset of the manual coursework, the students received written comments from the teachers or peers. The problems included real life applications of the topics discussed. Some tasks involved the use of a typical mathematics software Octave. For solving the problems, students were offered guidance in drop-in sessions that took place in a specially designed learning space. The students could also ask for help anonymously in an online chat room.

There was no final exam. Instead, grades were determined by formal self-assessment.

Students based their self-assessment on a learning objectives matrix which contained the objectives of the course, concerning both mathematical content and transferable skills. The latter included skills such as reading mathematical text and giving and receiving feedback. The students assessed their mastering of each topic and awarded themselves a grade for the course, with written reflection justifying their choice. The self-assessment was compared automatically to the coursework completed by the student, and if the two agreed, the grade given by the student to her/himself was confirmed. In case of discrepancies, the student was asked to justify their opinion or suggest themselves another grade.

## Goals of the Study

The aim of this study is to analyse the blended reflection-centred learning environment described above from two perspectives: 1) What were the levels of deep and surface learning experienced by the students, and what kind of subgroups of students were there in terms of their learning approaches? 2) Which contextual factors (Baeten et al. 2010) did the students connect with deep and surface learning approaches? These questions need to be asked in order to develop the reflective-centred learning environment in the direction that would foster deep learning approach. We need to find the student groups that require help in developing their learning strategies, and separately, we need to know which components of the course are best suited to promoting deep approach.

## Data Collection and Analysis

Learning approaches were tested with a ETLQ-questionnaire validated in Finland (Parpala, Lindblom-Ylänne, Komulainen, & Entwistle, 2013). The deep approach and surface approach subscales both consisted of four items ($\alpha = .62$ and $\alpha = .75$, respectively). The statistical measurements were conducted with IBM SPSS Version 24.

The qualitative data concerning the second goal of the study was collected after the pilot course with the same questionnaire as the learning approaches. The descriptive, one-shot questionnaire was designed with the guidelines of Lodico and colleagues (2010, p. 159–171). The questions were used both in research and in the development of the course, and the questions concerned, for example, the experiences about self-assessment ("*How did you experience the fact that there was no exam in this course?*") and support ("*How have you been able to benefit from the feedback during the course?*"). The questions about supportive elements in the reflective-centred learning environment were based on the interview questions by Mumm and colleagues (2015). The data was collected in Moodle.

The qualitative analysis was based on content analysis by Miles and Huberman (1994). The pool of all the open answers of the course feedback was used as a source for data. First, the content analysis was started as conventional (Hsieh & Shannon, 2005). We searched the data for all the expressions of deep and surface approach; this step was influenced by the previous knowledge about the theory of those approaches. Since the length of the answers varied, the analysis unit was chosen to be a coherent idea present in the text (Schreier, 2012, p. 131–134). There were 74 units where the students described their learning approach as deep or surface; these units were then reduced, deep and surface approaches separately. This way we looked for the contextual factors of the learning environment that influenced the learning approaches. The reduced expressions were grouped into categories, which were then grouped again as category classes and subclasses. Finally, the found category classes were connected with the theory of the elements of a blended learning environment (Manninen et al., 2007).

## Findings

**Levels of deep and surface approach.** Overall, deep learning approach (M = 3.89, SD = .66) was reported to be higher than surface learning approach (M = 2.07, SD = .70) after the course. A cluster analysis was conducted to determine whether there were any subgroups of students in terms of learning approaches. Deep and surface approach factors were considered to be the cluster variables, since that choice is aligned with the research question and the chosen variables encode the maximum amount of information about the students' learning approaches (Theodoridis & Koutroumbas 2006). Since there was no preconceived idea about the correct number of clusters, a hierarchical cluster merging was used for exploratory design (Antonenko et al. 2012). Ward's algorithm (Ward 1963) was chosen for clustering algorithm to decrease the differences among the clusters. The scores of the variables were standardized to Z-points before the analysis.

The data was first analyzed in the form of a dendrogram. Observing large gaps between the cluster sets (Olson & Biolsi 1991) identified three or four separate clusters. The number of clusters was ensured by performing a discriminant function analysis on the data (Romensburg 1984). The solution with three clusters predicted cluster membership by 92 %, whereas the solution with four clusters predicted that by 95,5 %. Since the four-cluster solution divided the students who reported a lot of surface approach into their own yet small group, it was selected as the most appropriate one for this study. The differences of the means of the main variables between the clusters are shown in Table 1.

Table 1
*Deep and surface approach, task points and course grades of the four clusters.*

| | | Surface approach | Deep approach | Tasks with | | | Grade |
|---|---|---|---|---|---|---|---|
| | | | | automatic feedback (max. 64) | no feedback (max. 40) | teacher feedback (max. 9) | (scale 1–5) |
| **Total** | M | 2.07 | 3.89 | 52.71 | 31.94 | 7.93 | 4.10 |
| n = 113 | SD | .70 | .66 | 10.45 | 8.76 | 1.70 | 1.45 |
| **Cluster 1** | M | 1.90 | 3.14 | 51.16 | 30.10 | 7.57 | 3.75 |
| n = 30 | SD | .41 | .51 | 10.68 | 8.19 | 1.96 | 1.74 |
| **Cluster 2** | M | 1.45 | 4.38 | 56.17 | 35.86 | 8.25 | 4.58 |
| n = 36 | SD | .28 | .41 | 7.65 | 7.34 | 1.76 | 1.20 |
| **Cluster 3** | M | 2.40 | 4.06 | 51.76 | 30.92 | 7.94 | 3.97 |
| n = 36 | SD | .28 | .41 | 10.75 | 8.56 | 1.57 | 1.45 |
| **Cluster 4** | M | 3.60 | 3.73 | 48.30 | 27.00 | 7.80 | 3.63 |
| n = 10 | SD | .39 | .48 | 14.92 | 11.45 | 1.03 | .92 |

The four clusters were compared using ANOVA. The assumption regarding the homogeneity of variance was met for all the other variables (Levene test, $p$ = .06– .73). The clusters 1 (n = 30), 2 (n = 36) and 3 (n = 36) are considered to be normally distributed by their variables. Cluster 4 (n = 10) was tested; all the variables were normally distributed (Kolmogorov–Smirnov test, $p$ = .61–.20). ANOVA was then used to identify differences between the clusters regarding the variables shown in Table 1.

Unsurprisingly, significant differences were found regarding surface approach (df = 3, F = 128.9, $p < 0.001$) and deep approach (df = 3, F = 45.19, $p < 0.001$). Apart from these differences the only significant difference between the groups was found regarding the points from non-assessed tasks (df = 3, F = 312.27, $p < 0.05$). Small yet insignificant differences were found between points from automatically assessed tasks (df = 3, F = 243.68, $p$ = .081) and course grades (df = 3, F = 4.73, $p$ = .078).

Finally, Bonferroni Correction Post Hoc Test was conducted to find out the exact clusters that had the most significant differences between them. All the clusters differed significantly in terms of surface and deep approach ($p < 0.05$) except clusters 3 and 4 that only differed in terms of surface learning. The students in clusters 1 and 4 were shown to have completed significantly less non-assessed exercises than the students in cluster 2 ($p < 0.05$). No other differences were found.

**Contextual factors connected with learning approaches.** The contextual factors connected with deep and surface learning approaches were investigated with a qualitative content analysis of the open answers of the students. The categories of contextual factors that promoted deep learning approach are shown in Table 2. The number of expressions found in each category is reported in brackets.

It was found that innovative assessment was the main contextual factor to enhance deep learning in the reflection-centred learning environment. Students also reported that student-centred course materials supported deep learning since they provided information about the exact learning goals and the relations between them. Interestingly, all the expressions found were connected with the digital learning environment, as seen in Table 2.

Table 2
*The contextual factors (Baeten et al., 2010) reported to promote deep learning approach.*

</table>

Students linked deep learning strategies directly with the learning environment in their open answers, but that was not the case with surface learning approach. Instead, surface approach was, for example, connected with traditional exams; students described that in other courses they might attempt to memorise the lecture notes a couple of days before the exam. Also, some students linked the non-assessed tasks with surface learning by mentioning that they completed them with lesser effort than the rest of the tasks, the reason being that the non-assessed tasks were unmotivating since no feedback was provided.

## Discussion

In our study, we found that the reflective-centred, blended learning environment, based on various formative assessment methods such as self-assessment, was a promising course experiment in terms of promoting deep learning approach. Quantitative and qualitative analyses were conducted to explore the levels of learning approaches within the student population and to find the course components that were connected with the processes of deep and surface learning.

Four student clusters differed from each other in terms of deep and surface learning approaches. Two of those student groups might be considered to be "at risk" as they reported either a high level of surface or a low level of deep approach. According to Wilson and Fowler (2005), there is a need to foster "deep shift" within the students that are typically surface-oriented learners. Our cluster analysis found only 10 students reporting high levels of surface approach, which might mean that our learning environment was able to foster deep learning even among those students that would typically be surface-oriented.

A qualitative content analysis showed that the students formed fewer connections between surface learning strategies and the course components than between deep learning and course components. This, together with the fact that the size of the cluster of students reporting high surface approach was small, indicates that in the future there might be a bigger pressure to promote deep learning approach than to prevent surface learning approaches in this kind of course context. These arguments should, however, be tested in a similar setting with pre-tests and deeper qualitative data.

The course grades did not differ significantly between the different clusters. We argue that this is because of the carefully built support system that allowed the students with less productive learning approaches to complete a large number of tasks, which then enabled them to assign themselves high grades. However, it was found that the students in "at risk" clusters completed less non-assessed tasks than their peers. Non-assessed tasks were also one of the only contextual factors that were linked with surface approach in the course feedback data. It might be that the lack of feedback for these tasks discouraged the students with less deep learning strategies from trying them, as these students were not prepared to reflect on their progress when there was no formal external assessment and no deep learning was therefore required. A similar effect has been observed in previous research, namely that there is a connection between tasks that do not require deep learning and the emergence of surface approach (Gijbels & Dochy, 2006; Struyven et al., 2006). In the future, there is a need to explore which elements of our non-assessed tasks promote surface approach.

In students' open answers, the reflection-centred learning environment was largely connected with expressions related to deep approach especially in terms of innovative assessment methods, which is in line with previous research (Baeten et al. 2010). Interestingly, all course components that students connected with deep learning approach were part of a digital learning environment (Manninen et al. 2007). Based on this finding and the large amount of deep learning approach reported by the students, we suggest that blended learning environments are viable surroundings for promoting deep approach. This finding has value especially in the context of large-enrolment courses, where digital tools can be used to alleviate the demand for resources needed to foster student-centred teaching.

There is a need to develop the digital self-assessment component of the course since it was connected with deep learning in our data. Studying the "at risk" clusters might help us in understanding how to engage different kinds of learners to reflect on their learning, and furthermore, to take responsibility of their own learning processes.

**Limitations of the Study.** The open questionnaire answers did not allow us to analyse further nor validate the four clusters of students in terms of learning approaches. Also, we focused on the contextual factors of the learning environment; a substantial analysis of the perceived contextual factors would shed more light on the roles of the different course components in supporting deep learning. In order to address these issues, broader qualitative data will be collected in the next implementation of the course, especially in the form of student interviews.

## Pedagogical Considerations in the Selection of Examples for Definitions in Real Analysis

Brian P Katz — Augustana College
Timothy Fukawa-Connelly — Temple University
Keith Weber & Juan Pablo Mejia-Ramos — Rutgers University

*This study investigates mathematicians' pedagogical practices and associated beliefs about the use of examples to instantiate definitions in a real analysis textbook. We used task-based interviews, asking participants to revise the introductory presentation of a concept, including definitions and examples, to be of higher pedagogical quality. All mathematicians believed that examples and counter-examples are important in learning about a concept. In this report, we concentrate on how mathematicians take the collection of examples and student thinking into account when deciding on which examples to use and the types of criteria they use to determine an appropriate collection of examples for a definition.*

*Keywords:* Real Analysis, Examples, Instruction

Leinhardt, Zazlavsky, and Stein wrote that "A primary feature of explanations is the use of well-constructed examples, examples that make the point but limit the generalization, examples that are balanced by non- or counter-cases" (1990, p. 6). Similarly, researchers have asserted that "exemplification is a critical feature in all kinds of teaching, with all kinds of mathematical knowledge as an aim" (Bills & Watson, 2008, p. 77). This study explores the use of examples as a part of pedagogical practice in proof-based courses, and, in particular, real analysis. In these courses, one important way of presenting mathematical subject matter is via examples. In particular, a recent study of 11 proof-based undergraduate mathematics lectures (each between 60 and 75 minutes) included, among the findings, that 65 examples were presented across the lectures, with every professor discussing at least one example, and the median professor discussed 5 examples during a single lecture. That is, the presentation of examples appears to be a common part of the pedagogical practice of mathematicians while giving instruction about proof-based mathematics.

### The Pedagogical Importance of Examples

Authors have claimed that examples are important in developing conceptual understanding (Mason & Watson, 2008; Vinner, 1991) and knowledge and use of examples is a mark of expertise in mathematics (Michener, 1978). Examples have been claimed to help students develop understanding of mathematical definitions (Antonini, 2006; Leinhardt, Zazlavsky, & Stein, 1990), and, examples can help students interpret, create, and prove mathematical theorems (c.f., Cuoco, Goldenberg and Mark, 1996; Lakatos, 1976). As part of the theorem generalization process, examples have been described as essential for generalization and abstraction (Antonini, et al, 2011). The perceived pedagogical power of examples (Antonini, et al, 2011; Bills & Watson, 2008; Mason & Watson, 2008) has led to, among others, the exploration of graduate students' use of examples to determine the truth of conjectures (Alcock & Inglis, 2008) and of the principles K-12 teachers use in selecting examples to use with their students (Rowland, 2008; Zodik & Zaslavsky 2008). For example, teachers use examples to motivate basic intuitions or claims about new material (Michener, 1978). Similarly, there is evidence that asking students to generate boundary examples can help clarify the need for criteria in a definition or hypotheses in a proof (Mason & Watson, 2001). Interviews with mathematicians suggest that they also attribute some of these pedagogical values to examples (cf. Alcock, 2010; Michener, 1978;

Weber & Mejia-Ramos, 2011; Weber, 2012). More, they report using examples as part of their presentation of proofs (Alcock, 2010; Weber, 2012), and to instantiate claims or definitions (Alcock, 2010). Observational studies provide evidence that these claims are representative of their pedagogical practice (c.f., Fukawa-Connelly & Newton, 2014; Mills, 2014).

Mills (2014) observed four mathematicians teaching advanced mathematics courses and found that they used examples to motivate the statement of a theorem, instantiate a concept, or illustrate results. She did not describe or classify which examples the instructors used or their associated rationale for these choices. Fukawa-Connelly and Newton (2014) provided some insight in this regard by investigating one professor's use of examples of the concept of group in an abstract algebra class, drawing on the notion of the enacted example-space. They found that relatively few examples were made part of the content of the class, but that each of them was used repeatedly. Finally, Cook and Fukawa-Connelly (2015) surveyed and interviewed algebraists about the examples of groups and rings that the believed to be most important for students to know at the end of an introductory group theory course. They found that algebraists typically named classes of groups (e.g., the cyclic groups) rather than concrete examples and that there was relatively little consensus about the set of examples that students should know. The rationales that the mathematicians provided for their choices focused on the familiarity and ease of instruction about examples (using words like *simple* and *nice*), the historical foundations of the subject, the ability to demonstrate different ideas and concepts (including helping students avoid inappropriate generalizations), those that allow helpful visual representations, and experience the prevalence and variety of groups and rings. Finally, we note that Peled and Zazlavsky (1997) differentiated between different types of counter-examples frequently used by mathematics teachers. The described specific (e.g., the integers) that can show a statement is not true, and general (e.g., where one length in a figure might be a variable) that can help explain why a statement is not true.

The current study build on the literature in two important ways. First, we note that only two of these studies identify specific examples that mathematicians use in their teaching, and only one study directly reports on the corresponding rationale for the mathematician's choice of examples. Yet, that study explored examples at the most general level; asking about the entire collection of groups and rings that students should know *at the end of a course*, rather than exploring the examples used to explain what a group or ring is to a student. While Fukawa-Connelly and Newton (2014) examined the examples used to instruct students on the concept of a group, they did not interview the professor and so were unable to provide any of the instructor's rationale for his pedagogical decisions. We found evidence that mathematicians attend to several different categories of information when considering the examples in their text: individual examples and their properties, the connection of examples and its properties, what should be explicit in the text and how/where is should appear, and aspects of student (or reader) thinking and their relation to the examples and concepts. In this paper we advance two claims:

1. Mathematicians attend to properties of the collection of examples: the size, diversity, and ordering of this collection as well as whether it has duplicates.
2. Mathematicians attend to the aspects of student/reader thinking while working with the text: interaction with prior knowledge, intuition/informality and expected lack of intuition, and teaching general cognitive skills.

## Methodology

### Rationale

In this study, mathematicians were given four (researcher-created) introductions to concepts from real analysis textbooks, each of which included a definition statement (or more than one) and may have included examples and discussion of the concept. The mathematicians were instructed to revise these introductions to improve their pedagogical quality. We assert that the mathematicians' pedagogical thinking and values can be observed through the additions to and deletions from the text, their evaluations of the elements present in the text, and the rationales they give for their revisions.

This approach can show strong evidence that the mathematicians do care about an aspect of an introduction, but their silence on an aspect is not evidence that it is unimportant to them. Because of this asymmetry, we designed the introductions to be diverse with respect to all aspects that we identified in our literature review (including the types of revisions that Lai, Weber, and Mejia-Ramos (2012) identified), pilot interviews, and personal teaching experience, including the presence and number of examples, formality and abstraction, motivation, precision, and presence of normative notation.

We used participants' revisions, evaluations, and rationales for the revisions to form hypotheses about what they believed a good pedagogical introduction to a concept should include, with a focus on what the appropriate exemplification of a definition would be. We note that the exemplification appropriate for a text may not be appropriate for a lecture and we do not intend our work to make any claims about exemplification in lecture.

## Method

**Participants.** The first author invited mathematicians to participate in the study. He solicited the participation of 10 mathematicians, and we do not have any a prior reason to believe these participants more interested in or capable at mathematics teaching than other mathematicians. The research expertise of the participants included analysis, applied math, functional analysis, analytic number theory, and geometric topology and their teaching experience ranged from two years as a graduate teaching assistant to over twenty years as a teaching-focused institution. All of them had taught or were preparing to teach real analysis. We assigned all mathematicians a single-initial designator (that is not either of their initials) and refer to them with gender-neutral pronouns in order to protect their anonymity.

**Materials and Procedures.** Each participant met individually with the first author for a task-based interview. Participants were presented with four revision tasks sequentially. For each, they were given a 1-page, complete textbook introduction to a concept that we believed to be mathematically correct, told that the target audience for the text was a student in a junior-level real analysis course, and asked to revise it to improve its pedagogical quality. After they finished revising each introduction, they were asked to describe each change and their rationale for it, about broad categories of changes if they did not make them (including changing the collection of examples), about the aspects of the introduction they left unchanged, whether anything in the introduction was atypical, about their goals, and whether any of their comments would have been different in some medium other than a textbook.

Participants were told to "think aloud" as they were making their revisions. Because this task asked participants to improve the pedagogical presentation of the definition and because we explained that it would be for a textbook for a specific undergraduate course, we assumed the participants would treat these as pedagogical presentations. At times, we did need to clarify that the presented materials constituted the whole of the presentation of the definition and that the next items would be propositions and proofs. Each interview was audio-recorded and subsequently transcribed, and participants were asked to make any needed written changes (although they often specified multiple changes aloud while writing relatively few in comparison); any written productions were subsequently scanned.

**Analysis.** To analyze the types of revisions performed, we used an open coding scheme in the style of Strauss and Corbin (1990). While we were sensitive to the prior literature, because none of it related to textbook authorship and none focused on real analysis, we believed that an open-coding scheme would be more appropriate. For each revision (including purely evaluative statements) that a participant made on the revision tasks, we made a general description of the edit and what aspect of the presentation it was describing and used these aspects as category names. We then went through the transcript and noted the reason given for the edit (if any). For the purposes of this study, we then collected all revisions related to examples, and ignored those about other aspects of the introduction. We again engaged in another round of open coding, developing categories of codes that described any revisions and related codes for the rationales that participants provided. As appropriate, we coded new instances using categories that we had already developed or created new categories as needed. As we coded, we continually refined our coding manual, including revising names and definitions of categories, and, noting which sets of categories were orthogonal and which were overlapping, such that a particular instance should not carry codes from both categories. Once the categories were formed, we recoded all the data and resolved any remaining issues through discussion.

## Data and Results

All of the mathematicians indicated that they believe that examples should be part of the pedagogical presentation of a definition. For example, on Definition 4, we presented the definition without any examples and all of them mathematicians indicated that their revision would include examples. Some suggested that 5 was the appropriate number of examples to include with the pedagogical presentation of a definition. Their descriptions of their goals for examples suggested that they were thoughtful about which examples would be included, the collection and sequencing of the examples, the relationship between the examples and the text, and, the range of examples presented. We chose to highlight 2 primary findings from these interviews that illustrate the types of thinking that mathematicians exhibited with respect to examples, first quantitatively then with specific quotes.

The interviews produced 184 distinct comments about examples to be coded, with a total of 626 codes assigned. Of these 116 codes were given for comments about individual examples, 62 about the collection of examples, 74 about the text and its explicit elements, and 45 about student thinking. These data support the claim that the mathematicians attend to all four of these aspects of the examples in a textbook introduction to a concept.

We have asserted more specifically that mathematicians attend to properties of the collection of examples: the size, diversity, and ordering of this collection as well as whether it has duplicates. The code Collection and its subcodes were present in the comments for all four definition tasks (7,17,12,26) for a total of 62 coded items. Similarly, Collection and its subcodes were present in the comments from all ten participant interviews (7,6,5,6,8,7,5,4,5,9). We have also asserted that mathematicians attend to the aspects of student/reader thinking while working with the text: interaction with prior knowledge, intuition/informality and expected lack of intuition, and teaching general cognitive skills. Thinking and its subcodes were present in all four definition tasks (14,9,9,13) for a total of 45 coded items. Similarly, Thinking and its subcodes were present in the comments from all ten participant interviews (3,5,4,4,2,2,3,9,9,4).

**Collection of Examples**

All of the mathematicians attended to both individual examples and the collection of examples. The most common subcode of Collection was Diversity, which captures the participants' comments that the collection has or should have individual examples with different properties. For example, they valued having both examples and non-examples, "extremes of behavior", simple and complex examples, and various representations.

In this subsection, we illustrate how the professors claimed that examples should help students make sense of what the concept is. Dana, in discussing Definition 1, was very explicit in describing the types of thinking that examples needed to support:

> I'm trying to head off any confusion about exactly what the definition is of the increasing function. I'm trying to expose students to kind of broaden their universe in their head of what mathematical functions are. They're not just the functions that you differentiate in your calculus class. They can include functions that are not smooth and aren't defined everywhere. … to familiarize them with different types of examples.

We interpreted Dana as claiming that examples serve a number of roles in helping students come to understand a concept. First, that students might be confused about a concept and that examples can mitigate that. Second, that examples can force students to consider unfamiliar instances of known concepts, to "broaden their universe," when considering special classes of the previously known concept. In doing so, there are particular types of variation that professors might attend to, for functions that might be "not smooth" or "not defined everywhere." While not every professor was as explicit as Dana, they all indicated the importance of examples in helping students broaden their collection of examples to include more 'exotic' (which they often described as unfamiliar or complex) cases of common concepts.

We further illustrate how professors attended to how examples (including counter-examples) might support students in interpreting concepts. The first important way that professors believed examples can support student understanding of the definition of a concept is by helping to interpret the concept and distinguish it from other, similar, concepts (all of the professors made comments indicating that this was a consideration). For example, many of the professors made explicit statements about the value of counter-examples. For example, Kai claimed, "having counter-examples is just as important as having examples, knowing what something is and what isn't." Similarly, Cody claimed, "I often say to my students, "For every new definition we learn, we want to think of "an example but we also want to think of a counter-example." Cody then provided a specific instance, related to Definition 1, for which a counter-example would be helpful, "Yeah. Also find a function which is not increasing or strictly increasing." We interpreted Cody's statement as claiming that a function that is not increasing or strictly increasing would help students to understand how Definition 1, strictly increasing, is distinct from increasing or not-increasing, that is, the counter example could help illuminate the meaning of the inequalities in the statement of Definition 1. Brett explained why counter-examples are helpful, "If you just have a positive example of something, that doesn't help you really compare. Unless you have both a positive and a negative example it's hard to use that." We interpreted Brett as claiming that comparing examples with different features, especially one that has all of the needed features of a concept with one that does not, is one way that a learner might come to understand a concept, and, without a counter-example among the collection of examples, students would be unable to make such comparisons.

Similarly, the professors claimed that examples allow students to distinguish a concept from other, similar concepts, such as between a lower bound and a greatest lower bound. The idea of using examples to help students distinguishing between similar concepts was mentioned by all the professors at least once and at least once during the discussion of each definition. We illustrate this with two representative quotes of professor's the claims about using examples to differentiate concepts. For example, in discussing Definition 2 (lower bound and greatest lower bound) Kai claimed:

> I would add one more example, or I would modify an example. There is an example of the infimum, there are examples of lower bounds or examples of not lower bounds but in example 1, I would add that it is a lower bound but it is not the greatest lower bound because that thing gives counter-example to what an infimum is. It's a lower bound but not the greatest lower bound because –pi/2 is a greater lower bound; so I would add that.

In this case, the professor is asking to add or modify an example so that one of the examples will be a lower bound but not a greatest lower bound. Brett asked for a similar revision, "You can probably say it's something like -pi is a lower bound but not an infimum, or you can say that …" Both of these professors were using examples to illustrate the difference between two, similar, concepts.

Second, the professors were very explicit that they attended to whether individual examples had properties that were not required by the definition, and, when all of the examples in the collection had the same extra properties. That is, the professors attended to whether examples had unnecessary properties. In discussing the definition of a convergent sequence, Morgan noted, "Note that the limit doesn't have to be attained though it can be and I will probably give an example of that." This comment specifically notes a property that the definition of convergent does not require, that the limit be attained, and that the professor thinks that a good pedagogical presentation would include examples with both cases. Similarly, Harper noted that, "I don't particularly see it in the numerical example that they give, but the pictorial example includes it, meaning that the sequence doesn't have to be on one side of the limit. I believe the numerical examples that I see right now, all of them stay on one side of the limit, but the diagram does not, so that is fine." Our interpretation of Harper's comment is that the definition of a sequence does not require that the sequence "stay on one side of the limit," meaning that this is a property that is not required. Second, Harper attended to whether each of the examples had this property, evaluating each of the numerical examples and the diagram, and noting that in the collection, at least one example does not have the unneeded property. Similarly, Dana gave a positive evaluation of an example illustrating a property of infima, "I like that example, the fifth one, because it shows that the infimum may be a member of the set or it might not. Either one is possible. I like this example, the set's an interval." Here, we interpreted Dana's evaluation as first stating the unnecessary property, whether the infimum is a member of the set, and then giving a positive evaluation of the fact that the collection of examples includes at least one example that does not have that property. In the presentation, we will further support these claims and illustrate additional ways that the professors believed that examples could support student understanding of a concept.

### Student Thinking

All of the mathematicians attended to student thinking in relation to the examples. The majority of the codes in this category were for Thinking rather than a subcode, indicating either that there were diverse aspects of thinking under consideration that did not come together into subcodes or that the participants most often talked about student thinking in the context of the particular concept rather than general principles about thinking. The most common subcodes captured participants' comments that examples would or should be familiar or unfamiliar to students, that working with examples in the context of a particular example taught a general skill, and that students would or would not have intuition about the examples. While the participants valued building intuition for the concepts, they also valued non-obvious examples about which students would not have intuitive conjectures or about which their intuition would be wrong because these both generate pedagogical situations that are useful for teaching students to work carefully with definitions and proofs.

For real analysis, the most common source of salient prior knowledge was calculus. Jesse observes that "analysis is trying to formalize calculus. An increasing function is something that they've seen in calculus a lot. They've never really talked too much about lower bounds and greatest lower bounds in calculus." Moving beyond description of familiarity for students, Morgan suggests revising a scatterplot to the graph of a familiar function:

> I guess I'm thinking of taking a standard graph of 1/x and thinking of what the infimum of the values of the function are. Which is sort of related to what this example was going to do but it seems to me that it's again this is a graph that they have seen before however I think that it is ... Would have presented it in a context or something that they had not thought before. Actually, they have thought about asymptotes so maybe it would be a way to relate this new concept with something that they have seen before."

Conversely, Kai suggests that "Examples that they have not seen before or wouldn't necessarily come up with on their own, I think, would be really good for them to see."

The goal, according to Harper is "to make students understand the definition as deep as they possibly can, hence the types of examples that I provide. That's the nature of how I studied things back when I was a student. It's like looking for things in the definition which are weird, which are non-intuitive yet are included in this definition." And for Kai, "learning how to be very intentional in applying the language and notation of the definition, I think, is a good skill." Examples "help students see the pathology of things that can happen" (Jesse).

## Discussion

This study has made two main contributions. First, it provides a fine-grained analysis of the factors that instructors consider when selecting examples to instantiate a particular definition as part of a textbook. The instructors all claimed that examples (and non-examples) are important in helping students understand a definition, and claimed that their goals in example selection are aimed at exactly this; helping students understand the particular definition. Their descriptions of their goals for examples suggested that they were thoughtful about which examples would be included, the collection and sequencing of the examples, the relationship between the examples and the text, and, the range of examples presented. In doing so, it provided further evidence that mathematicians are thoughtful about their instruction. More, one of the criteria that we described show that mathematicians take student thinking into consideration in their choices of examples; attempting to avoid common errors, 'head off' inappropriate overgeneralizations such as by ensuring that the collection of examples does not all share a particular unneeded property, and support the construction of a rich example space. Due to limited space, we have only been able to discuss two of our categories of codes and those two without much detail. We will develop these and other themes in more detail and show more data in a presentation in at the conference.

Figurative Thought and a Student's Reasoning About "Amounts" of Change

Biyao Liang
University of Georgia

Kevin C. Moore
University of Georgia

*This paper discusses a student coordinating changes in covarying quantities. We adapt Piaget's constructs of figurative and operative thought to describe her partitioning activity in terms of the extent that it is constrained to carrying out particular sensorimotor actions on perceptually available material, and we relate such descriptions to her thinking about quantitative amounts of change. We conclude the paper by discussing how characterizing these nuances of student thinking in terms of figurative and operative thought contributes to current literature on covariational reasoning and conceptualization of concept construction.*

*Keywords:* Cognition, Piaget, Covariational Reasoning, Amount of Change

Researchers have shown that students' *quantitative* and *covariational reasoning*—the mental actions involved in conceiving measurable attributes changing in tandem (Carlson, Jacobs, Coe, & Hsu, 2002; Thompson, 2011)—are critical for their learning of function and rate of change (Ellis, 2011; Johnson, 2015; Thompson & Carlson, 2017). Stemming from the complexities of students' thinking, these researchers have called for investigations that identify nuances in students' covariational reasoning. We answer these researchers' calls by drawing on Carlson et al. (2002) and Saldanha and Thompson's (1998) notions of covariation to characterize a student's reasoning about amounts of change in various contexts. We extend extant literature using Piaget's (2001) notions of *figurative* and *operative* thought to explain the extent a student's reasoning was constrained to sensorimotor actions and perceptual results from those actions.

**Quantitative Reasoning, Covariational Reasoning, and Partitioning Activity**

Thompson (2011) described that the mental construction of a *quantity* involves "conceptualizing an object and an attribute of it so that the attribute has a unit of measure" (p. 37). Despite Thompson's use of "measure," he emphasized that reasoning about a specified quantity's value is unnecessary when reasoning quantitatively; sophisticated conceptions of quantity entail reasoning about a quantity's magnitude (i.e., amount-ness) while anticipating that it has an infinite number of measure-unit pairs (Thompson, Carlson, Byerley, & Hatfield, 2014). Such distinction between a quantity's magnitude and its measures enables us to account for reasoning about covarying quantities that is not constrained to the availability of values; focusing on a quantity's magnitude affords characterizing mental activity in terms of perceptual material associated with a quantity's amount-ness (e.g., a segment that represents a quantity of distance).

An individual imagining variations in a quantity's magnitude (and hence value) is positioned to reason covariationally. When reasoning covariationlly, "a person holds in mind a sustained image of two quantities' values (or magnitudes) simultaneously…one tracks either quantity's value with the immediate, explicit, and persistent realization that, at every moment, the other quantity also has a value" (Saldanha & Thompson, 1998, p. 299). Building on Saldanha and Thompson's (1998) covariation, Carlson et al. (2002) specified mental actions involved in coordinating quantities, among which students' coordination of amounts of change of one quantity with respect to changes in another (Mental Action 3 in their framework) is central to our work here. An individual coordinating amounts of change imagines quantities' magnitudes accumulating in successive states (and possibly anticipates continuous covariation between these states; see Thompson and Carlson (2017)). To illustrate, a student reasoning about covarying quantities B and K can envision the magnitude ||B|| accumulating in equal accruals, construct the accumulation of ||K|| in terms of corresponding accruals, and coordinate those accruals in ||K|| to conceive ||K|| increasing by decreasing amounts with respect to ||B|| (see Figure 1a-c for an illustration with respect to the Taking a Ride task in Figure 3a). Because coordinating amounts of change involves the activity of constructing a magnitude's accumulation in terms of accruals, we use *partitioning activity* to refer to students' mental and sensorimotor actions associated with their producing and reasoning about these increments that may represent amounts of change.

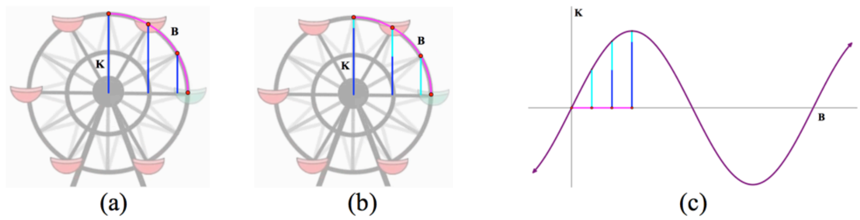

*Figure 1. As quantity B increases by equal amounts (denoted in pink), quantity K increases (denoted in dark blue, (a)) by decreasing amounts (denoted in light blue, (b)), which can be represented in a Cartesian system (c).*

## Figurative and Operative Thought

*Table 1. Figurative and Operative Partitioning Activity*

| Partitioning Activity | Foregrounded Actions of Partitioning Activity |
|---|---|
| *Figurative Partitioning Activity* | Repeating sensorimotor actions of partitioning tied to particular perceptual material and results; Potentially constrained to *available* perceptual material; Conceived invariance is with respect to sensorimotor actions and their perceptual results |
| *Operative Partitioning Activity* | Sensorimotor actions subordinate to mental actions (e.g., quantitative and covariational reasoning); Can anticipate partitioning activity on available or hypothetical perceptual material; Conceived invariance is with respect to coordinated mental actions and their transformations |

We have found the theoretical distinction between *figurative* and *operative* thought (Piaget, 1976, 2001; Steffe, 1991; Thompson, 1985) useful in developing models of students' partitioning activity. Piaget (1976, 2001) characterized figurative thought as based in and constrained to sensorimotor actions and perception, and he described operative thought as the coordination of mental operations so that these coordinations dominate figurative material (i.e. sensorimotor actions and perceptual material). We emphasize that characterizing a student's thinking as operative does not imply her thinking does not entail fragments of figurative material. Likewise, characterizing a student's thinking as figurative does not imply that her thinking does not entail operative schemes. A researcher's sensitivity to these distinctions is an issue of "figure to ground" (Thompson, 1985, p. 195). When a student's thinking foregrounds carrying out repeatable (mental or sensorimotor) actions and the results of those actions, it is figurative; when a student's thinking foregrounds the coordination of actions and transformations of those actions and their results, it is operative. The issue of foregrounding is important for describing students' partitioning activity because such activity necessarily entails figurative material (e.g., drawing and producing graphs and partitions) and likely entails operative schemes (e.g., understanding a coordinate systems in terms of directed distances). In characterizing students' partitioning activity in terms of figurative or operative thought, we thus make the distinctions in Table 1.

To illustrate these distinctions, consider a student determining if the graphs in Figure 2a and Figure 2b represent the linear relationship $y = 3x$. With respect to Figure 2a, a student who engages in figurative partitioning activity could imagine the graph in terms of the successive movements of one axes mark to the right (denoted in blue) and then three axes marks up (denoted in red), and associate such movements with a positive slope (Paoletti, Stevens, & Moore, 2017). With respect to Figure 2b, the student could conceive movements to the right (denoted in blue) along the graph as corresponding to movements down the graph (denoted in red), and associate such movements with a negative slope. In each case, the student's thought is dominated by carrying out or repeating particular sensorimotor actions to the extent that associations (e.g., a line falling left-to-right necessarily has a negative slope) are tied to that activity and its results. Hence, the student concludes that the two graphs are different.

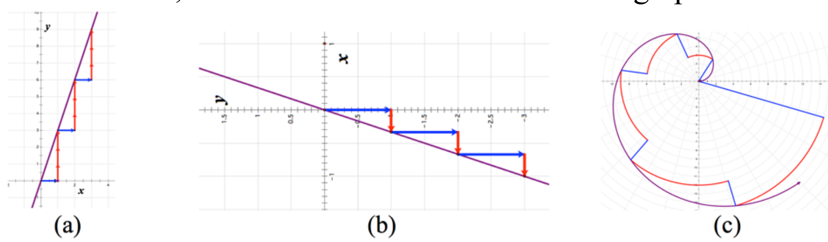

*Figure 2. (a) A graph that represents the relationship of y=3x in a Cartesian coordinate system, (b) a rotated graph of (a), and (c) a graph that represents the relationship of r=3θ in a polar coordinate system.*

In comparison, a student who engages in operative partitioning activity could conceive that both graphs are such that any directed change in $x$ corresponds to a directed change in $y$ three times as large as that in $x$. The student's partitioning activity is operative because she can coordinate and transform activity specific to each graph to conceive an underlying invariance that dominates figurative differences in activity. The student might anticipate re-presenting invariant partitioning activity in other contexts or coordinate systems (e.g., polar coordinates, Figure 2c). The anticipation of re-presenting partitioning activity aligns with Moore and Silverman's (2015) *abstracted quantitative structure*: a structure of related quantities a student has internalized as if it is independent of specific figurative material (i.e., representation free).

## Methods

This paper reports results of a semester-long teaching experiment (Steffe & Thompson, 2000) with prospective secondary mathematics teachers (PSTs; Lydia, Emma, and Brian). They were in their first semester of a four-semester secondary mathematics education program at a large university in the southeast United States. We conducted 10-11 teaching sessions (1 to 2 hours each) with each PST. The project principal investigator (the second author) served as the teacher-researcher (TR) at every teaching session. At least one other research team member was present as the observer(s). Each session was videotaped and digitized for analysis. In both ongoing and retrospective analyses efforts, we conducted conceptual analysis (Thompson, 2008) to develop models of PSTs' mathematics. Specifically, our iterative analyses efforts involved constructing hypothetical mental actions that viably explained the PSTs' observable and audible behaviors. We continually searched the data for instances that the models could not account for, and we modified our models or we attempted to explain developmental shifts in a PST's meanings. In this paper, we focus on the case of Lydia because of particular aspects of her partitioning activity that were consistent throughout the teaching experiment. We consider it important to characterize her ways of thinking in order to add nuances to our prior conceptualizations of students' quantitative and covariational reasoning.

## Task Design

We describe Lydia's activity on three related tasks: (1) Taking a Ride, (2) Which One, and (3) Circle. Taking a Ride included an animation of a Ferris wheel (Desmos, 2016) (see Figure 3a) and focused the students on constructing the covariational relationship between the *height* of the green rider above the horizontal diameter of the wheel and its *arc length* traveled (the sine relationship; Moore (2014)). Which One (Figure 3b) was presented after students' first encounter of Taking a Ride. It included a simplified version of a Ferris wheel (left) with the position of a rider indicated by a dynamic point. The topmost line segment (shown in blue, right) represented the arc length the rider had traveled counterclockwise from the three o'clock position. Students could vary the segment length by dragging its endpoint with the dynamic point on the circle moving correspondingly. We asked the student to determine which of the six red segments, if any, could accurately represent the rider's height above the horizontal diameter as the rider's arc length varied. Segment 1 is a normative solution and segments 2-6 vary with either different directions or rates. In students' initial attempt on these two tasks, we did not prompt them to graph because we wanted to gain insights into their reasoning with displayed magnitudes in contexts that minimized the influence of their previously constructed graphing meanings. For Circle (Figure 3c), we asked students to graph the relationship between the *horizontal distance* and the *arc length* associated with a dynamic point (i.e., the cosine relationship). Collectively, we designed the series of tasks to provide different figurative material to tease apart the extent that a student's reasoning was dominated by figurative or operative thought.

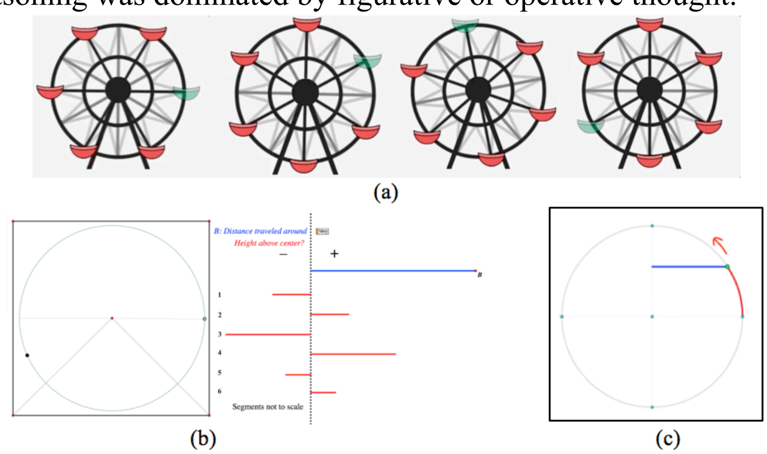

*Figure 3. (a) Snapshots of Taking a Ride, (b) Which One (with segment numbers labeled), and (c) Circle.*

## Results

In this section, we illustrate Lydia's partitioning activity with a focus on the figurative material constituting her partitioning activity as she considered a variety of representations.

### Re-presenting Partitioning Activity

In the first teaching session, we worked with Lydia on Taking a Ride (Figure 3a). With much effort, Lydia constructed what we perceive to be successive amounts of change of height for successive, equal changes in arc length (see her construction in Figure 4a-c). Noticing that the blue segments (in Figure 4c) decreased in magnitude, Lydia concluded that, "[A]s the arc length is increasing... [the] vertical distance from the center is increasing ... but the value that we're increasing by is decreasing." Suggesting she was excited that she had identified this relationship, she explained with enthusiasm, "I just discovered this by myself." This revealed that her activity of drawing partitions and identifying amounts of change was novel to her at the time.

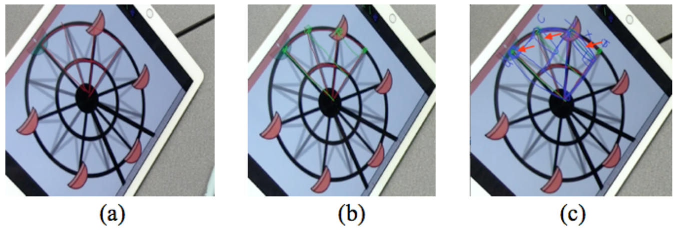

*Figure 4. Lydia (a) partitioned the distance traveled in equal increments, (b) identified height of the green rider in each successive state, and (c) identified amounts of change of height.*

Immediately following this task, we presented the Which One task (Figure 3b). After some explorations, Lydia claimed that she would like to choose a red segment that is moving at a constant rate. She eliminated four of the six segments and had hard time deciding which of the other two segments was moving constantly (Figure 5a). She then decided to orient one of them (a normatively correct solution) vertically, and put it inside the circle (Figure 5b). She then confirmed that the length of that segment matched the height of the dynamic point for different states (Figure 5c). When asked if the segment entailed the amounts of change relationship constructed in the initial Taking a Ride task, she responded:

*Lydia*: Not really…Um, I don't know. [*laughs*] Because that was just like something that I had seen for the first time, so I don't know if that will like show in every other case…Well, for a theory to hold true, it like – it needs to be true in other occasions, um, unless defined to one occasion.

*TR*: So is what we're looking at right now different than what we were looking at with the Ferris wheel?

*Lydia*: No. It's – No…Because I saw what I saw, and I saw that difference in the Ferris wheel, but I don't see it here, and so –

*TR*: And by you don't see it here, you mean you don't see it in that red segment?

*Lydia*: Yes.

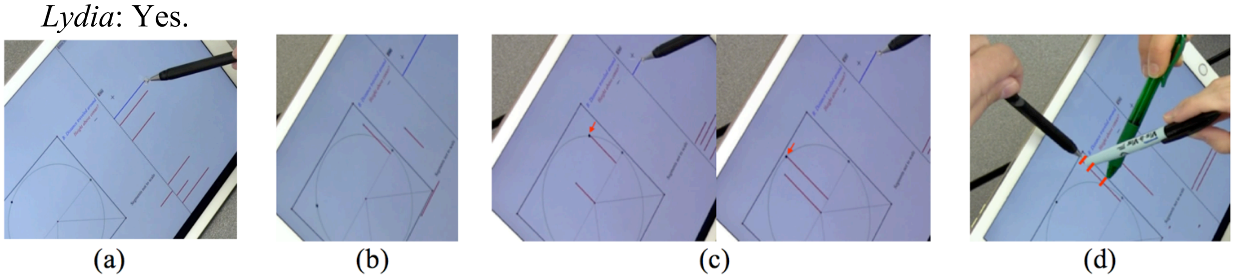

*Figure 5. (a) Lydia was working on the Which One task, (b) checking the red segment point-wisely, and (c) we were assisting Lydia to identify amounts of change in height.*

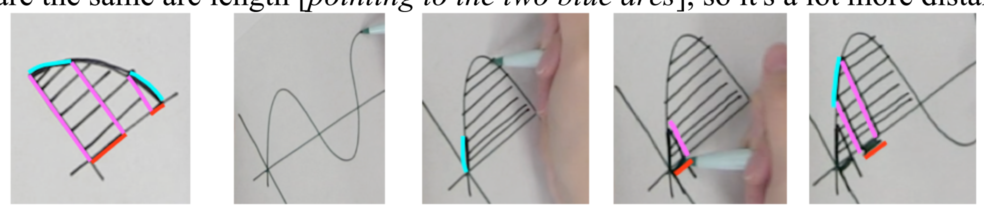
Lydia described height increasing by decreasing amounts as a "theory" that needed to be tested in this new situation. Her knowing that the red segment worked for each state did not imply by necessity that the red and blue segments existed in a covariational relationship consistent with that between height and arc in Taking a Ride. Following this exchange, and after the researchers created perceptually available material by using pens to denote amounts of change of the red segment (Figure 5d), Lydia responded in surprise that her "theory" held true.

We characterize Lydia's partitioning activity as figurative due to her difficulty re-presenting such activity from one context to another. She identified successive height accruals on the Ferris wheel (Figure 4c), but her understandings of amounts of change were rooted in carrying out activity and creating perceptually available increments in that context. When moved to a context with magnitudes changing continuously, she did not anticipate or re-present her partitioning activity. That is, as she considered successive red segment states in Which One, she was unable to hold in mind the red segment associated with a prior state to compare it to a current state.

**Situations, Graphs, and Figurative Material**

The TR began the fourth session by asking Lydia what she recalled from the previous sessions, in which she worked on Taking a Ride (Figure 3a) and Circle tasks (Figure 3c). She started with drawing the first quarter of a circle (see Figure 6a for work):

> **"**So we kind of said as the arc length is increasing in the first quadrant that our X distance is decreasing [*drawing the horizontal segments within the circle from bottom to top in Figure 6a*], and then…distance will decrease more in the same amount of space. So like from here to here [*highlighting the bottom blue arc*], then we'll say these are the same arc length [*highlighting the top blue arc*]…so we're going to take this point here [*marking a point at the top of the far-right pink segment*] and then drag it down [*drawing the far-right pink segment*], we've only lost this much [*highlighting the shorter red segment*]. And then from here [*drawing the middle pink segment*] to here [*tracing the far-left pink segment*] we lost this distance [*highlighting the longer red segment*], but we're saying those are the same arc length [*pointing to the two blue arcs*], so it's a lot more distance."



(a) (b) (c) (d) (e)

*Figure 6. (a) Lydia's drawing of the circle situation, (b) Lydia's graph, and (c)-(e) her construction process.*

Lydia's partitioning activity appeared compatible with that from previous sessions, and thus the TR asked Lydia how such activity related to graphing the relevant relationship. Lydia drew a graph (Figure 6b) and explained how the graph related to her partitioning activity in Figure 6a:

> "As we go up in arc length [*highlighting the blue curve in Figure 6c*]…that distance is decreasing [*drawing the horizontal segments from bottom to top in Figure 6c*], and so we see that here [*drawing the pink segment in Figure 6d*] is like this [*highlighting the red segment in Figure 6d*], and then [*highlighting the blue curve and drawing the pink segments in Figure 6e*] ... here is this [*drawing the red segment in Figure 6e*]. So that's the same conclusion we had gotten from the circle, so then we can say that this circle relates to this graph."

Lydia's partitioning activity across the situation and graph included: (a) drawing horizontal segments emanating from the circle and curve (see Figure 4a and 4c), (b) tracing arcs from lower end points to higher end points on the circle (denoted in blue, see Figure 6a) and tracing a curve on graph in the same manner (denoted in blue, see Figure 6c and 6e), (c) drawing vertical segments from the end points produced by the arcs and curve to a horizontal segment or line (denoted in pink, see Figure 6a, 6d and 6e), and (d) drawing horizontal segments between two pink segments and comparing their lengths (denoted in red, see Figure 6a, 6d, and 6e). We characterize Lydia's partitioning activity as figurative due to it foregrounding repeated sensorimotor actions that produce similar perceptual results (e.g., partitioning along something curved, drawing vertical segments, and drawing and comparing horizontal segments).

Providing additional evidence that Lydia's partitioning activity was figurative, later in the teaching session, Lydia drew a similar graph (Figure 7a) in order to discuss the relationship between "height" and "arc length". Her activity included tracing from left to right two equal horizontal segments (denoted in red, Figure 7a), drawing vertical segments from end points of the vertical segments to the curve of her graph (denoted in pink, Figure 7a), and tracing two corresponding curves on her graph (denoted in blue, Figure 7a). She compared the lengths of these curves and concluded that the increases in height became smaller. Similarly, on a circle, she traced two horizontal segments (denoted in red, Figure 7b), drew vertical segments (denoted in pink, Figure 7b), and traced and compared two arcs on the circle (denoted with blue, Figure 7b). Again, Lydia's figurative partitioning activity involved her carrying out same sequence of sensorimotor actions on her graph and circle, the elements of which entailed similar perceptual results (e.g., the sequence of drawing horizontal and vertical segments, and curves).

(a) (b)

*Figure 7. (a) Lydia's new with drawn partitions, and (b) Lydia's circle with drawn partitions.*

**Discussion**

Characterizing a student's thinking of amounts of change in terms of figurative or operative partitioning activity is significant in that it allows us to describe nuances in Carlson et al. (2002)'s covariation framework and, more generally, mental actions involved in quantitative reasoning (Thompson, 2011). A student's amounts of change understandings can differ in the extent that her partitioning activity is restricted to particular sensorimotor actions and the perceptual results of these actions. In this paper, we illustrated that a particular student's partitioning activity was figurative because it involved her seeking to repeat sensorimotor actions in a particular order across various situations. Furthermore, her partitioning activity was constrained to having perceptually available material. Consequently, when confronted with a novel situation in which these figurative elements were absent or carrying out the sensorimotor actions failed (e.g., Which One), she had difficulty re-presenting partitioning activity.

von Glaserseld (1982) defined *concept* as "any structure that has been abstracted from the process of experiential construction as recurrently usable…must be stable enough to be re-presented in the absence of perceptual "input" (p. 194). Characterizing partitioning activity as we have enables us to extend and apply this definition in the context of students' reasoning about relationships between covarying quantities. When a student abstracts her partitioning activity so that it is not tied to particular figurative material, thus mentally anticipating transformations of such (e.g., changing orientations or representations), she has constructed a *concept* related to this relationship (e.g., the concept of sine or rate of change). As Lydia's activity indicates, it is important for researchers to consider students' activities among a variety of contexts before making claims about their covariational reasoning and meanings. Moving forward, we call for continued explorations into how students reflect upon their partitioning activity and abstract quantitative relationships and structures (e.g., rate of change).

Mathematical Knowledge for Teaching Examples in Precalculus: A Collective Case Study

Erica R. Miller
University of Nebraska-Lincoln

*The purpose of this collective case study is to examine mathematical knowledge for teaching examples in precalculus. The instructors involved in the study were experienced graduate teaching assistants who were teaching their course for the third time and were identified as good teachers. Utilizing a social constructivist and cognitive theory approach, I analyzed video recordings of enacted examples. The central question that guided this analysis was: What is the mathematical knowledge for teaching examples in precalculus? The goal of this study is to examine undergraduate mathematical knowledge for teaching from the perspective of practice, instead of relying on existing frameworks. As a result of this study, the author developed a model of mathematical knowledge for teaching examples in precalculus that includes knowledge of representations, students, instruction, specialized content, and connections when enacting high cognitive demand examples.*

*Keywords:* Mathematical knowledge for teaching, undergraduate, precalculus, cognitive demand, examples

## Introduction

Mathematical knowledge for teaching (MKT) has been defined as the "mathematical knowledge needed to perform the recurrent tasks of teaching mathematics to students" (Ball, Thames, & Phelps, 2008, p. 395). While MKT has been studied extensively at the elementary level (Ball et al., 2008; Carpenter & Fennema, 1991; Heather Hill, Sleep, Lewis, & Ball, 2007; Ma, 2010) and at the secondary level (Krauss, Baumert, & Blum, 2008; McCrory, Floden, Ferrini-Mundy, Reckase, & Senk, 2012; Rowland, Huckstep, & Thwaites, 2005), research on MKT at the undergraduate level is still a growing field (Speer, Smith, & Horvath, 2010). The goal of this study is to contribute to that field by building upon the link between MKT and cognitive demand (Charalambous, 2010) in order to study mathematical knowledge for teaching examples in precalculus from the perspective of practice.

### Problem

Often, it is assumed that earning a degree in mathematics is what initially qualifies ones to teach at the undergraduate level. Historically, undergraduate instructors learned to teach by following the role model of mentors. However, Bass (1997) points out that there is much that cannot be learned through observations alone. To address lack of teaching preparation, many doctoral programs today offer teaching professional development (PD) for graduate teaching assistants, who will make up the future workforce of undergraduate instructors (Bressoud, Mesa, & Rasmussen, 2015; Ellis, 2014). While offering some teaching PD is better than none, the content of what is being taught is an important aspect to consider.

Of course, pedagogical knowledge is a component of teaching and should be included in GTA PD. However, studies have shown that despite their formal mathematical education, GTAs still lack mathematical knowledge that is needed for effective teaching (Kung & Speer, 2009; Speer & Hald, 2008). In these studies, the authors rely on existing frameworks for MKT that where developed at the K-12 level. While it is reasonable to assume that K-12 and undergraduate MKT are similar, Speer points out that there are important differences between K-12 and undergraduate teachers that need to be attended to (Speer, King, & Howell, 2014). Therefore, the goal of this study is to examine MKT at the undergraduate level from the perspective of practice, instead of relying on existing frameworks.

## Significance

As previously stated, there is little research on MKT at the undergraduate level. But why is it important to study MKT to start with? First, studies have found that *pure content knowledge* is not a predictor of teaching quality and student achievement (Begle, 1972; Greenwald, Hedges, & Laine, 1996; Hanushek, 1981, 1996). However, studies at the K-12 level have shown that *MKT* is a predictor of teaching quality and student achievement (Hill et al., 2008; Hill et al., 2007; Krauss et al., 2008). This knowledge is not usually taught in content courses, hence why many GTAs seem to be lacking MKT. While no measures of MKT at the undergraduate level exist, it is reasonable to assume that this positive relationship still exists at the undergraduate level. Therefore, if we can identify what MKT at the undergraduate level looks like and integrate it into GTA PD programs, we can have a positive impact on undergraduate education.

The other question that is reasonable to ask is why focus on precalculus? As the number of students needing to take introductory math courses for their degree increases, the teaching burden of math departments increases (Ellis, 2014). Approximately 1,000,000 college students take introductory level math courses each year (Gordon, 2008). Of these, approximately 85-90% are non-STEM intending (Rasmussen, Ellis, Lindmeier, & Heinze, 2013) and success rates are typically around 50% (Gordon, 2008). Even for STEM-intending students, studies have found that difficulty passing introductory-level courses is contributing to the "leaking pipeline" of students leaving STEM (Thompson et al., 2007). Therefore the instructional quality of precalculus has a large impact on undergraduate students.

## Background

While research on MKT at the undergraduate level is sparse, there does exist a large body of research on K-12 MKT. While my goal is to examine MKT at the undergraduate level from the perspective of practice instead of using existing frameworks of MKT that were developed at the K-12 level, the two are bound to be closely related. In an effort to situate my study within the existing field of research on MKT and avoid the assumption that I am attempting to study MKT at the undergraduate level in an epistemological vacuum, I will first present a broad overview of existing research on MKT. Also, I chose to study MKT by building upon its relationship with the cognitive demand of tasks. This decision was motivated by Charalambous' (2010) exploratory study, which found that MKT and the cognitive demand of enacted tasks are positively related.

**Mathematical knowledge for teaching.** Following the studies that showed that subject matter knowledge was not a predictor of teaching quality and student outcomes, Lee Shulman (1986; 1987) proposed that researchers begin studying pedagogical content knowledge. Shulman defined pedagogical content as going "beyond knowledge of subject matter per se to the dimension of subject matter knowledge for teaching" (1986, p. 9). Shulman situated pedagogical content knowledge in contrast to subject matter knowledge, which is "the knowledge, understanding, skill, and disposition" of a subject matter (1987, p. 8). Since then, math education researchers have begun looking into professional knowledge for teaching mathematics. Hill, Rowan, and Ball (2005) found that elementary teacher's MKT was a significant predictor of student gains. Similarly, Baumert et al. (2010) showed that secondary teachers' MKT was a predictor of student outcomes. In both of these examples, the mathematical knowledge that is specific to the work of teaching is not *usually* taught in general undergraduate mathematics courses. Therefore, using the number of math courses taken beyond calculus is not the same as measuring content knowledge for teaching.

Speer, Smith, and Horvath (2010) conducted a literature review to search for empirical research on the practices of collegiate teachers of mathematics. As a result, the authors identified only five articles, indicating that "collegiate teaching *practice* remains a largely unexamined topic in mathematics education" (p. 100). Since then, more studies have been published specifically on MKT at the undergraduate level (Bargiband, Bell, & Berezovski, 2016; Callingham et al., 2012; Castro Superfine & Li, 2014; Firouzian & Speer, 2015; Hauk, Toney, Jackson, Nair, & Tsay, 2013; Jaworski, Mali, & Petropoulou, 2017; Musgrave & Carlson, 2017; Rogers & Steele, 2016; Rogers, 2012; Speer & Wagner, 2009; Vincent & Sealey, 2015). However, some of these studies utilize existing frameworks for MKT that were developed at the K-12 level, which can be problematic (Speer et al., 2014). Therefore, the purpose of this study is to contribute to this growing body of research by examining MKT at the undergraduate level from the perspective of practice.

**Cognitive demand and task unfolding.** Smith and Stein (1998) define *lower-level demand tasks* as "tasks that ask students to perform a memorized procedure in a routine manner" and *higher-level demand tasks* as "tasks that require students to think conceptually and that stimulate students to make connections" (p. 269). Stein, Remillard, and Smith (2007) also created a framework to describe the temporal process of task unfolding and factors that contribute to this transformation. In this process, teachers utilize a written task to formulate their intended task, which in turn influences the enacted task. Each phase in this process is motivated by the goal of producing student learning and is influenced by factors, such as teacher's beliefs and knowledge. In 2010, Charalambous found that there was a connection between elementary teachers' MKT and their ability to enact tasks at a high level of cognitive demand. It is this relationship between MKT and cognitive demand that I plan to build upon in this study.

### Purpose and Research Question

The purpose of this collective case study is to examine mathematical knowledge for teaching examples in precalculus. I will do this by first examining cognitive demand in order to identify examples that were enacted at a high level of cognitive demand. Building upon Charalambous' (2010) results, I believe that these examples will provide me with fertile ground for examining MKT. While I believe that MKT influences every stage in the process of task unfolding, this report will focus on the final stage of task unfolding. The central question that guides this study is: *What is the mathematical knowledge for teaching examples in precalculus?* To narrow the focus of this study, I will primarily attend to answering the following two subquestions:

1. What mathematical knowledge enables instructors to enact examples at a high level of cognitive demand?
2. How can we characterize this knowledge?

## Methodology

### Theoretical Framework

In order to study teacher knowledge, I will utilize a social constructivist lens as well as cognitive theory of the teaching process. A social constructivist lens assumes that "multiple realities are constructed through our lived experiences and interactions with others" (Creswell, 2013, p. 36). Social constructivist researchers believe that reality is shaped by individual experiences, utilize an inductive method of emergent coding, and often collect observational data. Schoenfeld's (1998, 1999) cognitive theory of the teaching process attends to teacher knowledge (as well as goals and beliefs) and how it influences decision-making. The reason why I chose this framework is because it attends to the reasons why a teacher makes certain instructional decisions and what knowledge enables them to do this. Also, it complements Stein et al.'s (2007) task unfolding framework in many ways.

**Setting and Participants**

For the purposes of this study, precalculus courses are defined to include the College Algebra, Trigonometry, and combined College Algebra + Trigonometry courses. The participants from this study were all instructors at the same large public university in the Midwest. At the university involved in the study, second-year graduate students make up the majority of the instructors for precalculus. Since second-year graduate students are teaching their own class for the first time, I chose to exclude them from my data set and instead only recruited participants who were teaching a precalculus course for at least the third time. The participants in this study included one Trigonometry instructor (Greg) and three College Algebra + Trigonometry instructors (Alex, Emma, and Kelly). All of them were graduate students in their third, fourth, or fifth year who had already earned their M.S. and were working towards their Ph.D. in mathematics. While they all were teaching their prospective course for the third time, they had 2.75 years of collegiate teaching experience on average. Also, all of the participants in this data set were recruited because their department had identified them as good teachers.

**Design and Procedures**

In order to answer my research questions, I am utilizing a collective case study design (Stake, 1995). In order to examine MKT more generally, I included multiple instructors and collected data on multiple examples. Since I have included a limited number of participants, there is little is known about mathematical knowledge for teaching precalculus, and I seek to propose new theoretical insight into MKT, I chose to utilize an exploratory case study (Yin, 2014). The unit of analysis I am focusing on is the examples enacted by precalculus instructors. Studying teaching from the perspective of practice can be difficult, so I utilized the frameworks of cognitive demand and task unfolding to help make the knowledge the teachers were using more visible. Building upon Charalambous' (2010) finding that MKT and cognitive demand are positively related, I utilized cognitive demand as a way to identify examples that would provide me with rich opportunities to examine MKT. Second, studying teaching through the task unfolding framework (Stein et al., 2007) allowed me to see the instructors' decision-making and examine how their mathematical knowledge enabled them to enacting examples.

Coding proceeded in two stages that concentrated on cognitive demand and then knowledge. In the first stage, I utilize the Task Analysis Guide (Smith & Stein, 1998) to code the cognitive demand of enacted example. Examples that were coded as enacted at a high level of cognitive demand were then analyzed in the second stage, which has two cycles. In the first cycle, I utilized inductive descriptive coding (Miles, Huberman, & Saldaña, 2014) to identify mathematical knowledge that enabled the instructors to enact the example at a high level of cognitive demand. This round of coding would help me to answer my first research question. To answer my second research question, I conducted a second cycle of pattern coding in order to identify emergent themes and relationships between the codes that resulted from the first cycle. A detailed description of this methodology can be found in Author (2017).

## Results

### Task Unfolding by Cognitive Demand

I will report the results from the first stage of analysis in brief, since the second stage of analysis primarily answers the research questions. In total, there were 39 examples included in the full data set. Of those, 13 examples were either included in the written lesson guide but not used by the instructor or included in their lesson plan but not enacted during class time. While these examples still involved the teacher utilizing their mathematical knowledge to make instructional decisions, this paper focuses on enacted examples, so they will not be discussed. Of the remaining 26 examples, 14 of them were enacted at a high level of cognitive demand. It is also important to note that all 14 of these examples were coded as procedures with connections tasks (Smith & Stein, 1998).

### Mathematical Knowledge for Teaching

In the second stage of coding, four main domains of knowledge emerged: representations, students, instruction, and specialized content. In addition, knowledge of connections between and within these domains was also a prominent domain of knowledge that emerged. For each of these domains, I will describe some of the related sub-codes and give examples of the mathematical knowledge that the instructors used in relation to these categories.

**Representations**. Since procedures with connections tasks are "usually represented in multiple ways" (Smith & Stein, 1998, p. 348), it is not surprising that representations emerged as a main domain of knowledge. Several instructors depended on *knowledge of representations that reflected student thinking*. For example, Alex introduced exponentials by having students compare simple and compound interest. After letting her students work on the problem for a while, she noticed that many students were working calculating compound interest recursively, so she drew a table that organized their calculations by year. Emma, on the other hand, recognized that her students were struggling to connect verbal descriptions of function transformations to their final graphical representations, so she drew the associated graph for each individual transformation. In teaching her students about the long-term behavior of polynomials, Kelly utilized *knowledge of accessible representations that still capture complexities* (e.g., $y = x, x^2, x^3$) in order to strip away unnecessary distractions and help her students focus on the important features.

**Students.** Instructors relied upon their knowledge of students in varying ways. Greg used *knowledge of common student struggles* and removed the goal statement from the written lesson guide in order to force his students to make connections between the problem and the content they had previously learned. Both Alex and Kelly applied their *knowledge of students' abilities* and designed their examples around tasks that students would struggle with, but were within reach. This also required the instructors to have *knowledge of student understanding.* Instructors also utilized *knowledge of appropriate questions to ask*, *knowledge of how to probe student thinking, knowledge of how to interpret student thinking,* and *knowledge of how to respond to student thinking* as they collaboratively worked through examples with the input of students. Emma also had to interpret and respond to student thinking, although she did so in the context of reviewing student quizzes and selecting an example that addressed a common mistake many students made. Another general sub-code that was categorized as knowledge of students was *providing explanations to students*.

**Instruction.** The two most common sub-codes that fell under the domain of knowledge instruction were *knowledge of instructional sequences* and *knowledge of problem scaffoldings.*

To help her students construct an exponential equation, Alex sequenced instruction so that students worked informally with concepts before they were formally defined, utilized familiar problems to reintroduce ideas, and provided motivation for topics. She also scaffolded their inquiry by introducing a table. Emma scaffolded problems by building connections between algebraic and graphical representations and sequenced instruction by first utilizing familiar, but inefficient, methods before introducing new, but more efficient, methods. Also, Greg utilized *knowledge of how to guide instruction towards the mathematical point* by choosing to not pursue a student suggested idea that might detract from the main goal of the example.

**Specialized Content.** While knowledge of course content influences all of the domains, some sub-codes related primarily to specialized content knowledge that goes beyond the content covered in the course. For example, instructors had to rely on their specialized *knowledge of reasonable and appropriate examples*. While some of this was planned, other times it was something that instructors had to do on the spot. For example, Alex initially introduced function compositions generally. However, she decided to make the example more concrete and constructed functions that were reasonable and appropriate. In order to come up with accessible representations that still captured complexities, Kelly drew upon her *knowledge of critical and non-critical features* of functions and their long-term behavior. In explaining why a certain answer was incorrect, Emma utilized *knowledge of how errors impact the final solution*. While these may all be examples of content knowledge that the instructors would like their students to develop, they were not part of the intended learning outcomes for the course and therefore make up specialized content knowledge that the instructors drew upon when teaching.

**Connections.** Given that all of the examples were coded as procedures with connections tasks, connections emerged as another main domain of knowledge. However, this domain is different from the others in that it is not independent, but rather captures knowledge of relationships between and within the other four domains. Instructors relied upon their knowledge of connections in a variety of ways. For example, Kelly drew upon her *knowledge of related topics* in order to illustrate how the multiplicity of zeros relates to the behavior of a polynomial function at its zeros. In order to help students understand the purpose of an example or a single step, Alex and Emma relied on their *knowledge of connections between mathematical computations and problem-solving goals.* In many cases, instructors combined their knowledge of connections and their pedagogical skills in order to build *knowledge of how to help students make connections*.

## Discussion

In analyzing the data, I found that knowledge of representations, students, instruction, specialized content, and connections enable instructors to enact examples at a high level of cognitive demand. Since knowledge of connections is really knowledge of how the other domains are connected, I represented this model as a pyramid (Figure 1) with specialized content as the base and connections as the edges. In addition to making connections to different domains, knowledge of connections can also be used within a single domain. Finally, knowledge of students, instruction, representations, and connections are all situated within and build upon knowledge of course content, but I chose to not focus on this type of knowledge in my model.

## Conclusions

Given that examples are an important part of teaching, this model can be used in designing teaching PD opportunities for GTAs. In particular, PD should be designed to help GTAs develop knowledge of representations, students, instruction, specialized content, and connections. This model benefits the community of math education by providing a decomposition of the knowledge used by instructors when teaching examples in precalculus. While it is similar to other models of MKT, it is also different in several important ways. First, the domains of knowledge are inherently connected. Second, while knowledge of representations and connections are implicit in many of the other models, they are not explicitly emphasized.

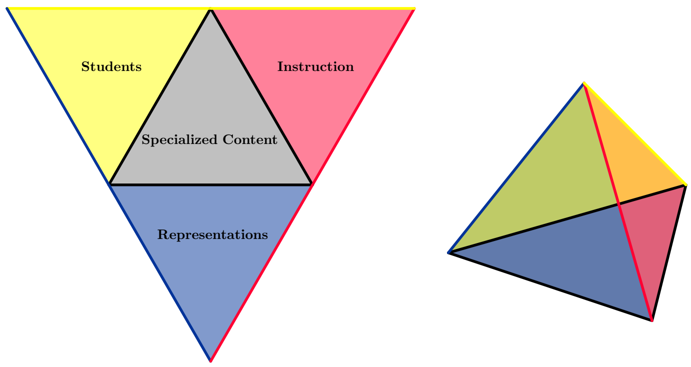

*Figure 1 Proposed model for mathematical knowledge for teaching examples in precalculus.*

## Limitations

First, as noted previously, the five domains of knowledge are not assumed to be independent. From a quantitative standpoint, this is a limitation of the model, but I believe it accurately reflects the interconnected nature of teaching. Second, since all of the high cognitive demand examples were coded as procedures with connections tasks, this model may overemphasize knowledge of connections and representations. However, "doing mathematics" may not be well suited for examples and it may be reasonable to assume that most high cognitive demand examples are procedures with connections tasks. Also, since this study was a collective case study and all of the instructors were graduate students, it may not be generalizable.

## Future Research

There is still much work that needs to be done to understand MKT at the undergraduate level, but this study provides a starting point for future investigations. In particular, it would be interesting to extend this study in several different directions. First, expanding the sample size and including instructors with a variety of backgrounds and teaching experience would test whether or not the model could be generalizable. Second, observing enacted examples that are "doing mathematics" tasks (Smith & Stein, 1998) would help further refine the model and test whether or not "procedures with connections" tasks had a large influence on the knowledge domains that emerged. Third, in order to understand post to better understand MKT at the undergraduate level at large, it would be beneficial to collect classroom data that focuses on more than just examples. Finally, my intention is to dig into the entire process of task unfolding and see what knowledge instructors use in the planning stage and utilize pre- and post-observation interview data to dig further into the knowledge used by instructors when teaching precalculus.

*Acknowledgements.* My deepest gratitude first goes to [faculty] for her support, guidance, and help as my dissertation advisor. I would like to thank all the [research group] members who contributed to discussions concerning the analysis and findings of this study. I would also like to thank the instructors whose participation made this study possible.

# Using Quantitative Diagrams to Explore Interactions in a Group Work and Problem-Centered Developmental Mathematics Class

Martha B. Makowski
The University of Alabama

Sarah T. Lubienski
Indiana University

*Despite low success rates and an academically vulnerable population, classes taught at the pre-college (or developmental) level have rarely been examined by mathematics education researchers. Mathematical Literacy, a recent developmental curriculum innovation, aims to better meet the unique needs of developmental students through group work and problem-centered materials. Using a novel quantitative representation of the classroom and descriptive statistics, this study examines the productivity of developmental mathematics students, their engagement with each other and the instructor, and their access to the curriculum in a Mathematical Literacy implementation. We find that students' engagement is regular, productive, and frequently involves the instructor. However, some students have less access to group discussions. Future implementations should focus on early identification of such students.*

*Keywords:* Developmental mathematics, community college, quantitative methodology

Enrolling over one million students (Blair, Kirkman, & Maxwell, 2013), mathematics classes offered at the pre-college level (often called *developmental*) serve those enrolled in academic tracks requiring advanced coursework, but not deemed knowledgeable enough to take college-level, credit-bearing mathematics classes. Most developmental mathematics is taught at community colleges (Blair et al., 2013), which serve students from drastically different stages of life, ranging from fresh out of high school to adults returning to school after many years (Cohen, Brawer, & Kisker, 2013). Problematically, many of the students who start developmental classes never finish (Bailey, 2009; Bailey, Jeong, & Cho, 2010), meaning that developmental coursework serves a gatekeeping function. Thus, examination of the issues surrounding the curriculum and instruction of these classes is critical.

Classroom-level research on developmental mathematics curriculum and instruction is limited, although calls for more high-quality investigations of community college mathematics are common (e.g., Condelli et al., 2006; Mesa, in press; Mesa, Wladis & Watkins, 2014; Speer, Smith, & Horvath, 2010). Most existing work focuses the instructional methods teachers use, rather than on the interplay between the curriculum, students, and instruction (Mesa, in press). Existing work shows that developmental teachers tend to use methods emphasizing skill acquisition (Grubb et al., 1999). Given that many students have previous taken and failed to learn the material (Hoyt & Sorensen, 2001), developmental students may benefit from teaching that uses different approaches.

## Mathematical Literacy at Fields Community College

Fields Community College (FCC; all names are pseudonyms), a large community college in a small Midwestern city, has recently become involved in the *Mathematical Literacy* movement (Statway and Quantway are the most well-known and widely implemented of these classes [e.g., Hoang, Huang, Sulcer, & Yesilyurt, 2017]). In addition to supporting student content learning, the designers of *Mathematical Literacy* aimed to (a) make the content relevant to the academic needs of the developmental students, and (b) highlight how mathematics informs students' lives.

To meet these goals, the *Mathematical Literacy* curriculum centers around real-world problem solving facilitated through group work, echoing the calls of the National Council of Teachers of Mathematics' (NCTM; 1989, 2000) push for more problem-centered instruction in the K-12 curriculum. Although similar in intent, *Mathematical Literacy* is tailored to meet the needs of developmental students, who, given their diversity in terms of demographics, life stage, and career objectives (Cohen et al., 2013), create a unique classroom of self-selecting, but often skeptical students. The differences between the developmental and K-12 populations, combined with the focus of *Mathematical Literacy* on group work, raise the question of whether and how these students will engage with the curriculum and their groups.

This study examines a *Mathematical Literacy* classroom, through a theoretical perspective focused on student enactment of the task as implemented (Stein, Grover, & Henningsen, 1996) and their patterns of interaction with the instructor. In particular, we ask:

1. Within their groups, how productive is student engagement with the curriculum materials?
2. Does everyone have equal access to group discussions within their groups?
3. What are students' patterns of interaction with each other and the instructor as they work?

To investigate these questions, we introduce a new method for examining classroom participation and productivity, demonstrating the utility of the method by showing results related to student talk within groups and instructor movement throughout the classroom.

## Methods

All the data for this study come from FCC, which implemented a *Mathematical Literacy* curriculum over the 2014-2015 school year. Data were collected in a single classroom taught by an instructor who had participated in the course development.

### Sample

The classroom started with 24 students, which adjusted to 22 students (6 men and 16 women) within the first week of the semester. Fourteen were White, six were Black, two were from Asian backgrounds, and one was Hispanic. Nineteen students agreed to be audio recorded in their groups. Because groups shifted throughout the semester and everyone in the group needed to assent to recording, at most 14 students were in audio-recorded groups at any given time.

### Data Sources

Data come from field notes and classroom audio, collected during weeks one, seven, 13, and 15 of a 16-week semester. This report focuses on the data from week seven. The full paper will include data from other weeks. Class met three times a week for 110 minutes and the first author was present for the entire class period. During observations, the instructor was audio recorded for the entire period. Student groups were audio recorded using table microphones. Recording started when the class transitioned to small-group work and stopped after the groups were gone. Field notes were taken.

### Analysis

The first two research questions examine how students engaged with the curriculum during group work and the equality of their participation. Using descriptive statistics and quantitative representations of the groups, we examine observed patterns of behavior within groups. For the third question, we perform a similar analysis, but look at patterns of engagement at the classroom level, focusing on instructor location and talk. All our results rely on (a) descriptive statistics on participation patterns, and (b) diagrams created from coded and timestamped transcripts of the classroom. Examples of these diagrams occur in Figures 1 and 2 in the results section. The methods for extracting descriptive statistics and generating the diagrams are described in the next few sections.

**Preparation of transcripts.** All group audio was transcribed in full. Turns were timestamped and began when a new person started talking or there was an extended gap in students' conversation. Transcripts were coded for:

1. Whether the instructor was present for each speaker turn.
2. The activity of the students in their groups.

To code the activity of students in their groups, we included isolated, non-related comments of individuals that were not remarking about something that others at the table were talking about. This decision reflects the fact that we were interested in group, not individual, behavior. At times, separate conversations occurred simultaneously. In such instances, turns were coded separately for the activity, and an indicator identifying that two conversations were occurring was added to the transcript. Group activities were coded as one of four main categories, which are elaborated on in Table 1:

1. Problems from the workbook, coded at the problem level.
2. Homework assignments, coded at the assignment level.
3. Class-related activities not directly related to a graded assignment.
4. Off-task talk.

*Table 1. Group activity sub-codes.*

| Code | Description |
|---|---|
| Problem From Workbook | Students work towards a solution on a problem from the workbook. These were coded at the individual problem level. |
| Homework Assignment | Students work on one of the two group homework assignments. These are coded at the assignment level (review or project). |
| Helping Other Groups | When students from other groups visited the recorded table and engaged in discussion with one or more group members about a problem the table had already solved. |
| Planning and Other Class-Related Talk | Negotiations about which assignment they should work on, group roles, times they could meet outside of class, check-ins to see if anyone needed help, organization talk as they transition to a new assignment, or discussions about mathematics not directly related to their work for the day. Classroom related discussions not related to completing the workbook problems or group homework assignments. |
| Off-task | Students talking about non-mathematical issues that did not directly contribute to their classroom assignments or the nature of mathematics. |

**Computation of times.** We computed the total time spent on each activity within groups by adding turn times together. This method of time calculation assumes that the group activity during periods of silence remained the same until the next utterance. Although this may not always be accurate, there is no reason to expect bias in favor of any activity.

**Creating group- and classroom-level diagrams.** Diagrams were created from timestamped and coded transcripts. All diagrams plot time against classroom or group activities and use colored regions to indicate different classroom-level activities (e.g., group work time, lecture). Group-level diagrams have two additional layers of information:

1. The *y*-axis lists the curriculum-level activities described in Table 1, with on-task activities lower and off-task group activities higher in the diagram.
2. Markers in the diagrams are linked to individuals to keep track of people through time as they move between group activities. Each color represents a unique speaker.

For all diagrams, markers indicate the start time of an individual's speaking turn, corresponding to the curriculum activity of the group at that time.

To visualize the whole class, we created diagrams that included multiple groups on a single plot (Figure 2 is an example). To minimize the overall complexity, three main modifications were made from the group-level diagrams:

1. Individuals within the same group are assigned the same color, rather than separate colors.
2. The instructor is tracked by her presence at the table rather than by her individual contributions using a larger, black marker.
3. Problem numbers are not explicitly labeled. To separate on- and off-task utterances, a dashed line cuts through the region for each group.

After creation, the diagrams were examined for participation patterns and deviations from the patterns. The diagrams are in some ways similar to the Chronologically Ordered Representations of Discourse and Features Used (CORDFU) diagrams that Luckin (2003) proposed. Our diagrams improve on CORDFU diagrams by using color strategically to separate individuals from each other, organizing the *y*-axis strategically, and clumping individuals around group activities to allow quick comparison of individuals.

## Results

### Group Engagement with Curriculum Materials

The average number of turns per individual suggests active, sustained conversations over the class, although individual participation varied greatly (Table 2). Emilia, in Group B, spoke an average of 38 times each day (about 3.4 minutes), while Craig, in Group D, spoke an average of 424 times a day (about 45 minutes). Groups spent an average of about 15 minutes off-task (Table 3), which includes a take a 10-minute break they were encouraged to take each class. Note that these averages reflect only table-level talk. Classroom observations documented students often texting or examining their phones during class. While these results only speak to off-task *talk*, when students were talking within their groups they generally discussed class-related issues. Thus, groups were productive in completing the materials.

### Access to Group-level Discussions about Material

The descriptive statistics suggest that student participation was not even within groups, but do not provide information on whether individuals had the opportunity to participate in group discussions about the material. To examine this question, we examined group-level diagrams. Several groups, in their diagrams, showed a closely working unit, with all members of the group either working on problems or going off-task together. However, this was not always the case. Figure 1 shows a group that clearly split into two overlapping sub-groups to cover the material. Closer inspection shows that in that group, although a student named Tyrone talked frequently (Table 2), it appears that he was supported through the material primarily by Sarah, rather than working through the material with his entire group. For example, Tyrone did not participate in completing the written task with the group on that day. This assignment, which will be elaborated on in the full paper, was one of the few opportunities for students to reflect on the mathematical content of the lesson.

*Table 2. Average number of turns and length of group contributions by individual per day.*

| Table | Individual | Days present | Average number turns (*SD*) | Total time (min) speaking (*SD*) |
|---|---|---|---|---|
| | Dave | 3 | 199(41) | 12.2(2.4) |
| | Felicia | 3 | 140(29) | 9.3(2.9) |
| | Sarah | 3 | 231(36) | 21.1(7.1) |
| | Tyrone | 3 | 371(71) | 30.4(8.0) |
| | Beth | 3 | 260(38) | 40.5(13.8) |
| | Carrie | 3 | 240(18) | 30.5(11.3) |
| | Emilia | 3 | 38(22) | 3.4(2.3) |
| | Henry | 3 | 189(21) | 17.4(3.3) |
| | Gabby | 3 | 116(22) | 9.3(3.2) |
| | Jen | 3 | 253(11) | 44.3(7.0) |
| | Carley | 3 | 231(82) | 15.4(15.4) |
| | Craig | 3 | 424(33) | 45.3(2.6) |
| | Fiona | 2 | 223(35) | 15.1(3.5) |
| | Helen | 2 | 206(131) | 14.3(9.1) |
| Total[a] | 14 | | 223(96) | 22(13.8) |

[a] This row reports the average contribution for each student, weighting each student equally.

*Table 3. Average time spent within groups on different group activities.*

| | Average[a] time (*SD*) | | |
|---|---|---|---|
| Activity | Total | Without instructor | With instructor |
| Workbook | 49.5 (5.9) | 41.8 (4.5) | 7.7 (1.5) |
| Reflections | 2.2 (1.9) | 2.9 (1.5) | 0.6 (0.6) |
| Group homework | 15.5 (13.7) | 11.9 (7.8) | 0.4 (0.3) |
| Planning and other class-related talk | 7.9 (2.4) | 6.0 (1.9) | 1.7 (0.6) |
| Helping | 1.9 (3.4) | 2.5 (3.0) | 0.0 (0.1) |
| Off-task | 15.8 (7.6) | 13.9 (6.8) | 1.9 (1.7) |

[a] Time was measured in minutes and averages were calculated by first computing the average time spent on each activity by group over the three days for which we have detailed records. We then averaged over the four groups.

## Students' Patterns of Interaction

Inspection of the classroom-level diagrams allow for easier comparisons of groups within a single day and more clearly show the instructor's patterns as she moved between groups. Figure 2 presents the class-level diagram for the same day shown in Figure 1. The diagram shows the instructor stopping at each group several times over the course of the period, although she spends markedly more time with Group A than the other groups. Interestingly, much of her time with Group A on the day shown in Figure 2 was off-task, rather than related to the curriculum materials. The graph also shows the instructor seems to arrive at groups while they are still actively solving a problem, rather than at the end of the problem (to help them finish the problem) or when they are off-task. There was not a time for whole-class discussion.

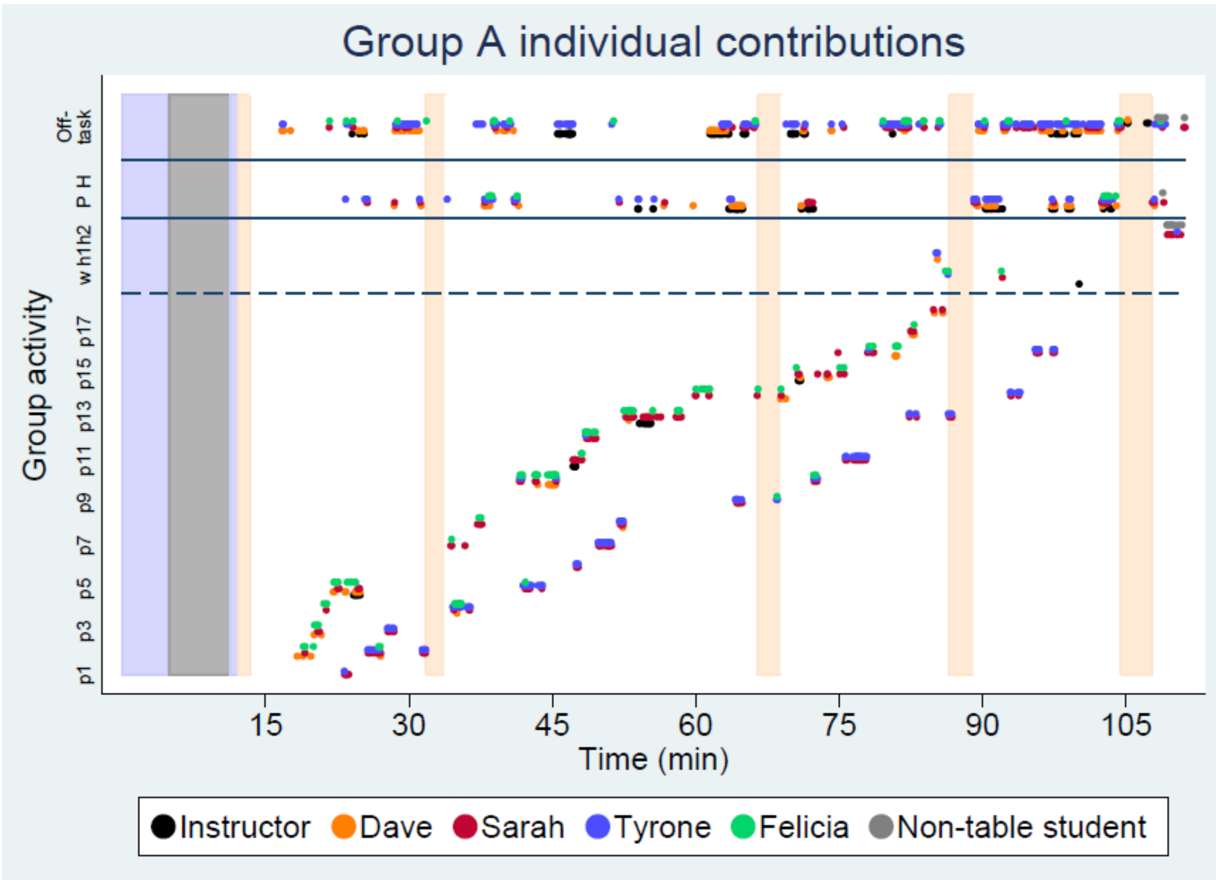

*Figure 1. Individual contributions to group activities for Group D. Each dot indicates when an individual started a new speaking turn. Recording of individuals started when the instructor opened the classroom up for group work (here, at minute 18). Light blue regions indicate when the instructor was returning assignments and checking in with students. Grey regions are when the students were engaged in a quiz or an activity related to the study. Light orange regions are when the instructor was lecturing to students and white regions are when the class was expected to be working in groups. The Group activity codes mean, in ascending order: problems 1 through 17 (skipping even problems) in the workbook, written reflection task (w), group homework assignments (h1 and h2), group planning and class-related talk (P), helping other groups (H), and off-task discussion.*

## Discussion & Conclusions

The *Mathematical Literacy* curriculum used at FCC was structured to provide students with multiple opportunities to engage in real-world problem solving. Student enactment of this curriculum showed that (a) students were regularly on-task and engaged with the curriculum materials, and (b) that student engagement with the curriculum was primarily within their groups. Whole-class discussions of the material were rare to non-existent but the instructor provided ample time for students to engage with the problems while the she monitored and supported their progress through regular visits. The instructor’s dramatic move away from lecture, the instructional method that dominates many developmental classrooms (Grubb et al., 2009), demonstrates that such an instructional shift is possible within developmental mathematics.

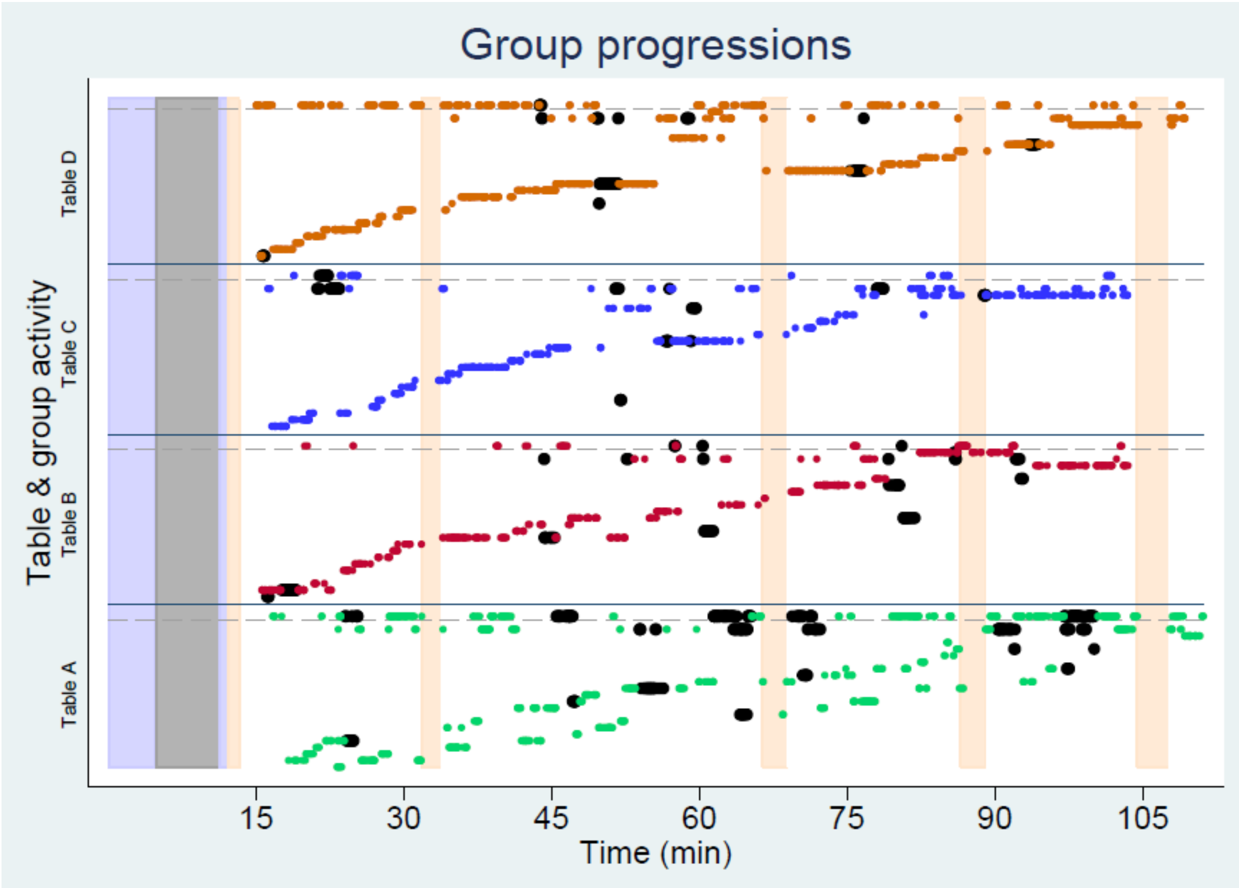

*Figure 2. Progression through group and classroom activities. See note for Figure 1 for an explanation of the shaded regions. Markers indicate that an individual started speaking at that time with respect to a particular classroom activity. Differently colored markers indicate different groups. The larger, black markers always indicate the presence of the instructor at the table, regardless of who spoke. Classroom activities are separated as they are in Figure 1; the dashed lines indicate the location of the off-task line for each group.*

Moreover, the students, although often having had many years of negative experiences in mathematics and only a short time frame to acclimate to group work and problem solving, can and did engage for sustained periods of time with mathematics problems in their assigned groups, a result that runs contrary to similar findings in K-12 mathematics: Wood and Kalinec (2012) offer one of the few looks at a group's time spent on a mathematics problem, and found that approximately 50% of the fourth graders' time was spent in off-task conversation. Adult students have been shown to have highly productive group work sessions in non-mathematical contexts (Barkaoui, So, & Suzuki, 2008). Our results suggest that developmental students in this context seem to exhibit a similar ability to self-regulate, perhaps because they have high achievement goal orientations (Mesa, 2012) and value efficiency in their education (Cox, 2009).

Although the regular engagement of the students and small amount of off-task talk is encouraging, the case of Tyrone and students like him who do not seem to have access to group level conversations about the material means that future implementations of *Mathematical Literacy* should consider ways to better meet such students' needs. Lastly, the use of quantitative diagrams, in addition to providing one method for helping to identify such students, can also be adopted as a research methodology that allows for the blending of qualitative coding with quantitative representations of the classroom.

Evaluation of Impact of Calculus Center on Student Achievement

Cameron Byerley
Colorado State University

Travis Campbell
Colorado State University

Brian Rickard
University of Arkansas

*Many universities are spending resources to establish math tutoring centers. Sharing information about the effectiveness of such centers is crucial to determine how to allocate resources. We illustrate methods of evaluating tutoring centers. We investigate the question, "what is the association between students' attendance at the Colorado State University Calculus Center and their grade in Calculus II?" We found a statistically significant positive correlation between students' tutoring center participation and their grades.*

*Key words:* Resource Center, Calculus, Student Support, Tutoring, Evaluation

The Characteristics of Successful Programs in College Calculus study (CSPCC) recommended that universities have "proactive student support services" and found that tutoring centers foster "student academic and social integration" (Bressoud, Mesa & Rasmussen, 2015, p.viii) Ninety-seven percent of the 118 US institutions that responded to the CSPCC survey question about tutoring centers had a tutoring center (Bressoud, Mesa & Rasmussen, 2015, p. 70). Tutoring centers in both the UK and the USA are asked to evaluate their success to secure and maintain funding (Personal Communication, Mills, 2017; Matthews et. al. 2012). In addition to evaluation for funding, tutoring centers should be evaluated to determine the "optimal strategies for delivery of support" (Kyle, 2010, p. 104). Tutor training, education level of tutors, format of tutoring, use of technology, location of center and more varies from center to center (Bressoud, Mesa & Rasmussen, 2015; Perin, 2004, p. 563-564).

## Conceptual Framework: What counts as success?

It is difficult to measure if tutoring centers achieve their goals using data that is commonly collected. One goal of tutoring centers is that students learn "mathematics worth knowing" (Thompson, 2008, p. 46). We want them to understand calculus as a sensible tool to understand the rate of change and accumulation of real-world quantities (Thompson, Byerley & Hatfield, 2013). However, good scores on calculus tests do not imply students are learning mathematics worth knowing. The CSPCC study collected Calculus 1 final exams from 253 US universities. They found "the exams generally require low levels of cognitive demand, seldom contain problems stated in a real-world context, rarely elicit explanation, and do not require students to demonstrate or apply their understanding of the course's central ideas" (Tallman, Carlson, Bressoud & Pearson, 2016, p. 105).

Another goal of tutoring centers is to help students complete STEM degrees. Centers help students become socially and academically integrated into the university, which helps retain first year students (Bressoud, Mesa & Rasmussen, p. 82; Solomon, Croft & Lawson, 2010; Tinto, 1997). We recognize women are more likely to switch out of a STEM degree even if they are equally qualified as men (Ellis, Fosdick & Rasmussen, 2016).

These goals are important, yet hard to directly measure given data commonly collected. Many centers report the difficulties of both running a tutoring center and gathering and analyzing quality data (Matthews, et. al, 2012). Despite the acknowledged limitations, we define success as a positive correlation between a student's attendance at the Calculus Center (CC) and the student's score in Calculus II after controlling for other variables impacting success. Future studies could consider students' scores on validated assessments on calculus concepts and students' persistence to graduation with a STEM degree.

## Literature Review: Evaluating Tutoring Centers

Matthews, et. al ( 2012) wrote the most complete literature review of evaluation of tutoring centers located in the UK, Ireland, and Australia. We discuss a subset of the studies reviewed, plus additional studies from the US.

Some studies found positive statistical relationships between student success in courses and tutoring center attendance (Dowling & Nolan, 2006; Cuthbert & MacGillivray, 2007; Mac an Bhaird, Morgan & O'Shea, 2009). All of these studies suffer from the difficult to avoid self-selection bias. Students who are more likely to use tutoring center are more likely to share other characteristics that impact grades such as motivation. Some studies used qualitative data to evaluate the effectiveness of centers. For example, Carroll and Gill (2012) qualitatively evaluated a tutoring center using student evaluations.

Not all studies found a positive relationship between tutoring center attendance and grades. For example, Walker and Dancy (2007) found that students who attended a physics tutoring center had 20 percent lower mean exam scores than those who never attended (p. 138). They hypothesized that students who struggled self-selected to use the tutoring center.

Cooper (2010) found that a drop-in multi-subject tutoring center helped increase students' GPAs and persistence in college. Students who came to the tutoring center at least 10 times had on average 0.2 higher GPA and were 10% more likely to persist in college. However, Cooper (2010) did not find a relationship between students' tutoring center attendance and performance in particular courses.

### Evaluating the Impact of Tutoring

There have been hundreds of articles about the impact of one-on-one tutoring. Topping (1996) reviewed the literature about peer-tutoring for undergraduate students. Although many studies "suffered from problems of self-selection to groups" (p. 335), Topping found evidence that having advanced undergraduates tutor newer undergraduates improved tutee's grades and was cost efficient (p. 338). Leung (2015) conducted a meta-analysis of studies on peer tutoring in all subjects at the K-16 level. Leung computed a weighted mean effect size, for studies on tutoring, finding a significant weighted mean effect size, $d$=.43, $p$<.001, for undergraduate tutoring. This was found to be a larger effect than tutoring at kindergarten and elementary levels but smaller than that for secondary education. Leung found significant effect sizes at all academic ability levels and all school levels, but the meta-analysis does not address the differences in going to a tutoring center versus having a one-on-one tutor.

Colver and Fry (2015) noted "a vast majority of research that is available relies exclusively on correlational, qualitative, or other similarly limiting methodologies that make it difficult to glean insight into the causal impact that tutoring might have on student success" (p. 16). Annis (1983) randomly assigned students to read articles under control, tutor, or tutee conditions. Students who tutored others had significantly greater learning gains than those who were tutored. Lidren and Meier (1990) randomly assigned psychology students to receive frequent, minimal, or no tutoring. They found a statistically significant positive relationship between tutoring and success on class exams. Arco-Tirado, Fernández-Martín, and Fernández-Balboa (2011) randomly assigned undergraduates to receive tutoring on study skills and found that there was no statistically significant relationship between tutoring and success.

## Causation versus Correlation

Administrators want to know if tutoring centers or some other intervention is a better use of funds. Tutoring centers would like to show the center *caused* student success. Demonstrating causal relationships requires random assignment to the treatment condition and students can not be randomly assigned to use or not use a tutoring center. A correlation between tutoring center attendance and course grades does not imply a causal relationship because students self-selected to use the tutoring center. It is possible that the weaker students are more likely to self-select to tutoring and that we could expect tutored students to have lower grades (Munley, Garvey & McConnell, 2010;Walker & Dancy, 2012). On the other hand, we could argue that more motivated students are more likely to use tutoring and are also more likely to engage in many other behaviors that will increase their grades. We are not the first to note that many studies of tutoring should include control variables "to rule out the possibility that students with better skills (higher GPA) are more inclined to seek help than those with poorer skills (lower GPA (Perin, 2004, p. 580).

Most of the studies Matthews, et. al. reviewed did not provide evidence that students' improvements in grades were caused by the tutoring center because the studies did not control for self-selection bias. For example, Pell and Croft (2008) used tables to compare the percentage of students who earn various grades and tutor center attendance. They did not control for other variables. MacGillivray and Croft (2011) advocated for tutoring centers to use more rigorous methods to evaluate tutoring center success. They wrote "the essential concept is to compare performance relative to a base measure for those who used [the tutoring center] with the same relative performance for those who did not" (p. 15). They suggested use of students' prior GPA, results on a first assessment, and diagnostic test data as possible baseline measures. They noted two studies that used diagnostic testing as a baseline measure (Dowling & Nolan, 2006; Bamforth, Robinson, Croft & Crawford, 2007). Mac an Bhaird, Morgan, & O'Shea (2009) used students' performance in past school-level examinations as a baseline. Although MacGillivray and Croft (2011) noted that general linear models are useful for analyzing the relationship between many variables and student performance, they only noted one study of tutoring centers (MacGillivray & Croft, 2003) that used general linear models.

Munley, Garvey and McConnell (2010) used the student's high school rank, SAT math score, current college GPA, number of credits the student is enrolled for, freshman or sophomore status, gender, race, participation in Greek life, student attendance of recitation session led by graduate teaching assistants, and course instructor as control variables. They found that students who were tutored did not have statistically significantly different grades. MacGillivray and Croft (2011) also suggested similar control variables and also suggested using a diagnostic test.

General linear models are considered useful in evaluating the impact of education interventions in general. As detailed by Theobald and Freeman (2013), the most commonly used methods to analyze learning gains pre-post test data in undergraduate STEM education -- raw change scores, normalized gain scores, normalized change scores and effect sizes -- fail to control for observable student characteristics; hence, researchers should instead use linear regression to control for observable factors.

## Statistical Methods

Colorado State University established a Calculus Center (CC) in August 2016. The tutoring is provided by faculty who teach calculus, graduate teaching assistants, and undergraduate learning assistants who also attend the course that they tutor. The data was collected from four large sections of Calculus II taught by three different instructors.

We will model the average relationship between performance in Calculus 2 and the number of visits to the CC by estimating a generalized linear model (GLM) of the binomial family with a logistic link function. The dependent variable is each student's total score minus attendance, midterm 1 and graph extra credit scores and is used as a measurement of performance. Performance will be modeled as a binary grouped variable: the sum of 636 independent homogeneous Bernoulli trails, implying that Performance has a binomial distribution with parameter 636 (Gujarati & Porter, 2009 p. 557; McCullagh & Nelder, 1989 p. 102). This estimation technique models the sigmodal, non-linear relationship implicit to bounded endogenous variables that is neglected by ordinary least squares estimation.

The parameter of primary interest to this paper is the number of visits to the CC. The initial regression will have six required variables that control for student motivation and mathematical ability and 13 additional test parameters. The required variables include: three diagnostic math questions, midterm 1, attendance, high school GPA, and an indicator of low previous performance (denoted LLP) taking value of one if student reports a C or lower in previous calculus class. The test variables are number of visits to CC, honors section indicator, the number of times the student took Calculus 1, the number of times the student took Calculus 2, the student's total credit hours, honors status indicator, first generation indicator, minority indicator, masters or second bachelors indicator, international student indicator, age, and male indicator. The final models are obtained by running all possible subsets of the test parameters and selecting the model with the least exogenous variables within 2 of the minimum corrected Akaike information criterion (AICc): a change in the AICc that is less than two is negligible (Burnham & Anderson, 2002; Cavanaugh, 2009). AIC is a goodness of fit measure which eliminates the subjective judgment in hypothesis testing (Akaike, 1974). AICc is AIC with a larger penalty for additional parameters. Using the minimum AICc in lieu of p-values is done for predictive accuracy as it minimizes the distance between the true model and candidate model (Burnham & Anderson, 2002).

In estimating student performance, ordinary least squares regression (OLS) is commonly used. However, performance scores are bounded and OLS estimates are not. In general, using OLS with a proportional dependent variable that is bounded between 0 and 1 is only valid if most observations are within 0.3 to 0.7. Approximately 20% of our observations satisfy this criterion. Hence, OLS estimates may entail non-normal and heteroscedastic residuals, unbounded predictions and a reduction in explained variability in the dependent variable (Gujarati & Porter, 2009). Therefore, we use logistic regression with a non-binary response variable. While logistic regression is most commonly used with a binary response variable, it can also be used with a bounded proportion that falls between 0 and 1 as suggested in Papke and Wooldridge (1996). One disadvantage to logistic regression is the large sample requirement relative to OLS. As a general rule, logistic regression requires at least 30 observations per predictor variable. However; some argue that there should be at least 50 observations per predictor variable (Burns & Burns, 2009).

To help address the potential problem of heteroscedasticity (Gujarati & Porter, 2009), we will report two models. The first will use all observations and the second will omit all observations for which $Cooks\ D_i > 3 * Mean(Cook's\ D)$ (Cook, 1977). Cook's Distance (Cook's D) is a measure of each observation's leverage and residual values. It is used to identify influential outliers in a predictor set. By removing influential observations with the Cook's D criteria, we investigate if the estimates are robust to outliers that may be caused by our inability to properly control for previous mathematical ability and motivation.

Students with high Cook's D values correspond primarily to three groups: low performance students, students who checked into CC more than 60 times, and high preforming students without intervention. Points with high Cook's D values should be examined for validity (Stevens, 1984). Some students came to the CC every week between their classes to work on homework for other classes. Some high-performing students never attended the CC because they did not need tutoring. Finally, some students did not use center and showed no signs of effort to pass the class. We are most interested in students who were attempting to pass the class, using the CC to study calculus, and were not already so strong mathematically that they did not need tutoring. These observations justify dropping the observations with high Cook's D values from the model.

The empirical model is as follows:

(1) $$L_i = \ln\left(\frac{P_i}{1-P_i}\right) = \beta_0 + \beta_1 CC_i + \beta_j \text{Control}_{\text{ji}} + \epsilon_i$$

where the model includes j = 1, …, k control variables and i = 1, …, n observations with

(2) $$P_i = \frac{\text{Performance}_\text{i}}{636}$$

Equation 1 is weighted by the variance function $V(P_i) = 636\ P_i\ (1 - P_i)$ to achieve a homoscedastic error term. Performance is being modeled as the sum of 636 independent homogeneous Bernoulli trails, $\text{Performance}_\text{i} \sim \text{Binomial}(636, P_i)$, implying

(3) $$E[\text{Performance}_\text{i}] = \frac{\text{e}^{L_i}}{1+e^{L_i}} * 636$$

To measure the accuracy of the model, we will construct the variable Pass Prediction as

(4) $$\text{Pass Prediction}_\text{i} = \begin{cases} 1, & for\ E[\text{Performance}_\text{i}] > 445 \\ & 0,\ \text{otherwise} \end{cases}$$

and the variable

(5) $$\text{Pass}_\text{i} = \begin{cases} 1, & \text{Student}_\text{i} \text{ recieved C or better} \\ & 0,\ \text{otherwise} \end{cases}$$

to estimate the percent correct pass prediction for sampled students as follows:

(6) $$\text{Correct Pass (\%)} = \left(1 - \frac{\sum|\text{Pass Prediction} - \text{Pass}|}{N}\right) * 100$$

We also predict the number of students who, assuming they received the average benefit from visits to the CC and assuming causality, could have passed the class if they had gone to the CC two times per week for 15 weeks and the number of students who passed because of the visits they made to the CC by summing the variables from equations (7) and (8). Let $\widehat{P_i}$ denote predicted performance for student `i'.

(7) $$\text{Pass if used optimal CC}_\text{i} = \begin{cases} 1, \widehat{P_i} - \beta_1 CC_i + \beta_1(30) > 445 \\ \quad 0,\ \text{otherwise} \end{cases}$$

(8) $$\text{Pass from CC}_\text{i} = \begin{cases} 1, \widehat{P_i} - \beta_1 CC_i < 446 \\ \quad 0,\ \text{otherwise} \end{cases}$$

## Results

Models of all possible subsets of the test variables along with the required variables were analyzed to determine the final model, where the AICc of the final model is within 2 of the minimum AICc with the fewest independent variables. The final model includes all required variables and all test variables except Total Credits, Age, and Male.

Note: *$p$<.1. **$p$<.05. ***$p$<.01 and p-values were not used to select model.

In the more common use of logistic regression with a binary dependent variable, the interpretation of the beta values is generally done by examining the $e^{\beta}$, which is the multiplicative change in the odds of an observation being included in the group of interest (commonly labeled as 1) for a one unit increase in the independent variable. With a proportion as the dependent variable, the interpretation is not as straightforward as when inclusion in the group of interest is not the objective. However, the sign of the beta still carries the same general meaning. Negative beta values have an $e^{\beta}$ less than 1 which is a decrease in odds, while positive beta values have an $e^{\beta}$ greater than 1 which is an increase in odds. In the context of this example, negative beta values are associated with variables that are believed to decrease the number of course points earned while positive beta values are associated with variables that are believed to increase the number of course points earned.

Using equation (4), a student's expected performance can be calculated using their given characteristics. Using the all observations model, the expected performance of the "average student" in the course, using average values for numerical variables and modal values for categorical variables, is 78.7% with five visits to the CC over the semester (79.3% using Cook's D omission model). The performance of an otherwise similar student who visits the CC twice per week is 81.2% (82.4% using Cook's D omission model). This has a smaller effect on performance than attendance in the course however. The performance of an otherwise average student who attends class half of a standard deviation above average student is 80.5% (81.0% using Cook's D omission model) while the expected performance of an otherwise average student who had half of a standard deviation more visits to the CC than the average student is 79.1% (79.9% using Cook's D omission model).

Knowledge of some pre-requisite material made a marked difference in students' expected performance. Overall, 71.6% of students did not answer the chain rule pretest question correctly. The students that answered the chain rule item correctly have an expected performance score 3.7 percentage points higher for an otherwise average student (for both models). Similarly, the 29.0% of students who correctly answered the gallons to liters unit conversion question have an expected performance score 1.6 percentage points higher (1.5 using Cook's D omission model). A correct answer on the rate of change question was associated with a lower expected performance score, though only .2 percentage points (for both models) and the association is insignificant.

While the endogenous variable Performance ignores points from midterm 1, attendance and extra credit, the model is still able to accurately predict if the sampled students actually passed the class with approximately 88% accuracy for the all observations model and 91% accuracy after omitting outliers. Out of the 683 students included in the first model, we estimate that 37 passing scores may be attributable to the visits these students made to the CC. We also estimate that 68 students could have passed the class if they had gone to the CC two times per week. Thirty-seven of these 68 students reported a C or worse in prior calculus classes, indicating potential success for the CC as an intervention if students with low prior grades were properly targeted. These three estimates should be taken with caution because they unrealistically assume a causal relationship between performance and visits to the CC and assume each student receives the average gain from their visit to the CC. The estimates, when taken as a percent of observations included in model, do not substantially change when omitting outliers, but do slightly decrease.

## Conclusion

The results of these analyses suggest that increased visits to the CC is associated with a higher likelihood of passing Calculus 2. In addition to controlling for prior student achievement, as other studies have, this study also includes variables to control for same-semester achievement and motivation by controlling for an early test grade and attendance in the course respectively. In addition, the included independent variables can be used to identify which students are at risk of failing and may be able to pass the course with additional assistance from the CC. This information could be used by teachers to target borderline students and encourage them to seek assistance.

As is common with similar studies, the issue of self-selection is a non-trivial one. Due to this, it is not possible to prove that increased scores are a direct cause of receiving assistance from the CC rather than being caused by other lurking variables such as student motivation, uncontrolled for ability, etc. In a separate survey of the same sample we asked students to respond to the following statement: "I believe that I earned a better grade in the course because of the help at the Calculus Center." Twenty-seven percent of the 151 students who responded strongly agreed with the statement and 29% agreed. Only 10% disagreed or strongly disagreed. Of course, students cannot know for certain the cause of their success in class. However, if most students had said that the CC did not impact their grade, it would be evidence that the correlation we found was primarily due to lurking variables.

Despite our inability to demonstrate causality, we still think the results are significant because of the other studies that found no correlation between visits to a tutoring center and course performance (Cooper, 2010; Walker & Dancy, 2007). Anecdotal evidence suggests that having our tutors attend the course they tutor for and meet weekly with the instructor to discuss the math coming up is one of the factors leading to the CC success.

# Developing Preservice Teachers' Mathematical Knowledge for Teaching in Content Courses

*In this paper we present evidence that a) providing opportunities for PSMTs to engage with simulations of practice and b) making connections between advanced perspectives on geometry and 7-12 mathematics allows PSMTs to develop MKT in university mathematics content courses.*

*Keywords:* Mathematical Knowledge for Teaching, Preservice Secondary Mathematics Teachers, College Geometry

Mathematics teachers draw on understandings of and connections between various knowledge bases while doing the work of teaching (Hill, Ball, & Schilling, 2008; NRC, 2010). These knowledge bases include but are not limited to typical problems for mathematics content, how that content is situated in the larger mathematical landscape, different ways students might come to know the content, and pedagogical strategies and principles that are specific to that content (Hill, Ball, et al., 2008). These types of understandings, often referred to as mathematical knowledge for teaching (MKT), should be explicitly developed in those people who seek to teach mathematics to others (Morris, Hiebert, & Spitzer, 2009; Silverman & Thompson, 2008).

Preservice secondary mathematics teachers (PSMTs) in the United States face great challenges in developing their MKT due to more demanding state mathematics standards (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010) and a lack of opportunity to learn mathematics in ways that apply that learning to teaching situations. In response, the Mathematics Teacher Education Partnership (http://mte-partnership.org) has engaged in systematic research, development, and implementation efforts to improve secondary mathematics teacher preparation. As part of this effort, the Mathematics of Doing, Understanding, Learning and Educating for Secondary Schools (MODULE($S^2$)) Project has developed, piloted, and studied the effectiveness of curricular materials in a College Geometry course. The materials, in the form of three modules, interweave aspects of MKT into a rigorous content course, can stand alone or be used to form a coherent and complete College Geometry course, and develop understanding of advanced content. In addition, the modules provide opportunities for PSMTs to develop their MKT and better understand the nature of the field of mathematics and its practice. The modules are designed to that the activities can be completed by non-education mathematics majors and education majors alike, because the work of and thinking in K-12 classrooms is a valid setting for applied problems in a mathematics course. In addition, because PSMTs will be expected to teach according to standards that view mathematics as a social construction rather than something that students receive (White-Fredette, 2010), it is critical that they learn college mathematics in an environment that both embraces this view and provides opportunity for PSMTs to develop MKT in secondary classroom contexts that also embrace this view. In this paper, we present our efforts to understand how the implementation of the MODULE($S^2$) curricular materials might help PSMTs develop MKT.

## Perspectives on MKT

One way researchers conceptualize MKT is to think of it as several intertwined types of subject matter knowledge and pedagogical knowledge. Hill et al. (2008) define six kinds of this knowledge in their MKT framework:

- Common Content Knowledge: knowledge to solve typical problems in a content area;
- Horizon Content Knowledge: knowledge of the larger mathematical context in which the mathematics one is teaching is situated;
- Specialized Content Knowledge: knowledge of content that is unique to or motivated by teaching situations;
- Knowledge of Content and Students: knowledge of how students think about, understand, or come to know particular mathematics content;
- Knowledge of Content and Teaching: knowledge of pedagogical strategies and principles specific to the mathematics content one is teaching; and
- Knowledge of Content and Curriculum: knowledge of available curricular resources and how to sequence instruction using those resources.

University faculty who teach mathematics content courses to PSMTs operate on two different levels with regard to MKT. First, we draw on our own MKT as we teach. Second, we can attend to how we facilitate developing PSMTs' MKT, not only in teacher preparation courses but also in mathematics content courses (Eli, Mohr-Schroeder, & Lee, 2013). This study investigates this second level. One way researchers might gain insight into *how* PSMTs' MKT develops is to analyze their responses to simulations of teaching practice assignments over a period of time. Simulations of teaching practice provide PSMTs with an opportunity to engage in enacting teaching practices by describing a realistic classroom scenario where student work or student thinking on a mathematics task is shared and PSMTs respond in some way (e.g., plan a class discussion or provide an explanation). Simulations of practice focus attention on key aspects of teaching that may be difficult for novices but are almost second nature for skilled teachers. They engage PSMTs in responding to student thinking – a valuable act in which PSMTs rarely engage (Grossman, Hammerness, & McDonald, 2009). Completing simulations of practice can help develop specific aspects of MKT, such as the ability to analyze student work to better understand the mathematical connections students make (Eli, Mohr-Schroeder, & Lee, 2013). Further, we know that teachers with stronger MKT foster student learning with greater mathematical richness and appropriateness than teachers with weaker MKT (Hill, Blunk, et al., 2008).

Silverman and Thompson (2008) provide a framework that we utilized for analyzing simulations of practice in order to determine how PSMTs' MKT developed over time. Within this framework, instruction is conceived of as the teacher creating space for students to reflect on mathematical ideas and formulate powerful understandings together in "similar and consistent" ways (Silverman & Thompson, 2008, p. 507). In this instructional setting, a teacher's MKT for teaching a particular idea can be measured by the extent to which the teacher has:

- an advanced understanding of the idea "that [carries] through an instructional sequence, that [is] foundational for learning other ideas, and that [plays] into a network of ideas that does significant work in students' reasoning" (Thompson, 2008, p. 32) – known as a *key developmental understanding* (KDU) of the idea;
- developed models of the many ways that students might come to understand the idea – known as *decentering*;
- an understanding of how others might think of the mathematical idea in a similar way;
- an understanding of the types of activities and discussions that might occur during those activities that would support others developing similar understandings of the idea;
- an understanding of how students who have come to understand the idea in this particular way are empowered to learn other related mathematical ideas (Silverman & Thompson, 2008, p. 508).

## MODULE(S$^2$) Geometry Materials

Three geometry modules were each implemented individually as a unit within a College Geometry course during this study. In all three modules, learners were expected to be generators of knowledge while exploring geometry questions and problems. We now describe the modules.

The first module, *Axiomatic Systems*, challenges PSMTs' understandings of axiomatic systems with an opening examination of the concept of straightness in Euclidean and Spherical systems. Further explorations include discussions of other non-Euclidean axiomatic systems (e.g., projective, neutral, and hyperbolic geometries) that require PSMTs to consider how propositions and concepts defined in one axiomatic system transfer to another. Examples of activities that focus on building MKT include analyses of a classroom vignette (involving angles formed by parallel lines and a transversal) in which the teacher suggests that the class could choose a different angle relationship axiom as their starting point. This activity points to ideas about the structure of axiomatic systems and challenges PSMTs to draw on that knowledge as they consider alternative lesson structures. Another MKT development activity engages PSMTs in exploring the midpoint quadrilateral theorem and its related corollaries in Euclidean geometry. In both activities, PSMTs are required to draw on their understandings of deep, underlying concepts that form the foundation of topics taught in high school mathematics.

The second module, *Transformations*, begins with an exploration of bijective functions which map elements from the real plane to the real plane. During this investigation, learners generate definitions of transformations and isometric transformations, and it challenges their ideas of how one might explore transformations of the plane (e.g., point-by-point analysis, algebraic methods, or graphical methods). The series of activities that follow serve to deepen the PSMTs' MKT for transformations as they delve into horizon knowledge (e.g. how isometries of the plane form a cyclic group under function composition) and other related areas of pedagogical content knowledge. Other activities that seek to develop MKT in this module ask PSMTs to examine sample high school student work on constructing reflections and rotations in order to consider what the high school students may have been thinking. By the end of the module, PSMTs define congruent shapes from a transformational perspective, and they see the structure of axiomatic systems at work when they come to understand that they must introduce a reflection axiom. The module culminates with proofs of the triangle congruence theorems from a transformational perspective. Teachers with MKT rooted in understandings of geometry from a transformational perspective can help students engage meaningfully with geometric thinking instead of relying on algebraic or arithmetic methods of solving a problem (Seago et al., 2013).

The final module, *Similarity*, builds on PSMTs' understandings of transformations by adding a dilation to produce similarity transformations. Once PSMTs construct a dilation and describe it with clear mathematical language, they discover the need for having a way to measure. This propels learners into explorations of the Pythagorean Theorem and measuring area within an axiomatic system. In this module, PSMTs explore whether all parabolas are similar, and they prove the Triangle Similarity Theorems. Throughout all three modules, the materials provide opportunities for PSMTs to connect advanced perspectives in geometry to the content of K-12 geometry standards in the CCSSM. We contend that the specific efforts to include an examination of realistic classroom scenarios, sample student work, prevalent misconceptions, and connections between geometric ideas work together to develop PSMTs' MKT.

## Methods

In this investigation, the second author taught a College Geometry course with 16 students that was required of PSMTs in a secondary mathematics certification program but was open to all mathematics majors. All 16 students agreed to participate in this case study designed to answer the question: How do the modules help PSMTs develop MKT? In order to measure whether or not an increase in MKT occurred during the semester, we utilized a nationally validated Geometry Assessment for Secondary Teachers (GAST) (Mohr-Schroeder, Ronau, Peters, Lee, & Bush, 2017) measure. Each PSMT took the GAST at the beginning and end of the course, and the research team scored responses after being trained by GAST staff. In order to gain insight into *how* the PSMTs' MKT changed, we analyzed pre- and post- simulations of teaching practice assignments according to the Silverman and Thompson MKT framework.

We focus on two simulations of practice in this report. In the first simulation of practice, PSMTs viewed the classroom scenario in Figure 1 and responded using the following prompts at the beginning (Pre) and end (Post) of the unit. The **Pre-assessment Prompt** was: *A class has been working on properties of quadrilaterals, specifically proving that the pair of base angles of an isosceles trapezoid are congruent. During the discussion, a student makes the statement shown in the clip. What is the student thinking? How should you respond?* The Post-assessment Prompt included two parts: ***Part 1*** *– Write the words the teacher should say in responding to this student, and* ***Part 2*** *– What do you think the student in the previous depiction meant, and what you say about the Van Hiele level of this this student's understanding?*

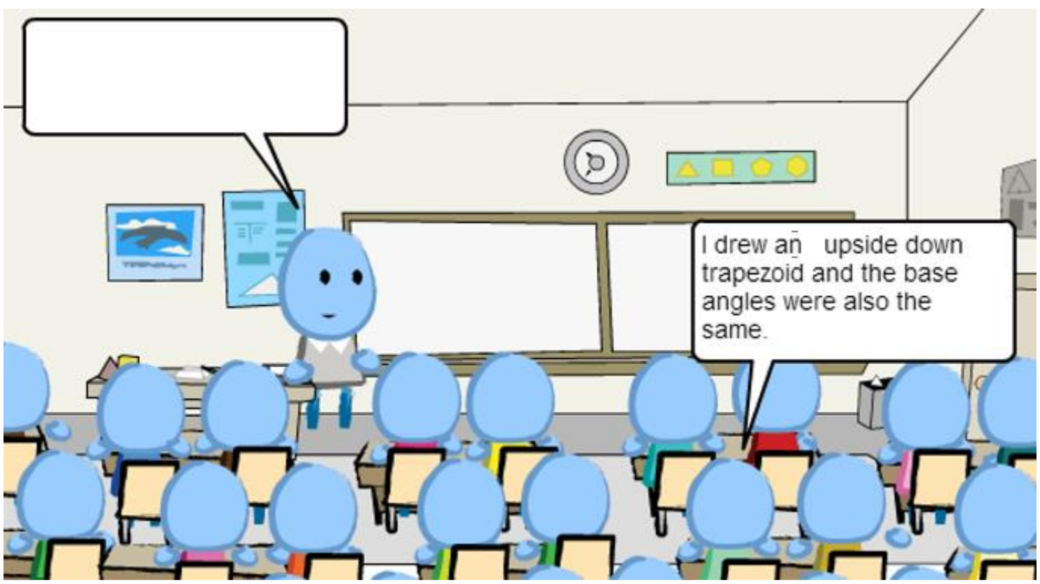

*Figure 1. A teaching scenario for simulation of teaching practice assignment #1.*

The second simulation of teaching practice utilized the student work in Figure 2 and the same prompt for both the pre- and post- assignment. The **Prompt** was: *Your students are working on reflection problems (reflecting segment* ***a*** *over line of reflection* ***r****). While circulating the room and observing the students' work, you encounter the two responses shown in the figures below. Explain how the students may have obtained their solutions and evaluate the result of their work. What feedback would you give the students?*

A research team of four coders analyzed PSMTs' responses to the pre- and post-assignments of both simulations of teaching practice. Here, we describe the five codes we matched to this framework. With regard to KDUs, it was difficult to find evidence to determine a) the level of advanced understanding for a PSMT's expression of a mathematical idea in the text of their response and b) whether or not the understanding was part of a network of ideas that carried through an instructional sequence. Therefore, if PSMTs made statements that were mathematically sound and we could envision the statement as being a critical piece of such a network of ideas, we coded the statement as ***KDU*** to indicate PSMTs may have at least a piece of a KDU. Because decentering means PSMTs understand models of ways students understand an idea that also differentiates their own point of view from another's point of view, we only coded for ***decentering*** when PSMTs provided more than one way of reasoning mathematically about the idea. If students showed evidence of understanding the way in which the student was thinking about the idea, we coded for ***understanding student thinking***. If the PSMTs' response suggested an activity that could be completed to advance student thinking, we coded for ***activity***. Finally, if a response showed evidence that the PSMT understands how understanding a mathematical idea in a particular way empowers the learning of another idea, we coded for ***connections***. As the team began coding, we found it important to also code for each ***incorrect mathematical statement*** as well as ***general discourse moves*** where the PSMTs sought to respond to students, promoting discourse to advance the lesson, but where the response did not specifically draw on particular mathematical ideas that would advance student thinking.

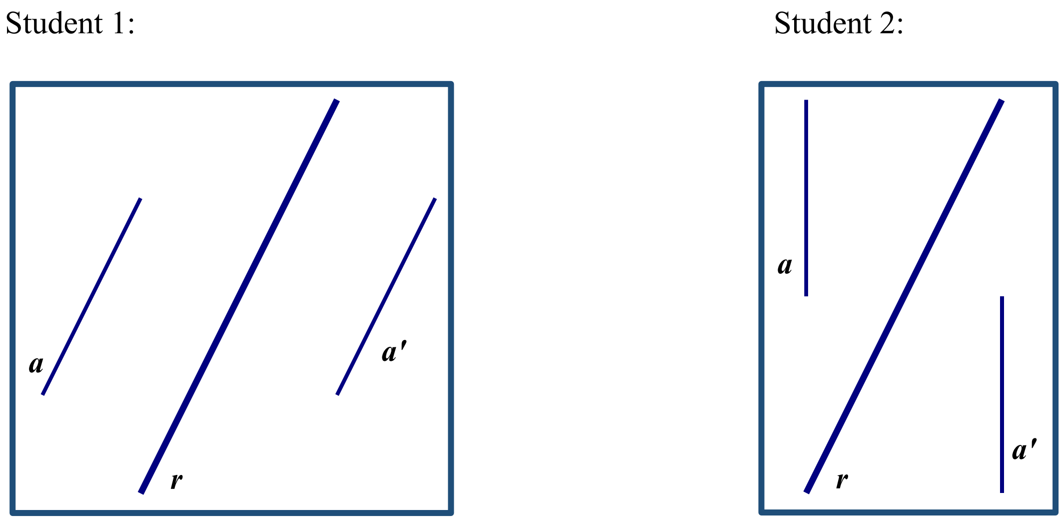

*Figure 2. Sample student work used with simulation of teaching practice assignment #2.*

Two coders analyzed half of the responses and a second pair of coders analyzed the other half. Then, each pair independently analyzed how the other pair coded their data, noting areas of disagreement. In this way, all four coders analyzed all of the simulation of practice data. All four coders then reassembled to negotiate disagreements in coding in order to arrive at a final coding of the PSMTs' responses. Once this step was complete, the team looked for patterns that emerged when comparing the case of each PSMT – focusing particularly on their responses to the simulations of practice pre-assignments and post-assignments.

## Results

A comparison of pre- and post-GAST scores revealed that PSMTs' MKT did indeed increase. The mean score on the pre-GAST was 8.7 out of a possible 16 and the post-GAST mean score was 10.7. A paired $t$-test showed that this difference is significant with a $p$-value of 0.002. An analysis of the simulations of teaching practice showed that PSMTs provided more evidence of the presence of MKT categories on the simulation post-assignment responses when compared to the pre-assignment, particularly with regard to ***KDU***s and ***understanding student***

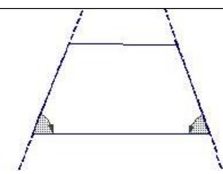
***thinking***. In addition, the number of instances of ***general discourse moves*** decreased dramatically from pre- to post, indicating that PSMTs progressed in their ability to respond to particular mathematical reasoning of students in their responses by the end of the course. In light of this, it is not surprising (though not necessarily encouraging) that there were slightly more ***incorrect mathematical statements*** in the post-assessments, because more PSMTs were making a greater number of mathematics-specific statements in their responses.

Here, we present responses from PSMT11, a case in the course that exhibited typical MKT development. In PSMT11's pre-response to assignment 1 (see Figure 3), we see a ***general discourse move*** asking students to state what they know or what inferences they could make about a particular idea. It is not clear how the mathematical ideas central in the question posed by PSMT11 were foundational to a connected network of ideas that could be used to advance students' understandings of base angle congruence in an isosceles trapezoid.

In contrast, part 1 of PSMT11's post-assignment response indicates ***KDU***s of rigid motions and variations in angle measure that informed the questions posed. Mathematics-specific questions that draw on understandings of rotations (upside down) and changing angle measures are clearly meant to cause cognitive conflict for the student and provide an opportunity for the student to reorganize their thinking about trapezoids. In addition, the question "Would all of our postulates and theorems still hold?" indicates an ***activity*** or class discussion that PSMT11 believes would hold potential to help the student progress in their understanding of the idea under discussion (and we agree). In both paragraphs of the part 2 response, PSMT11 provides evidence of a ***KDU*** of congruence as well as the ability to ***understand student thinking***, even if imperfectly – the student showed evidence of understanding congruency, but PSMT11 did not acknowledge it in the last sentence of the response.

**Pre:**

What do we already know or what inferences can we make about congruent angles in shapes?



**Post:**

**Part 1:** Would it matter if your trapezoid is 'upside-down'? Could our base angles be obtuse instead of acute? How would this affect our conclusion? Would all of our postulates and theorems still hold? Does a shape change its properties based on orientation? Why or why not?

**Part 2:** The student literally turned their trapezoid upside down and concluded that the 'new' base angles were also congruent. Rather than understanding that these 'new' base angles actually represented the summit angles from the right side up trapezoid, the student assumed that since the orientation of the trapezoid changed, then the base angles might also. After finding that this was not the case, the student came to the conclusion that the 'new' base angles were also congruent without deducing that the summit angles of the original trapezoid were congruent along with the base angles.

The Van Hiele level of understanding this student might possess would be considered a Level 0, which refers to Visualization. The student lacks understanding of the parts of the trapezoid functioning together, and rather views the trapezoid as a 'total entity.' This student is able to identify the trapezoid, use geometric language to describe it, and can reproduce it, but they are unaware of the special properties that it may possess, such as parallel lines and congruencies.

*Figure 3. PSMT11's responses to pre- and post- simulation of practice assignment 1.*

In the pre-assignment for simulation 2, (see Figure 4) PSMT11suggested an ***activity*** by posing questions about folding paper to visualize reflections and further student thinking. We also see ***activities*** in PSMT11's post-assignment, but she further elaborated by understanding student thinking and exhibiting multiple KDUs. The statement, "The student 'reflected' the original image but the student failed to notice the orientation of the line of reflection" indicates PSMT11's attempt to ***understand student thinking.*** In contrast to PSMT11's pre-assignment, ***KDU***s were prominent in the post-assignment. For example, she recognized that when an image is reflected over a line, distance is preserved and segments in the image are congruent. Additionally, PSMT 11 used her KDU of reflections to develop activities when she explained that "we must use perpendiculars to measure our distances" (***KDU***) and then posed questions that she could ask to advance student thinking (***activities***). Though we see more KDU in the post-assignment we consider this may be due to the nature of the geometry course.

| |
|---|
| **Pre:** If you folded your paper across the dotted line, would your reflection process still hold? Why or why not? What can you do to your conclusion so that it does hold? What does it mean for something to be reflected? Think about your answer in terms of mirroring. |
| **Post:**<br>***The Student's Solution***: This student noticed that the original image is parallel to the line of reflection, yet they unsuccessfully performed a proper reflection. The student 'reflected' the original image but the student failed to notice the orientation of the line of reflection. It is true that the new image is the same distance away from the line of reflection as the original and the new image is congruent to the original, but if you metaphorically 'folded your paper in half,' the image would not lie on top of itself. The new image's endpoints would not fall on the same perpendicular as the original image's endpoints, which is the main factor contributing to this misconception. The endpoints of each image must fall on the same perpendicular. The midpoint of the perpendicular will fall on the line of reflection.<br>***My Feedback***: What would happen if you folded your paper across the line of reflection? How does this reflection differ from your answer? Compare your answer to the actual reflection. What do you think went wrong? I know you know that the distance from the line of reflection to each image must be congruent and the lines themselves must be congruent. But think about if you were that line, and you looked directly into the line of reflection (like it was a mirror)... would that reflection be skewed to the left? Where would the reflection be? Why? This is why we must use perpendiculars to measure our distances from the line of reflection to our image. Your new image's endpoints will lie on the same perpendicular as the endpoints of your original image. |

*Figure 4. PSMT11's responses to pre- and post- simulation of practice assignment 2.*

## Discussion

In this report, we present evidence of PSMTs' development of MKT. In particular, after learning in a College Geometry course with MODULE($S^2$) curricular materials, we observed the development of PSMTs' KDUs of mathematical ideas and the ability to more fully understand student thinking. In addition, PSMTs significantly decreased their use of general discourse moves. We attribute this advancement of MKT to the PSMTs completing activities that are grounded in the work of teaching. Baumert and colleagues (2010) make a similar argument, that solely focusing on common content knowledge develops "only a limited mathematical understanding of the content covered at specific levels" in the school curriculum (p.167). Providing opportunities for PSMTs to engage with simulations of practice and activities that make connections between advanced perspectives on geometry and 7-12 mathematics allows them to begin to bridge the gap between college coursework and classroom teaching and meet the challenge of developing MKT in their university mathematics content courses.

Shape Thinking and the Transfer of Graphical Calculus Images

M. Katie Burden
University of Central Arkansas

Jason Martin
University of Central Arkansas

*Shape thinking has previously detailed how students may view function graphs. Students using static shape thinking view a function graph as if it were a wire where learned rules, formulas and quantities appear as a consequence of the perceived shape. This study presents a case study that demonstrates how static shape thinking can be extended to other graphs seen within calculus. Results demonstrate how one first-semester calculus student perceived a "triangular" shape within a function graph. Quantities appeared as a consequence of this perceived shape and his reasoning on multiple related tasks was influenced by his transfer of this perceived shape onto subsequent graphs. Even the the student's reasoning led to inaccurate responses to interview tasks, his reasoning was accurate and consistent within his perception.*

*Keywords:* Calculus, Shape Thinking, Quantitative Reasoning, Transfer, Derivative

Oftentimes students identify solution procedures by the type of question found in particular locations in the textbook, and thereby reduce calculus to a set of disjoint procedures that are conceptually unavailable when removed from the exact setting in which the procedure was presented (e.g., Bezuidenhout, 2001; White & Mitchelmore, 1996). Students' often view their procedural knowledge as irrelevant in "quantitatively complex situations" and have difficulty with reasoning quantitatively when relevant to even seemingly straightforward applications of mathematical concepts (Lobato & Siebert, 2002, p. 88). The quantitative complexity of the concept of derivative at a point is outlined in Zandieh's (2000) work where student understanding is framed within three "layers" of process-objects pairs. Carlson, Jacobs, Coe, Larsen, and Hsu (2002) asserted that students can struggle with derivatives because of an impoverished understanding of function that lacks a coordination of quantities foundational for reasoning about dynamic relationships captured by functions' rules. Carlson et al. (2002) outlined the mental actions needed for productive reasoning about the derivative of a function. In particular, emphasis was placed on Zandieh's ratio layer and the mental actions of coordinating the amount of change in one quantity with changes in the other quantity.

We speculate that interactive images can support the development of mental actions coordinating amounts of change of quantities. Furthermore, research suggests that engaging students in multiple problems from which to generalize can promote a richer understanding of a concept than might otherwise be achieved (Oehrtman, 2008).

This report is part of a larger study investigating the effects of contextual and graphical images of derivatives from multiple contextual problems using virtual manipulatives (VMs). For this paper, focus is placed on an interesting case and we ask the following question:

> What might students transfer while interacting with images graphically modeling similar quantitative attributes of different situations related to the concept of derivative?

## A Research-Based Approach to Interactive Image Design

This section provides a review of relevant literature as it relates to the design of the images contained within the VMs. VMs were adopted because they can show continuous change in real time (Castillo-Garsow, 2012) and can be used to aid students in making sense of calculus concepts by highlighting connections between multiple representations, developing quantitative reasoning, and supporting exploration of formal limit definitions (Cory & Garofalo, 2011; Thompson, Byerley & Hatfield, 2013; Thomas & Martin, 2017).

All problems presented in this study (Figure 1) were adapted from Oehrtman's (2008) approximation framework. Oehrtman (2009) found that students' spontaneous reasoning using an approximation and error analysis cognitive model for limit closely resembled the formal structure of limits while simultaneously supporting students in productively engaging quantitatively complex situations. Repeated structured reasoning using quantities and relationships between quantities associated with approximations and error analysis can encourage student generalization to shared structures across similar contextual situations.

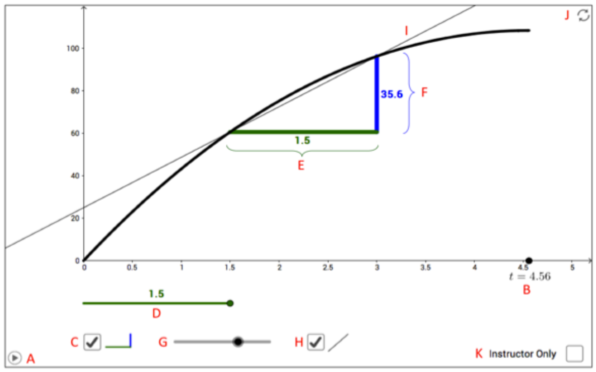
*Figure 1. Four approximation problems used in each interview.*

VMs were created by the second author using GeoGebra 5 (Hohenwarter & Fuchs, 2004). Figure 2 presents an overview of key attributes of a graphical VM indicating the interactive capabilities of the VM within the context of the bolt problem.

The mental actions of conceiving of, creating, and making inferences with covarying quantities are a "foundation from which the student can reflect upon to develop mathematical understandings and reasoning" (Moore, Carlson, & Oehrtman, 2009, p. 3). Covariational reasoning is defined as "cognitive activities involved in coordinating two varying quantities while attending to the ways in which they change in relation to each other" (Carlson et al., 2002, p. 354). Carlson et al. (2002) went on to describe developmental levels of student's images (Thompson, 1994) of covariation based on the accrual of mental actions progressively supporting more sophisticated covariational reasoning in the context of derivative. In particular, Levels 1 and 2 involved coordinating changes in one quantity with changes in the other quantity. Levels 3 and 4 included the same mental actions as from Levels 1 and 2 and additionally involved coordinating amounts of change of one quantity with changes in the other quantity.

Students typically read the problem prior to interacting with a VM. When they first interacted with a graphical VM, the axes and the play/pause button (Figure 2 A) were the only visible attributes of the VM. We anticipated that the inclusion of the play button might help support developmental Levels 1 and 2. After the animation played, students could reveal (Figure 2 C) depictions of amounts of change. For the graphical VMs, these depictions of amounts of change initially appeared as attributes of multiple "triangles" along the curve (not depicted in Figure 2). Once amounts of change were depicted, the student could adjust (Figure 2 D) the amount of change of the independent quantity and highlight (Figure 2 G) particular intervals. After an interval had been highlighted, the student could reveal a secant line for the highlighted interval (Figure 2 H). The VMs' abilities to reveal, adjust, and highlight depictions of amounts of change were included to support Levels 3 and 4. For the purpose of our research, it was up to the student to conceive of and coordinate measurable attributes of the VM that coincided with



A Play/Pause Button
B Slider for independent variable
C Checkbox toggles amounts of change on/off
D Slider for change in independent variable
E Horizontal line segment
F Vertical line segment
G Slider highlights single interval
H Checkbox toggles secant line show/hide
I Secant line

K Checkbox toggles axes labels on/off

*Figure 2. Interaction points for a graphical VM where particular amounts of change have been highlighted. *Note: The letters A-K and corresponding descriptions on the right did NOT appear on the original VM.*

approximating the requested instantaneous rate. In particular, when interacting with a graphical VM, students needed to conceive of the *lengths* of the horizontal and vertical attributes of "triangles" as representing the amounts of change.

## Theoretical Background: Shape Thinking and Transfer

For this study we focus on one of two modes of thinking based upon the extent to which an individual engages in quantitative and covariational reasoning while reasoning about graphs.

### Static Shape Thinking

Static shape thinking entails a view of a function's graph as "an object in and of itself, essentially treating a graph as a piece of wire (graph-as-wire)" (Moore & Thompson, 2015, p. 784). The mental actions and operations that students engage during static shape thinking are rooted in Piaget's (2001) figurative thought "based in and constrained to sensorimotor experience (including perception)" (Moore, 2016, p. 324). Thus, a student exhibiting static shape thinking relies on the most salient perceptual cues of shape. Equations, function names, rules and properties of the function appear as consequences of shape. This view of the graph of a function may serve the student well in particular situations, such as function translations; however, static shape thinking obfuscates student's ability to view functions as emergent through covarying quantities. Static shape thinking does not mean students lack quantitative reasoning, but that when quantities appear, they appear as a consequence of the shape.

To better describe a student's meanings and ways of thinking while engaging in shape thinking, Moore and Thompson (2015) drew upon Thompson, Carlson, Byerley and Hatfield's (2014) definitions of *understanding*, *meaning*, and *ways of thinking*.

> *Understanding* is an in-the-moment state of equilibrium, which may occur from assimilation to a scheme or from a functional accommodation specific to that moment in time. A *Meaning* is the space of implications that the moment of understanding brings forth—actions that the current understanding implies. *Ways of thinking* are "when a person has developed a pattern for utilizing specific meanings…in reasoning about particular ideas" (Thompson et al., 2014, p. 12). (Moore & Thompson, 2015, p. 784)

### Actor-Oriented Transfer

"Actor-oriented transfer is defined as the personal construction of relations of similarity between activities" (Lobato & Siebert, 2002, p. 89). In this study we adopted transfer as actor-oriented “to understand the interpretative nature of the connections that people construct between learning and transfer situations” (Lobato, 2012, p. 239). In particular, we desired to better understand the idiosyncratic interpretative nature of the connections that students were constructing as they progressed through the four problems (Figure 1) using the provided VMs (Figure 2). Due to the quantitative complexity of the problem situations, we anticipated that the nature of their interpretive engagement would be supported by quantitative and covariational reasoning. Quantitative and covariational reasoning have been shown to support students in conceiving of relevant mathematical structures within contexts and generalizing to a common mathematical structure shared by multiple contexts (Lobato & Siebert, 2002; Ellis, 2007; Thompson, 2011). In particular, students' in-the-moment understanding of a VM is influenced through an interaction of prior learning experiences, their interpretation of the problem, and quantities and relationships conceived concerning the problem's situation and conceived concerning the attributes of the VM. The space of implications that a moment of understanding brings forth can evidence transfer through the quantities and relationships between quantities conceived as similar to quantities and relationships from prior situations and prior VMs.

## Methods and Analysis

Five students from a first-semester calculus course at a medium-sized university voluntarily participated in this study. The participants were A-B range calculus students majoring in a STEM field. Interviews occurred after the concept of the derivative and during definite integral instruction using Briggs, Cochran, and Gillett (2015). Each student was assigned to one type of representation (contextual or graphical) and level of interactivity (VM or static) throughout all interviews. This paper focuses on one student, pseudonym Jeremy, who viewed graphical VMs.

Jeremy participated in four 20 to 45 minute individual interviews where one problem from Figure 1 was presented per interview. He began with the bolt problem since velocity is the most commonly used physical example of derivative within calculus (Zandieh, 2000). In the second interview, he was introduced to the sphere problem and so on. All problems presented different situations but shared a common derivative structure and method for obtaining approximations to support transfer. Using a laptop computer, Jeremy interacted with four VMs, each depicting a different graphical image corresponding to the current problem, and each image similar to the image depicted in Figure 2. He was also provided with a calculator and smartpen.

While interacting with each VM, Jeremy was asked to identify on the image what depicted what he was approximating, approximations, and errors when applicable. Furthermore, he was asked how he could improve any approximation he might have produced. This task was intended to support student use of the VM to explore average rate of change over smaller intervals of the independent quantity. To evaluate his developmental level (Carlson et al., 2002) in relation to the current image, he was asked to complete the statement, “For any fixed amount of the change in (time/radius/distance/time), the amount of change in (height/volume/gravitational force/mass) is (increasing/decreasing/neither).” He was also told to compare rates at different instances, such as comparing the speed of the bolt at two and four seconds. Jeremy was repeatedly asked to indicate attributes of the image that supported his responses to interview questions.

Interview data consisted of written notes from his smartpen and audio and video records, including screen capture and one camera capturing gestures toward the screen. Data were analyzed with the intent to reconstruct in-the-moment understandings and meanings based upon the quantities and relationships between quantities conceived upon the situation and VM image. Records of Jeremy's responses to interview questions were coded for instances of the appearance of quantities and relationships with particular attention paid to amounts of change and his interpretation of how these amounts were represented within the current image. Noting the appearance of quantities together with the current interview question and Jeremy's indicators of attributes of the image corresponding to such quantities, provide evidence for the origin of his reasoning. The analysis of Jeremy's reasoning concerning the bolt problem served as a baseline with which to compare his reasoning on subsequent tasks. To document transfer, special attention was paid to any moment in which Jeremy explicitly applied attributes from previous interview problems even though these attributes might be irrelevant for the new situation.

## Results: A Case Study from a Graphical Virtual Manipulative

This section describes Jeremy's reasoning as he progressed through the four problems.

### Jeremy's Reasoning During the First Interview

In the first interview, Jeremy described getting an approximation by taking the derivative of the function because "the derivative of position is velocity." As the animation played, he said, "It's pretty much showing […] the position with respect to time." He then stated that the vertical axis was showing meters. He noted that he could use the graph to make an approximation, and after he was asked how he would do that, he gave the formula "position divided by time."

**The appearance of quantities based on perceived shape.** After he was directed toward the "clickable features," Jeremy selected the checkbox that toggled the horizontal and vertical line segments denoting amounts of change. He said, "This makes me think of an area function." He then began talking about integrals and Riemann sums he was studying in class, "I think these shapes represent rectangles, it looks weird because it's in a way that I've never seen it." He then drew his own version of the Riemann sum showing an "overestimate" (Figure 3a), and concluded that the area under the function depicted the distance traveled.

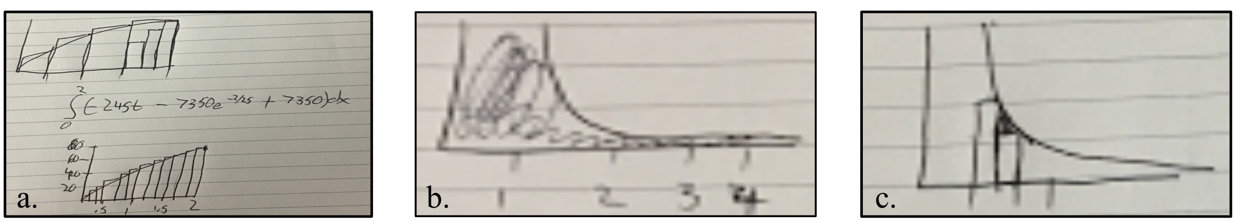

*Figure 3. Jeremy's graphical depictions involving areas and rectangles.*

After he displayed the secant line, he called it the "tangential." In this moment, he said that the "tangential" indicated the rate of change and moved both sliders to increase the number of "triangles" and to get the secant line to "land on" the point corresponding to $t = 2$. He stated that this method would give him the rate of change at two and repeatedly mentioned using the formula "position divided by time" to obtain an approximation. Even though Jeremy had been talking about "tangential" lines and a rate formula, he went on to say that to get a better approximation he would "take the integral from zero to two." Jeremy was viewing an image with many "triangles" depicted as he made this comment. Jeremy eventually reminded himself that since the image was the graph of position he needed to take the derivative to obtain the velocity. He was asked if there was a way to approximate the rate of change without taking the derivative. He said it was just "geometry" and went back to using the rectangles under the curve.

The previous paragraphs have detailed how Jeremy cued off of his perception of the image in front of him and his remembrances of learned rules and facts. For Jeremy, one of the most salient features of the images were the "triangles." When he cued off of the "triangles" or the "geometry" of the image, Jeremy "saw" rectangles and that reminded him of Riemann sums. When he cued off of the "tangential" lines or the physical situation, he was reminded of derivative and rate of change but neglected related quantitative meanings depicted on the graph.

**The appearance of amounts of change.** Once given the fixed amounts of change question, he looked at the image and said, "From 0 to 4.5 the height increases." The question was restated with emphasis on the "*amount of change,*" but he continued to neglect amounts of change. When asked to compare the rate of change at one second to the rate at four seconds, Jeremy finally spoke of amounts of change in reference to rates as he gestured over the graph of the function.

> The rate of change is definitely slower. As you can see, the height from zero to one [gesturing over the $x$-axis from $x = 0$ to 1] is in a difference of forty [upward gesture to the function at $x = 1$], but the height from three to four [gesturing over the $x$-axis from $x = 3$ to 4] is barely twenty [making the same upward gesture to the function but at $x = 4$].

In this moment, the fixed amounts of change and the comparing rates questions appeared to help focus Jeremy on quantities relevant to rate that were depicted on the image.

**Transfer Enabled by Static Shape Thinking During Subsequent Interviews**

When presented with the sphere VM, Jeremy stated, "Oh this is just another approximation problem." He then concluded he could produce an approximation by "doing the same thing as last time" and inquired if the image in front of him was depicting, "straight up triangles?" Clearly, Jeremy had engaged in attempting to transfer his way of reasoning about the first problem to the next problem and that this reasoning was influenced by his "triangles."

**Implications of triangle reasoning.** Throughout all four interviews, Jeremy continued to cue off of the "triangles" and imbue "rectangles" upon the image even though no rectangles were ever depicted. When looking at the triangles in the VM for the sphere he said, "I want to use a rectangle to estimate the area under the curve, and that will tell me the rate of change." He then reproduced the graph from the bolt problem and illustrated a rectangle under it.

As a consequence of Jeremy's "rectangles," he spoke frequently of the area under the curve (Figure 3b) and using the rectangles to approximate the area under the curve (Figure 3a). In addition, his graphical structure based on his perceived rectangles evolved to include quantities related to overestimates, underestimates and error. For example, he described the triangles as depicting error as "area that's not captured" by the area of the rectangles corresponding to an underestimate (Figure 3c). He observed, "the more rectangles I put in, the more accurate the estimation gets," and noted that the VM "program doesn't take the shapes under the curve to infinity." He described the integral as a limit of rectangles with no error, "An integral is pretty much this, but making your shapes [go to] infinity to where there is no error." When asked for detail to explain why area approximated instantaneous rate, he expressed uncertainty but remained steadfast that area under the curve depicted the appropriate rates of change.

**"Tangential line" reasoning.** Throughout the interviews, Jeremy continued to talk about the displayed secant lines as if they were "tangent lines." For him, his "tangential lines" represented the instantaneous rate of change at a point while simultaneously evolving to "fitting" the "hypotenuse" of his "triangle." Even though he had related rate of change to amounts of change during the first interview, in subsequent interviews he had difficulty describing amounts of change in relation to any rate. For example, in the second interview he drew a picture of the graph with several lines illustrated and compared rates where greater rates corresponded to steeper slopes. When asked to describe what the lines showed, he said, “Oh, the rate of change at that point.” When asked to identify the attribute of the lines that was the rate of change, he faltered. By the third interview, his notion of area was influencing how he compared rates, claiming that a “significantly higher” area corresponded to greater rate. Jeremy detailed how the area under the curve in Figure 3b from zero to one corresponded to a greater rate than from three to four because there was significantly more area under the curve from zero to one.

**Learned rules and lower level mental actions.** In addition to his graphical attributes that could produce instantaneous rates, Jeremy repeatedly stated his learned rule that derivatives would give instantaneous rates. Even so, when cuing off of the image, he continued to claim that he could take the integral over an interval to produce an instantaneous rate. Furthermore, in all four interviews, Jeremy repeatedly indicated no more than Level 2 reasoning while responding to the fixed amount of change questions. Neglecting amounts of change, he repeatedly described how the one quantity would change with respect to the other quantity.

## Discussion

The nature of static shape thinking rooted in figurative thought based upon the most salient features of graphs suggests that Jeremy’s ways of thinking about these graphs likely represents a large population of students. Indeed, every student in our larger study spontaneously mentioned seeing “triangles” when viewing graphs.

Jeremy may seem contradictory at moments, yet he did not come into any observable state of cognitive conflict that ultimately led to any abandonment of approximating instantaneous rates using Riemann sums. Why not? Jeremy’s reasoning becomes very structured and consistent throughout the interviews. Consider Jeremy’s reasoning *as if* the problems in Figure 1 could be solved using definite integrals. Jeremy identifies 1) what he is approximating as area under the curve, 2) approximations as areas of rectangles, and 3) error as the area of “triangles.” In addition, 4) he can make approximations more accurate by including more rectangles and 5) has imagined the definite integral as taking the number of “[rectangle] shapes under the curve to infinity” where there is “no error.” Jeremy’s development and repeated use of this reasoning demonstrates this reasoning as a way of thinking concerning these tasks. This way of thinking was likely reinforced by his ability to answer approximation questions with corresponding graphical attributes.

Jeremy’s way of thinking developed through his repeated transfer of “triangular” shape and the space of implications that such transfer brought forth. It makes sense that static shape thinking would likely enable transfer due to the low cognitive demand of figurative thought. Thus, static shape thinking served Jeremy well by supporting transfer and supporting his development of his way of thinking about these tasks. Keep in mind, Jeremy “saw” rectangles.

The interview protocol focused on students’ perceptions of the images and did not include interventions intended to illuminate the irrelevance of area quantities to instantaneous rate. Thus, this study provides insight into how calculus students might perceive these types of graphs when no interventions are provided. Data from our larger study suggests that interventions designed to bring a student’s attention to the context may support students in moving away from static shape thinking. For example, we have observed notable differences between student reasoning when viewing graphical VMs compared to students viewing VMs depicting contextual images.

# The Relationship Between Students' Covariational Reasoning When Constructing and When Interpreting Graphs

*Kristin M. Frank*
*Towson University*

*Abstract: Graphing tasks require students to engage in at least one of two activities: construct a graph and/or interpret a graph. Ideally, the meanings a student re-presents when constructing a graph are consistent with the meanings the student constructs from his/her sketched graph. However, this coherence is nontrivial. In this paper I present results from clinical interviews with university precalculus students to illustrate how students' graphing actions can be governed by different images of covarying quantities. More specifically, I present two students' mathematical activity to illustrate how these students' imagined quantities to covary in different ways depending on whether they were reasoning about a situation, constructing a graph, or reasoning about that sketched graph. I conclude by hypothesizing that the way a student coordinates two quantities' measures (e.g., asynchronous coordination of varying quantities or static coordination of measures) can inhibit him/her from imagining the same covariational relationship when constructing and interpreting graphs.*

Keywords: Graphing, Covariational Reasoning, Cognition

Researchers have found that students who imagine quantities to covary in a situation are not necessarily able to re-present that imagery graphically (e.g., Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Moore, Paoletti, Stevens, & Hobson, 2016). Moore et al. (2016) suggested that students' meanings for graphs (such as graphs starting on the vertical axis, being read or drawn left-to-right, and passing the vertical line test) inhibit students from re-presenting images of the phenomenon that include covariational relationships. When students held these meanings for graphs they re-presented imagery that was distinct from how they initially imagined the quantities to covary in the situation. In this paper I extend Moore et al.'s (2016) work by exploring how the images a student constructs of the phenomenon influence both the graph the student constructs as well as the meanings the student constructs from that sketched graph. More specifically, I characterize two university precalculus students' graphing schemes to study the relationship between how the student initially understands the quantities to covary, the understandings he/she re-presents when constructing the graph, and the understandings he/she constructs from his/her completed graph.

## Background

Covariational reasoning is "the cognitive activities involved in coordinating two varying quantities while attending to the ways in which they change in relation to each other" (Carlson et al., 2002, p. 354). Thompson and Carlson (2017) leveraged past research on variational and covariational reasoning to propose six major levels of covariational reasoning (see Figure 1) that are not constrained to reasoning about specific function types or methods of representation. Thompson and Carlson explain that the level of a students' covariational reasoning depends on three constructions: (1) the quantities the student is conceptualizing, (2) how the student imagines those quantities to vary, and (3) how the student coordinates and unites two changing quantities both in thought and representation. I elaborate on these three constructions in the following paragraph.

| *Major Levels of Covariational Reasoning* | |
|---|---|
| Level | Description |
| Smooth Continuous Covariation | The person envisions increases or decreases (hereafter, changes) in one quantity's or variable's value (hereafter, variable) as happening simultaneously with changes in another variable's value, and they envision both variables varying smoothly and continuously. |
| Chunky Continuous Covariation | The person envisions changes in one variable's value as happening simultaneously with changes in another variable's value, and they envision both variables varying with chunky continuous variation. |
| Coordination of Values | The person coordinates the values of one variable ($x$) with values of another variable ($y$) with the anticipation of creating a discrete collection of pairs ($x$, $y$). |
| Gross Coordination of Values | The person forms a gross image of quantities' values varying together, such as "this quantity increases while that quantity decreases". The person does not envision that individual values of quantities go together. Instead the person envisions a loose, non-multiplicative link between the overall changes in two quantities' values. |
| Pre-coordination of Values | The person envisions two variables' values varying, but asynchronously, one variable changes, then the second variable changes, then the first, etc. The person does not anticipate creating pairs of values as multiplicative objects. |
| No Coordination | The person has no image of variables varying together. The person focuses on one or another variable's variation with no coordination of values. |

*Figure 1:* Thompson and Carlson's Major Levels of Covariational Reasoning, highest to lowest (Thompson and Carlson, 2017, p. 23)

Thompson (1990, 2011) explained that a quantity is a mental construction of a quality of an object that one can imagine measuring. Students construct quantities by conceptualizing an attribute to be measured and the way in which they would measure it. How the student imagines each quantity to vary constitutes her variational reasoning[1]. A student's conception of time is closely related to her variational reasoning since imagining a quantity's measure to change necessarily involves imagining time elapsing. Thompson (2011) described two ways students conceptualize time: experiential time "the experience of time passing" and conceptual time "an image of measured duration" (p. 27). Both experiential time and conceptual time are essential to covariational reasoning. For example, to construct what Castillo-Garsow (2012) calls smooth images of change one must imagine change in progress so that she imagines a quantity changing in her experiential time. Conceptual time, on the other hand, is essential to coordinate two quantities' measures at distinct moments in time (Thompson, 2011). The final construction Thompson and Carlson (2017) describe is the construction of a multiplicative object. As Saldanha and Thompson (1998) explained, a multiplicative object is a cognitive construction that enables one to hold two quantities in mind *simultaneously*. If one has coordinated two varying quantities through a multiplicative object then she anticipates that as one quantity changes the other quantity is changing as well. As a result, the student is able to hold both quantities in mind as they change together.

## Theoretical Perspective

[1] See Thompson and Carlson (2017) for description of six major levels of variational reasoning.

According to Piaget (1967, 1985), actions are the source of all knowledge. Individuals organize their actions into schemes that include when to apply the action, an anticipation of the result of acting, how these actions work together, and eventually how these actions can chain together. As one engages in mathematical thinking he activates different scheme(s) in order to make sense of the task.

In mathematics, students are often asked to re-present their mathematical activity in the form of diagrams, graphs, formulas, tables, etc. If the student understands the graph (or formula, table, etc.) to be a depiction of his thinking then the student has an image of the mathematical activity he re-presented and the graph is a *representation* of that image. I emphasize the distinction between re-presenting and representing to be able to study student's graphing activity in the case the student does not anticipate he is representing, or creating a picture of, his mathematical thinking to then reason about.

## Methodology

The subjects in this study were three university students: Ali, Bryan, and Sue. At the time of the study these students had recently completed precalculus but had not yet taken calculus. These students were selected to participate in the study because they collectively demonstrated different ways of engaging in covariational reasoning in a recruitment interview (see Frank, 2017 for more details on recruitment and selection). After being selected, each student participated in a two-hour one-on-one task based clinical interview (Clement, 2000). The purpose of the clinical interview was to characterize each student's meanings for graphs.

After completing the interview process I engaged in retrospective analysis by identifying instances that provided insights into the relationship between the understandings the student re-presented when constructing a graph and how the student understood his/her sketched graph. I used these instances to generate tentative models of each student's schemes for graphing. I tested these models by searching for instances that confirmed or contradicted my model and repeatedly refined my model until it accounted for the student's mathematical activity.

## Results

Of the three students who participated in the study two students (Ali and Bryan) conceptualized graphs in terms of varying quantities. Sue, on the other hand, conceptualized graphs as pictures of an object's motion (consistent with Monk's (1992) notion of *iconic* translations). In this section I describe how Ali and Bryan imagined quantities to covary when reasoning about a situation, when constructing a graph, and when reasoning about their sketched graphs.

### *Pre-Coordination of Values: The Story of Ali*

When Ali created a graph from a contextual description of a situation she engaged in two distinct activities. First, Ali generated a shape by tracking one quantity's variation as she imagined that variation in her experiential time. Then, Ali used the properties of the shape she created to reason asynchronously about the variation of the two quantities labeled on the graph's axes. If the shape she created did not match her anticipation of how each quantity varied, then she guessed shapes from her memory of past graphing activities until she picked a shape that matched how she imagined each quantity to vary. This suggests that Ali used distinct and uncoordinated systems of actions when generating graphs (drawing shapes) and understanding her sketched graphs (reasoning about two quantities' asynchronous variation). I will illustrate Ali's graphing scheme with her engagement in the skateboard task (see Figure 2).

A skateboarder skates on a half-pipe like the one shown. The skateboarder goes across the half-pipe and then returns to the starting position.

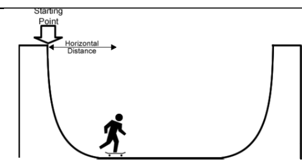

*Figure 2:* Description of skateboard task.

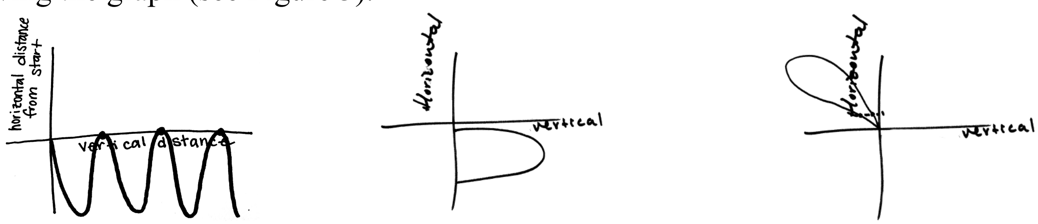
I asked Ali to graph the skateboarder's horizontal distance to the right of the starting position relative to the skateboarder's vertical distance above the ground. Ali made three attempts drawing the graph (see Figure 3).



Ali's first attempt | Ali's second attempt | Ali's third attempt

*Figure 3:* Ali's three attempts to graph skateboarder's horizontal distance from start relative to his vertical distance above the ground.

On Ali's first attempt she drew an oscillating curve in the fourth quadrant (Figure 3). Since Ali imagined the half-pipe below ground, it seems Ali made this graph by tracking how she imagined the skateboarder's vertical distance changing as she imagined the that variation in her experiential time. After drawing the curve, and without prompting, Ali determined her graph was incorrect because "the graph I drew is showing that the vertical distance is increasing the whole time." She went on to draw two more shapes (Figure 3) and each time appropriately reasoned why her sketched graph was incorrect. For example, Ali rejected her second attempt (a side-ways U-shape in the fourth quadrant) since it showed the vertical distance was positive when she wanted to show the vertical distance was negative. After Ali rejected her third graph I asked her to explain her approach to graphing (Excerpt 1).

*Excerpt 1:* Ali's explanation of making graphs by guessing and checking shapes

Int: What are you doing when you are trying to figure out what graph it could be?
Ali: Um. Well I think of like. I either focus. I go back and forth with like okay vertical distance and horizontal distance. So I think of potential like, I guess shapes, that can be drawn and then I'm like does this fit the characteristic of the horizontal distance. If it doesn't then it is out and I think of another one. And so. That's how I usually go about with graphing graphs until I eventually - I'm like this one fits both criteria.

In Excerpt 1, Ali describes her three-step approach to graphing: (1) draw a shape by "think[ing] of potential … shapes that can be drawn", (2) consider what the shape conveys about the variation of each quantity *separately*, and (3) adjust the shape until it matches how she imagined each quantity to vary. This final step is significant because it implies Ali constructed two distinct images of the quantities' covariation; Ali constructed an image of each quantity's variation from the graph that she compared to her image of each quantity's variation from her understanding of the situation. This suggests Ali had an image of the quantities' variation that she could have re-presented when making her graph.

I hypothesize Ali did not make her graph by re-presenting the images of varying she constructed from the phenomenon because she attended to each quantity's variation separately, what Thompson and Carlson (2017) called a *pre-coordination of values*. For example, Ali attended only to the skateboarder's vertical distance when determining the validity of her first and second graphs and attended only to the skateboarder's horizontal distance when determining the validity of her third graph. Additionally, in Excerpt 1 Ali explained that she "go[es] back and forth with like vertical distance and horizontal distance…like does this one fit the characteristic of horizontal distance". I take this as evidence that Ali understood the shape of a graph to show how each quantity varied separately.

By imagining each quantity's variation separately I claim that Ali did not have a single image from having coordinated two quantities' variation that she could attend to when making her graph. In other words, Ali did not have a way to think about making one shape that would convey how the skateboarder's horizontal distance changed *and* how the skateboarder's vertical distance changed. Instead, Ali was constrained to making a graph by re-presenting only one of her images of variation (first attempt in Figure 3) or guessing and checking shapes (second and third attempt in Figure 3). In summary, it seems Ali's asynchronous coordination of the two quantities' variation inhibited her from attending to both quantities' variation when making her graph.

*Coordination of Values: The Story of Bryan*

Like Ali, Bryan demonstrated different conceptualizations of the varying quantities when constructing his graph and when reasoning about his graph. More specifically, Bryan constructed graphs by re-presenting his experience imagining a continuously varying quantity but he did not reason about his graph in terms of a quantity's continuous variation. Instead, he reasoned about his graph by coordinating static states in each quantity's variation. I will illustrate Bryan's graphing scheme with his engagement in the bottle evaporating task[2].

In the bottle evaporating task I asked Bryan to imagine a spherical bottle filled with water that was left outside to evaporate. Then I asked him to graph the height of water in the bottle relative to the volume of water in the bottle as the water evaporated. Before Bryan constructed a graph he reasoned, "When volume is maximum the height should be maximum and when volume is zero height should be zero." This suggests Bryan coordinated two quantities' measures at two moments in time. He proceeded to draw a straight line from the top middle of the plane that fell from left to right (see Figure 4, red line).

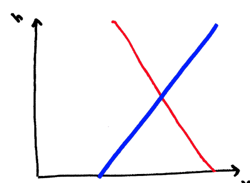


*Figure 4:* Bryan's initial (red) and revised (blue) graph for the evaporating water problem (task adapted from Paoletti & Moore, 2016)

[2] Bottle evaporating task from Paoletti and Moore (2016).

From my perspective, the line Bryan drew was not a re-presentation of the pairs of measures he imagined in the situation. Instead, it seems Bryan made his initial point with the anticipation of showing the simultaneous state of maximum height and maximum value. Then he drew a line by imagining the height of the water decreasing as he imagined the water in the bottle evaporating. This suggests that Bryan constructed his graph by imagining the gross variation of the height of the water in the moment he imagined that variation in his experiential time.

After Bryan drew the line he reconstructed his initial image of two pairs of quantities' measures to reason that his graph should show maximum height and maximum volume. He determined that his graph did not show this relationships saying, "It doesn't make sense. Because over here (*points to start of line in top middle of plane*) it says height is maximum but volume is not maximum (*points to intersection of line with horizontal axis*)." Bryan drew a new graph that was a vertical reflection of his original graph about its midpoint; his graph now decreased from right to left (see Figure 4 blue line). Bryan explained that now he understood his graph to show the height is maximum when the volume is maximum and also show the height is minimum when the volume is minimum.

In summary, Bryan engaged in three distinct activities when completing the bottle evaporation task. First he imagined each quantity's (discrete) variation and coordinated the two varying quantities by constructing pairs of measures, a point's coordinates. Then he drew a line by re-presenting his experience attending to one quantity's gross variation as he imagined it changing in his experiential time. Finally, he reconstructed his initial image of pairs of quantities' sizes to determine if the behavior of the sketched graph matched his anticipation of the relationship between the quantities' measures.

I hypothesize that Bryan did not make his graph by re-presenting his initial image of pairs of measures because he could not anticipate creating these pairs of measures as he imagined a quantity to continuously vary in his experiential time. In other words, it seems that Bryan needed to imagine a static state in the quantities' variation in order to coordinate two quantities' measures. As soon as he imagined one quantity's measure to change he could no longer coordinate two quantities' measures. This implies that the way Bryan coordinated two varying quantities inhibited him from re-presenting his understanding of how two quantities change together when making his graph.

## Discussion

Ali and Bryan both demonstrated different images of covarying quantities when making a graph and when reasoning about that sketched graph. While this highlights the meanings students learn to impose on the products of their graphing actions, the findings from this study suggest that the meanings students construct from their sketched graph are consistent with how they imagined the quantities to covary in the situation. In the examples above, Ali reasoned separately about two quantities' smooth variation both when reasoning about the situation and when reasoning about her graph. Similarly, Bryan reasoned about pairs of measures both when reasoning about the situation and when reasoning about his graph. This suggests that while a student might have distinct experiences making a graph and reasoning about that graph these experiences are actually governed by the same scheme. More specifically, the student's activity making a graph is the result of an accommodation to their scheme for covariational reasoning in order to have actions available to them that persist under variation. For both Ali and Bryan this accommodation involved attending to one quantity as she/he imagined it changing in her/his experiential time. This is significant because it implies that students engage in different levels of covariational reasoning throughout their graphing activity because they are unable to re-present how they initially imagined the quantities to change together.

This study provides evidence that the nature of the student's coordination can inhibit him/her from re-presenting his/her understanding of how the quantities covary in the situation. For example, Ali coordinated two quantities' variation by imagining each quantities' variation separately. As a result, she did not have a single coordinated image to attend to when making her graph. Ali anticipated that she could use whatever shape she made to see the variation of each quantity, but she did not have a way to think about how to make that shape. Instead, she made her graph by guessing shapes until she picked one that appropriately matched how she imagined each quantity to vary.

Bryan coordinated two quantities' variation by coordinating static states in each quantity's variation and constructing the coordinates of a point in the Cartesian plane. However, as soon as he imagined one of the quantities to vary he no longer had an image of a static state in which he could coordinate two measures. As a result, when he attempted to construct his graph he did not continuously coordinate quantities' measures. Instead, Bryan made his graph by imagining one quantity changing in his experiential time. After making his graph, however, Bryan imagined coordinating measures to reason about what his sketched graph represented; he appeared to reason about an infinite collection of points on his graph. In summary, since Bryan's image of plotting points did not persist under variation, Bryan could not re-present his coordination of the quantities' variation as he imagined a continuously changing phenomenon.

Researchers repeatedly emphasize the importance of holding two quantities in mind when constructing a graph (e.g., Moore et al., 2016; Whitmire, 2014). This study provides further evidence that this is a nontrivial construction. More specifically, students need to construct ways to organize their images of varying quantities so that they can hold two quantities in mind as they imagine both quantities to change. I hypothesize that if students hold both quantities in mind then they have something new to represent in a graph – namely the coordination of two quantities. Teaching experiments with Ali and Bryan (see Frank, 2017) suggest that conceptualizing a point as a correspondence point, imagining a graph being made of Tinker Bell's pixie dust, and imagining the phenomenon happening in little chunks (e.g., taking baby steps) might support students in coordinating their images of varying quantities[3] and re-presenting this coordination in a graph .

Future Middle Grades Teachers' Coordination of Knowledge Within the Multiplicative Conceptual Field

Andrew Izsák and Sybilla Beckmann
The University of Georgia

*We report theoretical and empirical results generated through studying several cycles of a number and operations content course offered to future middle grades mathematics teachers. A main feature of the course is using an explicit, quantitative definition for multiplication to connect a range of topics in the multiplicative conceptual field (Vergnaud, 1983, 1988). Course topics include multiplication and division with both whole numbers and fractions, proportional relationships, and linear functions. The theoretical results include a mathematical analysis of multiplication as coordinated measurement and a (still emerging) psychological framework that emphasizes coordinating diverse cognitive resources. Empirical data come from clinical interviews conducted with 6 future teachers enrolled in the content course in Fall 2016. One empirical result is the importance of connecting partitioning quantities, dividing measurements by whole numbers, and multiplying measurements by unit fractions when expressing relationships between quantities through multiplication expressions and equations.*

*Keywords:* Quantitative Reasoning, Multiplication, Equations

Improving instruction in topics related to multiplication remains a central challenge for mathematics education. For purposes of the present report, we consider multiplication and division with whole numbers and fractions, proportional relationships, and linear functions of the form $y = \mathrm{m}x$. The importance of these topics has been emphasized by curriculum standards (e.g., National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010; National Council of Teachers of Mathematics, 2000) and national reports (e.g., Center for Research in Mathematics & Science Education, 2010; National Mathematics Advisory Panel, 2008). Nevertheless, despite several decades of research, the topics listed above pose perennial challenges for both students and teachers, and difficulties with these topics can be a primary obstacle to college readiness (e.g., National Center on Education and the Economy, 2013). The present report comes from an on-going NSF-funded study in which we are investigating ways to help future mathematics teachers develop integrated and coherent understandings of topics related to multiplication.

## Background

We draw on Vergnaud's (1983, 1988) construct of the *multiplicative conceptual field* (MCF) that consists of "all situations that can be analyzed as simple and multiple proportion problems and for which one usually needs to multiply or divide" (Vergnaud, 1988, p. 141). Vergnaud included whole-number multiplication and division, fractions, ratios and proportions, linear functions, and further topics in the MCF.

Most research on teachers' understandings of the MCF has concentrated on deficits with respect to particular topics. Although many teachers can use algorithms to determine the product of two fractions or decimals, a host of studies (e.g., Behr, Khoury, Harel, Post, & Lesh, 1997; Eisenhart et al., 1993; Graeber & Tirosh, 1988; Graeber, Tirosh, & Glover, 1989; Harel & Behr, 1995; Sowder, Philipp, Armstrong, & Schappelle, 1998; Tirosh & Graeber, 1990) have reported constraints on in-service and preservice teachers' performance when explaining products of fractions or decimals embedded in problem situations. Similarly, although many U.S. teachers can compute the quotient of two fractions or decimals using algorithms, they often experience difficulties explaining division when it is embedded in problem situations (e.g., Ball, 1990; Borko et al., 1992; Graeber & Tirosh, 1988; Jansen & Hohensee, 2016; Lo & Lou, 2012; Ma, 1999; Simon 1993; Tirosh, 2000).

The small handful of studies on teachers' capacities to reason about proportional relationships report that middle grades teachers perform poorly on test items that, ideally, their students should be able to solve (Post, Harel, Behr, & Lesh, 1991). Teachers can have difficulty distinguishing missing-value problems that ask about proportional relationships from ones that do not (e.g., Cramer, Post, & Currier, 1993; Fisher, 1988; Lim, 2009), can have trouble coordinating two quantities in a proportional relationship (e.g., Orrill & Brown, 2012), can make additive comparisons inappropriately (e.g., Canada, Gilbert, & Adolphson, 2010; Lim, 2009; Son, 2010), and can have trouble conceiving of a ratio as a measure of a physical attribute, such as steepness or speed (Simon & Blume, 1994; Thompson & Thompson, 1994). With respect to problem-solving strategies, teachers can rely heavily on cross multiplication or other formal methods (e.g., Fisher, 1988; Harel & Behr, 1995; Orrill & Brown, 2012), guess at arithmetic operations (Harel & Behr, 1995), and search for key words (Harel & Behr, 1995).

## Theoretical Frame

In contrast to the numerous studies that have emphasized deficits in teachers' understandings of particular topics included in the MCF, in our project we concentrate on emerging competence characterized as developing a coherent perspective that connects various topics related to multiplication. Our conjecture is that teachers might better understand individual topics within the MCF by developing a single lens that ties them together. The framework we present for such an integrated understanding combines mathematical and psychological perspectives.

Figure 1 shows the quantitative definition of multiplication upon which we have converged. It applies to situations in which there is a quantity (the product amount) that is simultaneously measured with two different measurement units (a "base unit" and a "group"). The most important aspects of this definition are (a) writing the multiplicand and multiplier in a consistent order to support a coherent view of multiplication, division, and proportional relationships (e.g., Beckmann & Izsák, 2015) and (b) interpreting $N$, $M$, and $P$ in Figure 1 as numbers that result from measuring quantities in terms of some designated unit.[1] $N$ and $P$ refer to measuring with base units, and $M$ refers to measuring with groups.

| $N$ | $\bullet$ | $M$ | $=$ | $P$ |
|---|---|---|---|---|
| How many base units make one group exactly? | | How many groups make the product amount exactly? | | How many base units make the product amount exactly? |

*Figure 1. A quantitative definition for multiplication based in measurement.*

The definition in Figure 1 can be used to coordinate an important swathe of the MCF—for instance, by viewing division as multiplication with an unknown factor and proportional relationships as instances where values for two of $N$, $M$, and $P$ co-vary while the value for the

[1] Our emphasis on numbers arising from measuring quantities in terms of designated units is consistent with aspects of Thompson's (2010) discussion of quantitative reasoning.

third remains fixed (Beckmann & Izsák, 2015). The definition in Figure 1 is also consistent with the definition for fractions found in the Common Core State Standards for Mathematics (CCSS; National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010) that presented the fraction $A/B$ and $A$ copies of the unit fraction $1/B$. Figures like that shown in Figure 2a can support the measurement perspective on unit fractions if one asks how many of the long strip make the short strip exactly (1/3). We have found that future teachers have little problem answering such questions and can extend this measurement perspective from unit fractions to non-unit fractions (Figure 2b). This appears to be a reliable foothold for future teachers when extending the measurement definition of multiplication shown in Figure 1 from whole numbers to fractions.

*Figure 2. (a) Interpreting 1/3 from a measurement perspective: 1/3 of the long strip makes the short strip exactly. (b) Interpreting 2/3 from a measurement perspective: 2 (1/3 of the long strip) make the short strip.*

Our psychological perspective is informed by diSessa's (1993, 2006) knowledge-in-pieces epistemology. Knowledge-in-pieces is a constructivist perspective in which learners come to know by using and refining knowledge as they construct interpretations of their interactions with the physical and social environment. The perspective characterizes the evolution from novice to expert knowledge as piecemeal construction, refinement, and reorganization of diverse fine-grained knowledge resources that are connected to varying degrees and whose use is often sensitive to context. Examples of cognitive mechanisms include refining the contexts in which resources are applied, forming new connections among resources, and loosening connections among others. In the present study, we examined the ecology of resources that future middle grades teachers used as they coordinated the definition of multiplication shown in Figure 1 with diverse problem situations that are contained in Vergnaud's (1983, 1988) MCF. Past research has used the knowledge-in-pieces perspective to demonstrate that coming to see diverse problem situations through a common lens can be a significant accomplishment (e.g., Wagner, 2006).

## Methods

In Fall 2016, we recruited six future middle grades teachers who were enrolled in a 2-semester sequence of mathematics content courses. The second author taught both courses. Both courses made extensive use of the definition of multiplication shown in Figure 1. The first course (Number and Operations) covered multiplication and division with whole numbers, the CCSS definition for fractions, the meaning of the equal sign, reasoning from definitions, multiplication with fractions, partitive and measurement division with whole numbers, and connecting division to fractions. The second course (Algebra) focused on proportional relationships, linear equations, and further topics. Teachers in the course were invited to participate in interviews, and the six were selected based on performance on a fractions survey administered the first week of the Number and Operations course.

This report focuses on the first three interviews we conducted during the Number and Operations course. The interviews were spaced a few weeks apart and were coordinated with whole-class instruction, most often so that the interviews provided information about the future teachers' reasoning before specific topics were introduced in the course. The first interview examined how future teachers thought about multiplication as a model of problem situations and how they formed equations of the form $y = \mathrm{m}x$ before the definition of multiplication shown in Figure 1 was introduced in the course. The CCSS definition of fractions had already been introduced and the interview tasks included fractional multipliers and multiplicands. The second interview took place after the definition in Figure 1 was introduced (only with whole numbers) and was designed to access future teachers' facility with the mental operations of splitting and units coordination that have emerged as important in research on children's fractional knowledge (e.g., Steffe, 2003) and also how they formed equations of the form $y = \mathrm{m}x$ at this point in the course. The third interview took place after instruction in fraction multiplication, division as multiplication with unknown factor, the distinction between partitive and measurement division in the context of whole numbers, and the connection between division and fractions. The third interview was designed to see how future teachers reasoned about division in the context of proportional relationships and linear equations, topics that would be covered in the subsequent algebra course. Many of the interview tasks asked future teachers to solve problems using a math drawing. Examples of such drawing include number lines and tape or strip diagrams.

We recorded all of the interviews with two cameras—one focused on the interviewer and research participant and one focused on written work—and collected all of the written work generated during the interviews. A third party transcribed the interviews verbatim. The present report is based on analysis of talk, gesture, and inscription as captured in the videos, transcripts, and written worked generated during the interviews. (In addition to the interview data, we also collected the participants' homeworks, quizzes, and tests assigned in the course.)

We analyzed talk, gesture, and inscription line-by-line for evidence of the knowledge resources that the future teachers appeared to employ. We wrote analytic notes to capture our interpretations of how future teachers were reasoning moment-to-moment. The notes included observations about similarities and differences both within a given teacher across different tasks and across different teachers on the same task. In some cases, we took future teachers' statements as direct and reliable reports of their thinking. In other cases, we made inferences about aspects of future teachers' reasoning that they would not likely be able to report directly.

## Results

Future teachers in the present study employed a complex ecology of cognitive resources when working on tasks across the interviews. To illustrate our results, we make three comments about that ecology that span all six participants and then provide more detailed description of one participant.

First, during the interviews, the future teachers demonstrated facility with whole-number factor-product combinations, algorithms for multiplying fractions, and cross multiplication for solving proportions. We assumed that when future teachers employed these resources, they drew on what they remembered from their K-12 mathematics education. Such resources can be viewed in a negative light when they interfere with reasoning about quantities directly. Although we did observe cases where future teachers determined numerical answers through computations, and thereby circumvented reasoning with quantities, we also observed cases in which future teachers used calculation constructively when solving and explaining problems in terms of math drawings. These data suggest that resources for numerical calculation are not necessarily in opposition to resources for reasoning with quantities but rather could be part of a larger ecology in which numerical calculation and reasoning with quantities support one another.

Second, the future teachers expressed a variety of meanings for multiplication and the equal sign. Meanings for multiplication included widely known ones such as multiplication is about repeated groups and that, in the case of fractions, "of means multiply." For these future teachers, repeated groups and "of" oftentimes appeared to be two disconnected understandings of multiplication rather than different expressions of a single, unified conception of the operation (such as the one shown in Figure 1). Meanings for the equal sign also included several well-known ones, such as an indication to complete a computation, an indication that two numbers co-occur (leading to equations that actually express ratios and look like the classic student-professor error), and the number on the left-hand side is the same as the number on the right-hand side. In one interview, we saw one participant encounter difficulties when he used all three of these meanings for the equal sign when working on a single problem. More generally, multiple meanings for multiplication and the equal sign often led to piecemeal reasoning across tasks which used different combinations of whole numbers and fractions for the multiplier (*M* in Figure 1) and multiplicand (*N* in Figure 1). These data suggested that sometimes future teachers experienced challenges during the interviews not so much because they lacked a particular cognitive resource but rather because they had trouble recognizing when some of those resources might be more useful than others. Knowledge-in-pieces' emphasis on knowledge refinement is well-suited to handle such phenomena.

Third, future teachers employed to varying degrees two mental operations on quantities highlighted in past research on children's fractional knowledge. These are splitting (e.g., Steffe, 2003) and different levels of units coordination (e.g., Hackenberg, 2010). Steffe's splitting operation is a fusion of partitioning and iterating. We asked versions of splitting tasks that made explicit connections to the measurement sense of unit fractions illustrated in Figure 2. None of the participants had difficulty with our splitting tasks. In particular, when presented with a strip like that shown in Figure 2a and told that the strip was a whole number of times (in actual interviews we numbers like 8) longer than a second strip, future teachers had no trouble constructing the second strip or explaining how many of the long strip made the short strip exactly. To illustrate, in case of a diagram like that shown in Figure 2a, all future teachers could explain that 1/3 of the long strip made the short strip exactly. Although, with an appropriate prompt, all the future teachers could express a measurement perspective on unit fractions, we saw differences in performance on tasks designed to elicit units coordination.

For the rest of our results section, we present examples of reasoning from Hanna around whole-number and fractional multipliers (*M* in Figure 1). We will sketch evidence that during the first interview Hanna was more proficient reasoning with and explaining whole-number multipliers than fractional multipliers, even though she also demonstrated a measurement perspective on fractions, and that during the second interview she had begun to coordinate a measurement sense of fractions with multipliers. The examples illustrate how mechanisms like coordination and refinement of fine-grained knowledge resources that are emphasized in the knowledge-in-pieces perspective are a good fit for reasoning we observed. In the full paper, we will present data from others of the six future teachers that also illustrate knowledge coordination and refinement and that provide perspectives on the multiplier and multiplicand that contrast with Hanna's.

We began the first interview with a set of word problems that described (to us) multiplication situations with different combinations of whole-number and fractional multipliers. This interview took place before meaning of multiplication shown in Figure 1 was introduced in the content course. During her first interview, Hanna solved a variety of problems with whole-number multipliers without difficulty, explaining that collecting objects into whole groups cued multiplication for her. For instance, she had no difficulty writing an equation that fit the tennis ball situation: *Jacinda has 4 cans of tennis balls. If there are 3 balls in a can, how many tennis balls does she have in all?* Hanna wrote 4 x 3 = 12 and justified her work as follows: "When you're dealing with different kinds of objects, it's easier to see with multiplication. Like if you had…instead of bags, if you had like 5 soccer balls and then another 5 soccer balls and they didn't even talk about bags, then I'd probably do 5 plus 5." A few moments later during the same interview, we asked her to write an expression or equation that fit the Chili situation: *Nick uses 1/5 of can* [sic] *of tomato paste in his chili recipe. The can contains 4 ounces of tomato paste. How many ounces of tomato paste does he use in his chili?* This time Hanna wrote "1(4) = 1/5 (X)" and explained that she was attempting to use ratios. She then stated that the problem was confusing because "1/5 is talking about of the can, 4 is talking about ounces. So those are two different things." Notice that Hanna attended to a similar feature of both situations—two different things—with very different results. These data provided initial evidence that she did not have a single conception of multiplication that she could apply across problems with whole-number and fractional multipliers.

In subsequent work, also from the first interview, Hanna demonstrated that she did not fully coordinate partitioning a quantity into equal-sized pieces, dividing the value of that quantity by a whole number, and multiplying the value of that quantity by a unit fraction. As she continued to work on the Chili task, she proposed dividing 4 ÷ 1/5 and explained:

> Because you're trying to find a part of the whole and like how much a part of the whole equals. So if you know…you know that the can is 4 ounces and you need…you want to find 1/5…how many ounces 1/5 of that can is then you need to divide 4 ounces by 1/5 to find out how many ounces there are in 1/5.

Later on during the first interview, Hanna worked a more complicated task: *One serving of oatmeal is 1/3 of a cup. For one meal, Chelsea are 2/5 of a serving. How many cups of oatmeal did Chelsea eat?* From the data we could not tell exactly why, but Hanna refined her connections between partitioning and numerical calculation. In particular, she offered a series of explanations, each of which included refinements to previous explanations. Her final explanation coordinated partitioning one serving into 5 parts with dividing 1/3 by 5. She wrote 2 (1/3 ÷ 5) and explained: "So first I divided my 1/3 cup into 5 pieces, because I know that she ate 2/5. So, if I divide it into 5 pieces and then multiply by 2, I can get my 2/5." A few moments later, Hanna acknowledged that she did not know how to compute 1/3 ÷ 5, which we took as evidence that she was not using results of this computation when refining her connections among partitioning, dividing, and actions that could support understanding fractions as multipliers.

Further evidence from the first interview that Hanna did not connect partitioning with multiplying by a unit fraction came on the Pebble task shown in Figure 3. Hanna had no trouble drawing the short path, defining $P$ to be the "amount of pebbles in the long path," and expressing the number of pebbles in the short path with the expression $P \div 8$. At the same time, she explicitly rejected multiplication as a viable option:

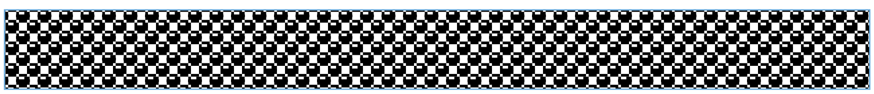
> I don't know how you would use multiplication, because you're trying to find out how much pebbles there are in 1/8 of this long path. So in order to get that, you have to divide the amount of pebbles by 8 to get, right? Yeah, to get that one amount of pebbles. To get…I don't know how you would you use multiplication honestly.

The second interview took place about 3 weeks after the first and after the definition of multiplication shown in Figure 1 had been introduced in the content course. At the time, the definition had only been used with whole numbers. During the second interview, Hanna demonstrated facility with measurement that went beyond her work during the first interview. When working on the task shown in Figure 4, she defined $b$ to be the "beads in short strip" and $B$ to be "beads in long strip." She then generated and explained the equation $B = b$ (LS/SS):

> So first I'm going to see how many short strips can go into my long strip. So I divide my long strip by my short strip, and then I'm going to multiply whatever I get. So how many short strips can go into my long strip times the amount of beads that are in my short strip, and then…then you get how many beads are in your big strip.

Notice first that Hanna appeared to apply a measurement sense to the fraction notation, LS/SS, when discussing "how many short strips can go into my long strip" and second that she connected this measurement sense to the multiplier. Further evidence from the second interview made clear that, although Hanna had made important steps in the right direction, she still had further to go when thinking about fractional multipliers.

The drawing below shows a 1 kilometer long garden path. It is 8 times as long as another garden path. Please draw the other path.



Imagine that the same two paths are covered with pebbles that are of uniform size and are spread evenly on both paths. The dots shown in the long strip indicate the pebbles.

If you knew the amount of pebbles covering the long path, how could you express the amount of pebbles covering the short path?

*Figure 3. The Pebbles task from Interview 1.*

Some strips of fabric have tiny beads sewn onto them. The beads are spread uniformly across each strip.

If you knew the amount of beads in the short strip, how would you find the amount of beads in the long strip?

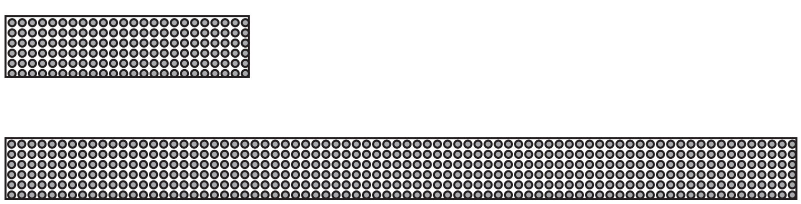


*Figure 4. The Beads task from Interview 2.*

## Conclusion

We are still a long way from illustrating how teachers might better understand individual topics within the MCF by developing a single lens that ties them together; but, the example of Hanna suggests processes through which teachers might construct such a lens. In particular, using the example of emerging facility with fractional multipliers we have illustrated how Hanna used fine-grained coordination and refinement of knowledge resources to extend her understanding of multipliers in the case of whole numbers.

How Do We Teach Thee? Let Me Count the Ways
A Syllabus Rubric with Practical Promise for Characterizing Mathematics Teaching

Sandra Laursen
University of Colorado Boulder

Tim Archie
IDEA Center

*Good methods to characterize teaching are needed to describe both current status and changes in teaching practice, and to link student outcomes to particular instructional practices. Such methods are understudied and thus the relative merits of different methods are not well understood. As part of a study examining multiple methods for characterizing teaching in college mathematics, we analyzed syllabi using three rubrics. Syllabi are authentic course artifacts that reflect course design and instructor's intentions; they are readily available from instructors. One of these rubrics, an evaluative rubric known as Measuring the Promise (MtP), proved useful in distinguishing courses taught by a sample of seven early-career instructors and a comparison sample of experienced active learning practitioners. Good correlation of MtP scores with observation scores using the well-established Reformed Teaching Observation Protocol suggest that the MtP may be a useful alternative to costly and time-consuming observations.*

*Keywords:* syllabi, observations, measurement of teaching

For many studies of higher education, it is important to characterize teaching: to describe teaching practice within an institution or across a discipline, to relate student outcomes to teaching practices, or to measure change in teaching practice over time. However, we do not yet have a good understanding of what can be learned from different approaches to describing teaching, nor the strengths and limitations of these approaches (AAAS, 2013). Yet descriptions of teaching practice form the foundation for claims about the effectiveness of various instructional practices, and thus also the basis of many current efforts to change such practices.

Our study is motivated in particular by a need for good methods to measure change in teaching after professional development of college instructors (CIPD). Funders and institutions need good evidence to determine whether, how, and in what forms, professional development may be a good investment. While better student learning is the ultimate goal, measuring student outcomes directly is not always possible, and faculty may need time to gain skill in the new techniques before student learning is measurably improved.

An alternative is to measure the degree to which faculty implement evidence-based teaching practices, such as those introduced in CIPD programs, together with a "golden spike" approach that links these practices to prior studies that demonstrate how these teaching practices influence student outcomes (Brown Urban & Trochim, 2009). Because teaching is a complex activity, this measurement, too, is challenging. Observational studies are viewed as most objective but are complicated and costly, while well-validated instructor surveys are not yet available (Felder, Brent & Prince, 2011). Course artifacts offer a wealth of teaching-related material that is readily accessible and authentic in representing the instructor's actual work, rather than her later representation of it—but it is less clear how to make inferences from these materials about the instructor's classroom instruction, teaching decisions or philosophy. To understand whether and how CIPD improves STEM teaching, we need valid and reliable measures of teaching practice that can be used to learn whether and how instructors' practices and choices change after CIPD.

This methods development study was exploratory by design, involving close examination of teaching practices in seven undergraduate mathematics courses taught by early-career instructors. We compared insights gained from a full suite of teaching measures: student and instructor surveys, observations, and coding of course syllabi and assessment items. The study focused on the potential of these measures to detect change in instruction, such as the changes that might result from professional development, but we did not directly study change. Thus the study is a close look at a small sample. We sought to identify methods that are both informative and practical for measuring teaching practice, and to make judgments about when and how these methods may be useful—alone or combined—in characterizing teaching. This work thus offers advice to researchers and evaluators to make intelligent choices for their own studies.

Our broad research questions were:

1. What are the affordances and limitations of behavior-oriented and outcome-oriented observations, faculty self-reports, student reports and classroom artifacts as methods for characterizing teaching in undergraduate mathematics classrooms?
2. What are the differences among characterizations of teaching in undergraduate mathematics classrooms that are based on these distinct types of measures?

Our study explored both descriptive and evaluative measures of teaching. Evaluative or "outcome-oriented" measures examine the aims and effects of instruction rather than the choesn activities, rating instruction against a specific standard for "good teaching," thus differing from strictly descriptive or "behavior-oriented" measures. Here we focus on two evaluative measures, a widely used observation protocol and a rubric for analyzing course syllabi. These two methods, observation and syllabus analysis, represent extremes of simplicity and complication in the logistics and invasiveness of data gathering and the demands of data analysis, so it is interesting to compare their potential as measures for characterizing mathematics teaching.

## Study Sample

We recruited instructors from MAA Project NExT (PN), New Experiences in Teaching, a professional development program for early-career mathematics instructors. Working with early-career instructors whose teaching methods were still developing, we were able to observe a range of teaching behaviors and skill levels that are likely comparable to those encountered in studying professional development outcomes for other instructors of undergraduate mathematics. We also sought to gather data from courses for varied student audiences and at varied curricular levels.

We solicited study participants through selected PN listservs, inviting respondents to read an online description of the study, review the consent form, and complete a pre-screening questionnaire about their courses and academic calendars. Ultimately, seven instructors took part.

This sample included variety across instructors, courses, departments and institutions. The *instructors* included 4 women and 3 men. Six were white and one was multi-racial; none were Hispanic. Five held tenure-track positions, one a long-term instructorship and one a visiting position. Their teaching experience (including TA work) was 3 to 10 years. Their *courses* spanned the early (3), middle (2) and late (2) undergraduate curriculum and a range of mathematics, STEM, non-STEM, and pre-service teaching audiences. Class size was small, 8-28 students. The six semester-based and one quarter-based courses met for 35-56 hours each. The courses were situated in *departments* that granted bachelors (3), masters (2) or doctoral (2) degrees as the highest mathematics degree. The *institutions* were diverse in geography, institution type and student enrollment; two had high minority student populations.

## Study Methods

Working with each instructor, we selected a single target course from which we collected all data. With this small sample we could not generalize about any particular instructional setting, but we could test the applicability of these methods in varied settings. Each instructor contributed data to support six study components:

a) Video observations of ten class periods, coded with descriptive and evaluative protocols
b) Instructor survey, end of course, self-reporting teaching practices
c) Instructor interview
d) Student surveys, end of course, including both descriptive and evaluative items
e) Course syllabus, coded with descriptive and evaluative schemes
f) Course-specific subset of assessments identified from the syllabus.

In this report, we focus on methods (a) and (e), using observation data as a benchmark to evaluate a syllabus rubric as a possible tool to characterize teaching with relatively low effort. The rubric also offers good potential as a tool for formative evaluation or for providing feedback to instructors as professional development. Elsewhere we discuss results from other methods.

### Why Study Syllabi?

As Eberly, Newton and Wiggins (2001) point out, the syllabus is both "the initial communication tool that students receive" and "the most formal mechanism for sharing information with students" (p. 1) about a course. Ideally, it is "a learning-focused document that communicates clearly and compellingly what students will gain from the course, what they will do to achieve the promise it lays out, how they will know whether they are getting there, and how to best go about studying" (Palmer, Bach & Streifer, 2014b). If, as these authors argue, the syllabus serves as a "framework for designing meaningful learning environments," then it follows that we may be able to diagnose the presence of such intentional and student-focused design from syllabi. Syllabus analysis offers advantages for data collection too: the syllabus is already written and widely available, so collecting it requires low instructor effort; it is brief, thus rapid to analyze; and it is public, so gathering it should not require special IRB permission.

### Analysis of Syllabi

We tested three syllabus analysis tools found in the literature. The SPROUT-S protocol is a descriptive protocol developed at UC Irvine to study the relationship of student academic outcomes to the use of "promising instructional practices" in undergraduate STEM courses (Reimer et al., 2016). The Penn State Engineering Education protocol (Zappe et al., 2015, 2016) is also descriptive, a list of 47 research-based practices in engineering education that is drawn from synthetic work by Hattie (2008) and Chi (2009) examining factors related to student achievement and student learning. While in principle a descriptive approach could assist in analyzing the presence or prevalence of certain instructional methods or philosophies, we found neither of these descriptive tools useful for our study, as we will describe in our presentation.

Instead, the analysis presented here focuses on an evaluative rubric, Measuring the Promise (MtP), a validated rubric from faculty developers at the University of Virginia (Palmer, Bach & Streifer, 2014a). As a rubric, it defines a coherent set of criteria and describes different levels of performance quality on the criteria (Brookhart, 2013). It could thus be used in formative evaluation—to guide professional development on course design—as well as a summative assessment tool. It is designed for use in any discipline.

The holistic and evaluative rubric is strongly literature-based (Palmer, Bach & Streifer, 2014b). The full rubric uses 16 items grouped into five categories: learning goals and objectives, assessment, schedule, classroom learning environment, and learning activities. Each item is rated gold, silver or bronze to indicate its relative importance in the scoring rubric—which is in turn based on its expected influence on student outcomes—and the rater classifies the strength of evidence about each as strong, moderate, or low. The authors specify their assumptions about the rater's background knowledge and provide examples of the kinds of evidence used to assess each criterion. Raters must understand Fink's (2013) significant learning goals, distinguish learning goals and objectives, and assess alignment of goals, objectives, activities and assessments in course design. With this background, modest training is required to achieve interrater reliability.

To emphasize the presence and quality of essential features, the scoring system weights both the features (3,2,1) and the evidence for them (2,1,0) (CTE, 2017). The maximum score is 58: a 'learning-focused' syllabus will score in the range of 41 and higher; a 'content-focused' syllabus at 18 or below. Syllabi in between are called 'transitional.'

For the early-career instructors, syllabi from seven courses taught in 2015-16 were coded using the MtP, plus two more syllabi representing earlier versions of the same course. For comparison, 12 syllabi were coded for courses taught in 2016-17 by 'expert' instructors known to use strongly student-centered teaching approaches.

**Observation Coding with RTOP**

The Reformed Teaching Observation Protocol (Sawada et al., 2002) was developed to evaluate the degree of "reform" toward student-centered teaching in science. RTOP's 25 items assess the degree to which the classroom is learner-centered in five categories: lesson design and implementation, propositional knowledge, procedural knowledge, communicative interactions, and student-teacher relationships. RTOP scores in K12 classrooms have been correlated with student achievement and used to assess change as a result of CIPD. It requires significant training and nuanced judgment against externally defined criteria for effective teaching.

We collected observation data for 8-10 class sessions taught by the early-career instructors using a portable video camera shipped to instructors and mounted behind students, facing forward. We followed RTOP data analysis methods outlined by Ebert-May et al. (2011). Five items forming five subscales are scored on a Likert scale 0-4. After initial training, six videos were randomly selected and coded by three raters. We tested interrater reliability by computing intraclass correlation coefficients (ICC) and achieved an acceptable ICC level (>0.80) for overall RTOP scores and for each subscale.

One rater then coded five randomly chosen class sessions for each of the seven courses. We computed RTOP and subscale scores for each class and calculated means of the five observations for each course. Total scores of 0-100 are classified into five categories using score breakpoints of 30, 45, 60, and 75, where scores ≤30 are interpreted as "straight lecture" and scores >75 as "active involvement in open-ended inquiry," with intermediate scores placed along a spectrum of interaction and inquiry. Because the classifications are framed in language common in discussing inquiry-based science, such as carrying out experiments, we re-interpreted the classifications for college mathematics, considering inquiry-oriented processes such as preparing, explaining and critiquing proofs or problem solutions, and explicitly considering alternative solutions.

## Results

Figures 1 and 2 show MtP scores for syllabi from courses taught by early-career (designated PN for Project NExT alumni) and experienced instructors (EX). As a group, total scores for courses of experienced instructors (mean 32 ± 12) were not statistically distinguishable from those of early-career instructors (mean 30 ± 13). However, 3 of 7 courses by early-career instructors, vs. only 1 of 9 courses of experienced instructors, were rated as content-centered. In both figures, arrows link pairs of syllabi for a single course that represent a particular instructor's historical and current practices; these pairs are discussed further below.

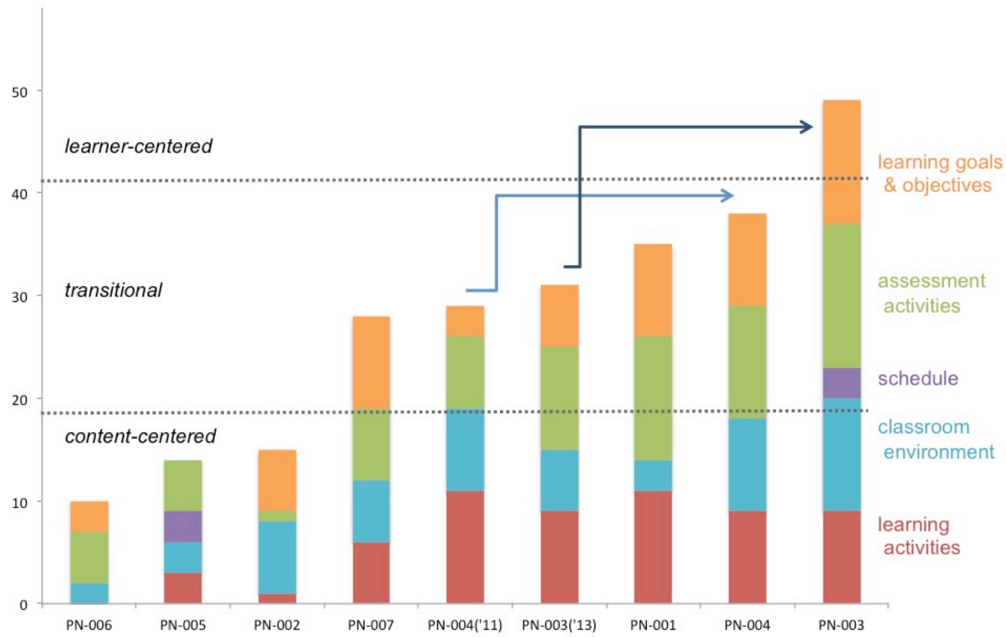

*Figure 1: MtP syllabus ratings for early-career instructors, by item category.*

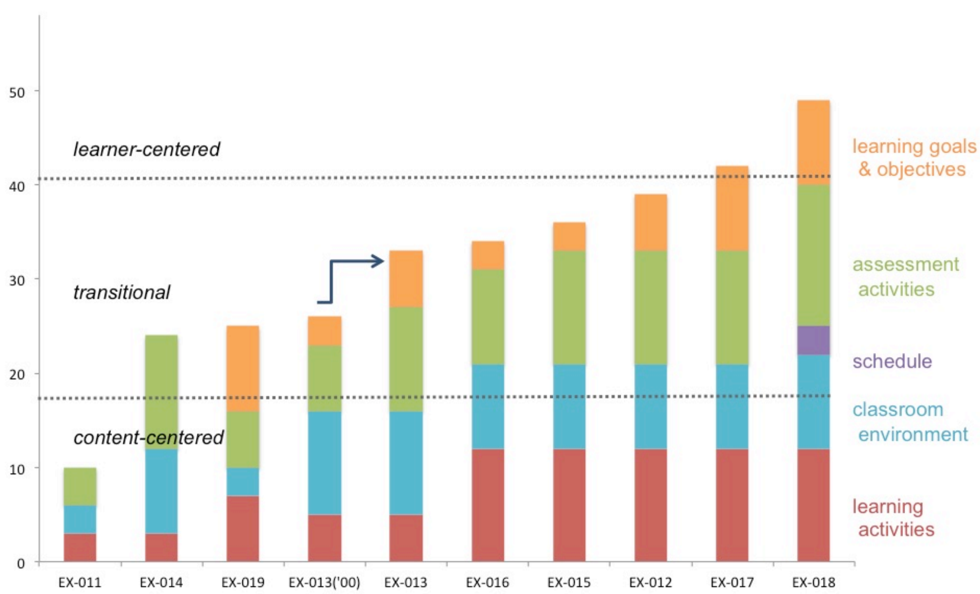

*Figure 2: MtP syllabus ratings for experienced instructors, by item category.*

Comparing subscores in detail reveals some more distinctive patterns of difference between early-career (PN sample) and experienced (EX sample) instructors. Scores on *learning goals and objectives* were slightly higher among early-career instructors (mean of 6.3 for PN vs 4.8 for EX, of 12 points maximum). Scores on *assessment activities* were fairly high for both groups (8.0 PN, 10.1 EX, of 12). In mathematics, homework is frequently assigned and used to give formative feedback. Scores on the *schedule* were low across the board (0.7 PN, 0.3 EX, of 6). Scores for the *classroom environment* were higher among experienced instructors (8.3 EX, 6.1 PN, of 12). Scores for *learning activities* were moderate to high among both groups, but somewhat more consistent among experienced instructors (6.6 PN, 8.3 EX, of 12).

Comparison of current/historic pairs of syllabi (marked by arrows in Figures 1 and 2) for individual instructors shows positive change over time for the three cases available that reflect the start of a teaching career as compared to now. Other data (not shown) suggests that very experienced instructors find a teaching groove and stick to it; their MtP score does not change.

These data suggest that the MtP has good discrimination on aspects of course planning that may differ between instructors of differing experience and/or skill. To relate the syllabus score to a measure based on actual classroom practice, we compared the MtP scores to mean scores on the RTOP (Figure 3) for the PN sample, for which we had both data types.

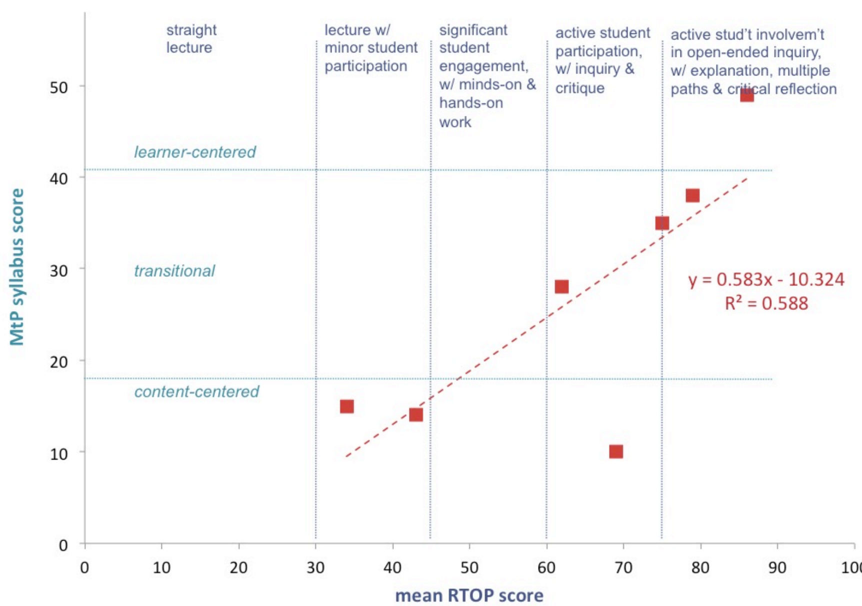

*Figure 3: Correlation of MtP syllabus scores with RTOP scores, including score classifications*

Five of seven courses score in the active learning ranges of the RTOP scale, while two scores are described as interactive lecture. Moreover, MtP syllabus scores correlate well (R=0.59) with mean RTOP scores. In general, low MtP scores reflect underdeveloped or incomplete syllabi; actual classroom practice may be more interactive and inquiry-driven than is shown in the document. For example, the outlying point in Figure 3 represents a course where we observed inquiry activities, peer to peer collaboration, and extensive use of multiple representations of mathematical ideas, yielding a medium-high RTOP score, but the syllabus was disorganized, overly rule-oriented, and uninviting to the learner as an entrée into the discipline.

## Discussion

In general experienced active-learning instructors scored high on the MtP items for *classroom environment, assessment* (especially formative assessment), and *learning activities*, thus the rubric does show evidence of their student-centered orientations. Some of the early-career instructors were also IBL users, and their syllabi reflect aspirations toward the same student-centered practices. The reverse trend for *learning goals and objectives*, where early-career instructors scored higher, may reflect greater exposure of early-career instructors to learning goal-setting through professional development or exposure to RUME work. In addition, interview data revealed that some departments had set common learning objectives for particular courses; thus the learning objectives may be inherited rather than originated by the instructor.

Low scores on *schedule* arose because information on the choice and sequence of topics was commonly missing in syllabi from courses using inquiry-based learning (IBL), which reduced the score on items related to the intellectual organization or conceptual flow of the course and its pacing. It is also possible that college mathematics instructors take course content as canonical, whether or not they use IBL. For instance, with high consensus about what goes into a Calculus 1 course, and with many students required to take it, instructors may not think to justify to students their choices about the selection and sequencing of big ideas. Content sequencing may also be seen as given if it is decided departmentally and used by all who teach the same course.

In the cases where we could compare two versions of a course, the observed changes in MtP score suggest that the rubric is sensitive to change over time in instructors' practice.

The strength of correlation between the MtP and the RTOP is somewhat surprising, given that the MtP is based solely on the written plan for the course, and the RTOP rates instruction as implemented in class. However, both are holistic measures that focus on instructional design and set standards for 'good teaching' that are literature-based and thus aligned in many respects. Coding of a separate observation sample with RTOP will tell us if this correlation is robust.

Both our study groups, early-career and experienced, were more learning-focused than a general university instructor population (CTE, 2017). Mean MtP scores exceeded the median pre-test score for faculty who enrolled in a week-long institute on course design—but were lower than the post-test scores for those faculty. However, our study samples do not represent college math instructors nationally; they were volunteers already participating in educator communities.

## Conclusions and Implications

The MtP emphasizes instructors' design choices, as reflected in their syllabus, and focuses on clarity and alignment of the course design. It does not attempt to judge how well a course is executed but does capture elements of how instructors view students, teaching, and their subject. The rubric offers high face validity, due to its grounding in instructional design literature, and good discrimination, due to the weighted scoring system. Moreover, syllabus analysis with the MtP offers advantages for both gathering and analyzing data. In these ways, we find the MtP rubric a tool with significant potential to be useful in studies of teaching or change in teaching.

The correlation of MtP with RTOP in this small data set is particularly intriguing, because it suggests the potential of MtP to substitute, in some studies, for time-consuming and costly observations. Like the RTOP, MtP does require specialized expertise to apply, but it is well supported with coder training materials. Analysis of a limited data set suggests that the MtP has promise in detecting change in individuals' practice over time, but may be less useful in characterizing entire groups of instructors, due to the variability within groups.

# Learning Our Way into Effective Professional Development: Networked Improvement Science in Community College Developmental Mathematics

Carlos Sandoval, Haley McNamara, Ann Edwards

*Every year, hundreds of thousands of college students are placed into, and do not complete, developmental math courses. The Carnegie Math Pathways, a nationwide initiative aimed at addressing this problem, is comprised of a student-centered instructional system that forefronts mathematical sense-making and conceptual understanding; structural changes to course offerings; and a system of faculty professional development. This paper reports on the use of Improvement Science, an approach grounded in methods and tools of quality improvement, to design, improve, and scale a professional development program for first-time Pathways instructors. We also report on insights derived from the improvement approach about effective professional development in the Pathways and findings related to common challenges faced when teaching the Pathways. We conclude with implications for professional development in higher education and the use of improvement science to scale effective professional development.*

*Keywords:* Developmental mathematics, professional development, community college, improvement science, continuous improvement

## Introduction

Over 14 million students are enrolled in community college, seeking an educational pathway to a productive career and better life. Between 50 and 70% of incoming community college students must take at least one developmental math course before they can enroll in college-credit courses (Bailey, Jeong, & Cho, 2010; Complete College America [CCA], 2012). However, 80% of the students who place into developmental mathematics do not complete a college-level math course within 3 years (Bailey et al., 2010). The pattern is similar in comprehensive 4-year institutions, where 20% of incoming students are placed into developmental math, and 63% do not complete a college-level math course within 2 years (CCA, 2012). Taken together, roughly 1.7 million first-time undergraduate students are placed into developmental math each year (CCA, 2012). Many of these students spend large amounts of money and long periods of time repeating courses; most simply leave college without a credential or developing a sufficient command of the mathematics needed to engage as productive citizens.

To address this national issue, the Carnegie Foundation for the Advancement of Teaching together with the Dana Center at the University of Texas at Austin developed an innovative, transformative strategy in undergraduate mathematics education: the Carnegie Math Pathways [CMP] program. The CMP consists of two distinct course sequences—Statway and Quantway, referred to collectively as the Pathways—that are designed to accelerate developmental students to and through college-level mathematics in one year. Their instructional design provides students with opportunities to learn mathematics content that is more engaging and relevant to their goals than they would encounter in traditional remediation and do so in pedagogical environments that are student- and problem-centered and that support students' persistence and engagement. The CMP initiative is organized as a Networked Improvement Community (NIC), a collection of institutions centered on addressing a particular problem and disciplined by the rigor of an approach called Improvement Science (LeMahieu, Edwards, & Gomez, 2015). The CMP NIC, currently comprised of over 65 IHE's (largely community colleges), organizes its collective efforts to dramatically improve the outcomes and quality of learning of their developmental math students.

We report here on an examination of a key component of CMP: the Faculty Support Program (FSP), professional development aimed at preparing and supporting first-time Pathways instructors. We address how Improvement Science is used to learn about effective professional development and for continuous program improvement. We begin with a discussion of the community college environment as it pertains to instruction and professional development. We then describe the FSP and our use of Improvement Science in the FSP. We then present a brief description of our findings pertaining to professional development in community colleges and conclude with implications, limitations, and directions for future research.

## Background and Context

### The Developmental Math Challenge

The reasons for the low success rates in developmental mathematics are complex. The structure of the traditional developmental math course sequence (Hodara, 2013) and the complexity of the course options are significant barriers to student retention and completion (Cullinane & Treisman, 2010). Also, developmental math instruction often does not employ research-based learning materials and pedagogical practices that can foster deeper student learning (Bransford, Brown, & Cocking, 1999). Many developmental math classrooms resemble the content-focused, knowledge transmission model so prevalent in undergraduate instruction (Bailey, Jaggars, & Jenkins, 2015; Grubb et al, 1999; Grubb & Gabriner, 2013). Instructional activities tend to focus on factual and procedural knowledge as opposed to conceptual content and mathematical sense-making (Mesa, 2011). Many developmental math curricula do little to engage students' interest and demonstrate the relevance of mathematical concepts to everyday life (Carnevale & Desrochers, 2003). In addition, instructors who may be open to alternative approaches, such as learner-centered models, are often skeptical of their efficacy for developmental students, who they perceive as weakly prepared and resistant to such strategies (Grubb & Grabiner, 2013). Many developmental math students have had negative prior math experiences leading to the belief that they are "not math people." These beliefs often trigger anxiety in students who encounter difficult math problems (Blackwell, Trzesniewski, & Dweck, 2007; Haynes, Perry, Stupnisky & Daniels, 2009).

### Carnegie Math Pathways "Change Package"

To address these long-standing challenges, the CMP NIC developed the CMP instructional system: a "change package" organized around Statway and Quantway. In Improvement Science (IS), a "change package" is a well-defined, evidence-based set of "change ideas" and associated metrics. The CMP change package consists of the following components:

**Accelerated pathways:** Rather than being faced with a maze of possible course options (Zeidenberg & Scott, 2011), students are offered an accelerated pathway that meets developmental math requirements and provides college math credit upon successful completion (Cho, Kopko, Jenkins, & Jaggars, 2012; Jaggars, Hodara, Cho, & Xu, 2015).

**Mathematics content relevant to college, career, and citizenship:** Statistics and quantitative literacy, respectively, are the core college-level content and conceptual organizers for Statway and Quantway, with developmental math learning goals integrated throughout. Both courses emphasize core mathematics skills needed for work, personal life, and citizenship, and stress conceptual understanding and its application in a variety of contexts (e.g., Gillman, 2006; Madison & Steen, 2008; and GAISE College Report ASA Revision Committee, 2016).

**Pedagogy supporting deep and flexible mathematics understanding:** Grounded in research on teaching for mathematical understanding and the development of mathematical practices (e.g., Bransford, Brown, & Cocking, 2000), CMP pedagogy emphasizes productive struggle with challenging problems (Schmidt & Bjork, 1992), making conceptual connections explicit (Hiebert & Grouws, 2007), deliberate as opposed to routine practice (Ericsson, 2008; Pashler, Rohrer, Cepeda, & Carpenter, 2007), opportunities for rich mathematical discourse (Moschkovich, 2007), and the role of collaborative learning in promoting mathematical sense-making (Esmonde, & Langer-Osuna, 2013; Webb, 2009).

**Productive Persistence supports:** Integrated throughout the CMP is an evidence-based package of interventions and practices to increase student motivation, tenacity, and learning skills. Based on research from social psychology, strategies focus on reducing student anxiety (Jamieson, Mendes, Blackstock, & Schmader, 2010), increasing a sense of belonging (Walton & Cohen, 2011), and countering fixed mindset (Dweck, 2006).

**Reducing language and literacy barriers:** Given students' diverse linguistic backgrounds, supports and interventions are interwoven into the curricula and pedagogy to assist students with the complex language and literacy demands of mathematics, with its different forms of representation and grammar (Gomez, Rodela, Lozano, & Mancevice, 2013; Gomez et al., 2015).

**Faculty professional development:** A robust professional development system has been crucial as the CMP have moved from early adopter colleges to institutional contexts with more adjunct and inexperienced faculty and limited institutional capacity—this is the focus of the analysis reported on in this paper.

## Teaching and Professional Development in Community College Mathematics

The shifts in pedagogy that the Pathways demand are challenging for many instructors due in part to their professional backgrounds and the availability of professional learning opportunities. Despite the emphasis on teaching in community colleges (Grubb et al., 1999), community college faculty are no more likely to have completed pedagogical coursework than faculty in research institutions. Heavy teaching loads and the low budget priority given to professional development prevalent in community colleges are not conducive for creating opportunities to learn about and develop instructional practices (Bailey, Jaggars, & Jenkins, 2015; Grubb et al., 1999; Tinberg, Duffy, & Mino, 2007). The problem is exacerbated in developmental education, where adjunct faculty, who often have heavier teaching loads, reduced access to professional development, and are assigned lesser status by their peers (Grubb, Badway, & Bell, 2003), constitute 76% of all developmental instructors (Center for Community College Student Engagement, 2014). Although evidence suggests that high quality professional development is critical for sustaining the impacts of systemic reform (Desimone, 2009; Fishman, Marx, Best, & Tal, 2003; Supovitz, Mayer, & Kahle, 2000), professional development in community colleges is described as ad hoc and lacking significant institutional support (Twombly & Townsend, 2008). Additionally, it typically consists of one-shot workshops that do not provide meaningful opportunities for professional learning (Bailey, Jaggars, & Jenkins, 2015; Huber, 2008).

Faculty professional development remains a critical and underutilized driver for improving student outcomes. Little research details the design of effective professional development centered on instructional improvement for developmental math instructors; nor has prior research documented challenges in trying to implement research-based professional learning experiences in community colleges (Twombly & Townsend, 2008). This paper focuses on efforts to address barriers to meaningful and effective professional development in community colleges, reporting on a specific professional development component, the Faculty Support Program (FSP), to prepare first-time Pathways instructors.

**The Carnegie Math Pathways Faculty Support Program (FSP)**

The design of the FSP is informed by the following set of principles derived from research on effective professional development, primarily from K-12 settings (Hawley & Valli, 2007; Hunzicker, 2010; Guskey, 2002; Garet, et al., 2001; LeMahieu, Roy & Foss, 1995): (1) program structure provides for sustained opportunities for professional learning; (2) learning activities are job-embedded, supporting emergent problems of practice; (3) learning activities are context/discipline specific; (4) learning activities provide opportunities for collaborative reflection; and (5) learning activities are centered around artifacts of classroom practice.

The context of the CMP NIC creates specific challenges for program design. CMP faculty are spread throughout the country and tremendous variability exists in the availability of campus resources. Participation in the FSP is voluntary and outside of professional obligations. Therefore, FSP offerings must be flexible and responsive to the needs of faculty, demonstrate clear value to faculty (and administrators), while also providing meaningful opportunities to develop practice. Thus, the FSP includes multiple modalities for faculty engagement, comprised of online activities and resources; intensive, face-to-face workshops, such as national and locally-based workshops; and one-on-one mentoring from designated Pathways faculty mentors who provide support in planning and teaching, including ongoing, just-in-time support.

The design principles and structural components of the program serve as critical guidelines in the spread, and scale of the FSP, particularly as the NIC grows rapidly. In 2015-2016, student enrollment quadrupled to 6220 students, resulting in 222 faculty members teaching the Pathways across 36 institutions nationwide (Hoang, Huang, Sulcer, & Suleyman, 2017). Additionally, the Pathways is spreading to settings widely variable in policy and culture. What is needed is an approach to learning about effective professional development across settings for program improvement. To do so, we employ an Improvement Science approach, detailed next.

## Approach and Methods: Improvement Science as an Approach to Theory Development, Knowledge Generation and Program Improvement

Educational interventions and programs demonstrate limited efficacy at scale (Elmore, 1996), potentially because traditional approaches to research and development often rely on promising interventions whose evidence for efficacy is limited to experiments conducted in controlled settings (Bryk, Gomez, & Grunow, 2011). As a result, such interventions usually rely on the fidelity of implementation by local actors. While appropriate for simple interventions that are procedural and artifact-centric in nature, complex interventions relying on individuals and their expertise across disparate institutions require a different approach (Bryk & Gomez, 2008). Thus, we employ Networked Improvement Science as an approach to improving and scaling the Pathways' system of professional development. Broadly, Improvement Science (IS) prioritizes addressing complex problems through learning deeply about causal systems; developing theories of action for achieving specific and measurable aims; iterative testing of promising ideas connected to theories of action; the use of measurement to determine performance and improvement; and scaling solutions (Bryk, Gomez, Grunow, & LeMahieu, 2015, p. 7). IS consists of a specific set of methods and tools aimed at improving outcomes through the generation of knowledge of what works, for whom, and under what conditions. In IS, theories—of the nature of the problem, of the local settings and systems, and of improvement—are explicated, tested, and refined over time, using diverse types and sources of data.

The generation of knowledge and development of theory using IS are accelerated through leveraging networks organized around a common aim. Thus, the CMP initiative is organized as a Networked Improvement Community (NIC), a group of institutions that share a common aim, a shared understanding of the problem being addressed, and use IS as a common approach (Russell et al., 2017). This network structure is comprised of individual faculty, institutions, and members of a central, organizing hub. The hub is an organization, the Carnegie Foundation for the CMP NIC, that collects and analyzes data from faculty and institutions to learn about implementation and drive improvement efforts. This affords the initiative the opportunity to accelerate the development, testing, and refinement of theory for and of improvement. The hub manages knowledge generated about problems being experienced and tested interventions so that efforts are not duplicated. We now illustrate one way that IS was utilized in the spreading and scaling of the FSP—the common measurement system we developed to manage and improve the program.

**The Faculty Support Program Measurement System**

Traditional mechanisms for feedback and evaluation of professional development programs are blunt tools; they inform program designers and facilitators about whether or not a program "worked" or how well it was received (Guskey, 2000), but often do not provide actionable feedback that can inform ongoing improvement. They generally do not provide insights into faculty's needs, resources, and constraints relative to the design and implementation of professional development programs.

In contrast, the management of the FSP utilizes Bryk et al's (2015) conceptualization of measurement for improvement. Measurement for improvement (a) creates a common language and cohesive vision of program quality across stakeholders; (b) includes an associated set of routines, protocols, and processes for reviewing the program performance, and (c) allows designers and managers to continuously examine and improve the program for its audience. The FSP leverages this framework to a) design structures and activities around a common vision of effective professional development and b) gauge program performance. The FSP measurement system framework was derived from the Institute for Healthcare Improvement's (IHI) system-level measures approach. IHI devised a suite of system-level outcome measures organized around a set of quality dimensions to assess the quality of healthcare and determine improvement priorities across a network of hospitals (Martin et al., 2007). The FSP's system-level measures (13 in total) are organized around the five dimensions of quality, represented in Table 1. These dimensions, along with our design principles, constitute the FSP design framework.

*Table 1 Faculty Support Program Quality Dimensions*

| Quality Dimensions | Definition |
|---|---|
| Effective | New faculty implement the Pathways with integrity and efficaciously |
| Efficient | Preparation and support structures are not wasteful of time, money |
| Responsive | The specific needs of new Pathways faculty are surfaced and met |
| Community-oriented | New faculty seek support from other faculty, new and experienced |
| Faculty-centered, faculty-owned | Faculty are centrally involved in the process of designing and improving FSP activities |

**Leveraging Network Structure and the Common Measurement System to Improve**

Comprising the FSP improvement infrastructure (in the form of its networked organization and measurement system) are a set of routines, protocols, and social processes for collecting and reviewing incoming data about the performance of the FSP as defined by the quality dimensions. Our current data sources and collection timeline are represented in Figure 2 below.

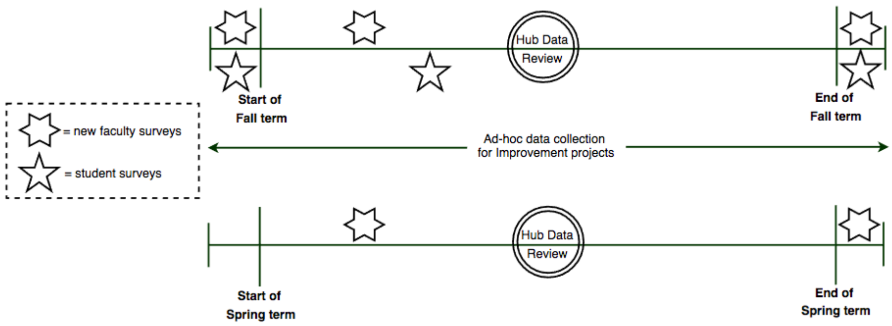

*Figure 1 FSP Measurement Sources and Timeline*

In 2015-16, data were collected from 222 faculty at 36 institutions nationwide. In 2016-17, 462 faculty members from over 65 institutions nationwide are participating. Using the FSP quality dimensions as a guiding framework, data are collected from the network and analyzed by the hub. Data are reviewed twice a year by a diverse set of stakeholders (faculty, institutional leaders, and hub members). During these reviews, stakeholders determine high leverage priorities for improvement, that is, problems that have potential to produce large improvements with relatively lower costs of time and financial resources. Stakeholders then launch improvement projects, often beginning with an investigation into the problems and then progressing towards small tests of changes that may eventually become stable components of the program. The knowledge generated through this process informs the ongoing refinement of our theories of teacher change and the design of professional development driving the work.

## Discussion of Findings

Through this improvement work, three major findings emerged related to the implementation of professional development for mathematics faculty in community colleges. First, the Pathways instructional materials were found to be a critical touchpoint for supporting professional learning. Second, common instructional challenges instructors face in enacting Pathways pedagogy were identified. Third, new instructors' existing relationships at their institutions were often primary sources of support and mentoring. This proposal addresses the first in depth and touches on the others ; if accepted, the final paper will elaborate on all.

### Leveraging Instructional Materials

In our interviews with Pathways faculty in the process of designing and improving the program, the curriculum materials emerged as a core source of instructional support. First-time instructors used the materials as references to better understand lesson tasks and goals and also to guide their implementation of specific pedadgogical moves and decisions within lessons.

CMP instructional materials include student lesson handouts presenting in-class tasks and brief readings and instructor notes, which are instructor-facing materials that contain all content in the student handout along with a) notes about tasks and lesson goals; b) guidance for the implementation of the lesson's activity structures, such as group work or whole-class discussion; c) facilitation guides for whole-class discussion; d) suggested activities or "scripts" for promoting productive persistence; and e) anticipated student responses to rich problems. The manner in and extent to which new Pathways instructors use these materials appears to depend on their familiarity and comfort with the Pathways instructional approach. For those whom the instructional approach is more novel, instructor notes act as a standard protocol to which the instructor adheres for at least the first time. Faculty have reported increased familiarity, comfort, and confidence in teaching the Pathways after using the instructor notes, and they relied on them less in subsequent courses. Instructors more familiar with Pathways pedagogy use the instructor notes as a reference for understanding the lesson objectives, the purpose of each task, and how the lesson is situated within the curriculum broadly. These instructors also annotate the notes with learnings and ideas for future reference, which are often later adapted or omitted upon further trial and reflection.

These findings signaled that, to at least some extent, the materials promoted engagement in some form of reflection on teaching. Although variation existed in how instructors used the materials, we found that nearly all first-time Pathways faculty had studied the instructor notes for each lesson. This finding has broad implications. First, the design of the instructor notes should address specific needs of the faculty. This finding spurred a comprehensive redesign of the instructor notes, in order to better meet the needs of new Pathways faculty and to more effectively surface resources, activities, and opportunities for professional development. Second, while faculty traditionally do not have much pedagogical training in or experiences critically reflecting on their teaching, adjunct and full-time instructors can and often do readily take up opportunities to reflect on their teaching and experiment with instructional moves and practices with which they are not familiar, particularly when those opportunities are accessible.

**Common Challenges When Teaching the First Time**

In a redesign of the FSP, the hub conducted 30 interviews with new faculty in the fall of 2014 to better target resources and design based upon evidence of faculty needs. Five common challenges faced by first-time Pathways instructors emerged: lesson pacing, promoting productive struggle, facilitating group work, sustaining productive persistence beyond the first 4 weeks of a term, and homework completion. If accepted, we will elaborate on this further.

**Leveraging Existing Social Relationships**

Key data collected by the hub as part of program improvement are measures of new instructors' engagement with their assigned Faculty Mentors. A program review in the fall of 2015 revealed low engagement. Through the resulting improvement process, we found that faculty saw local colleagues as a critical source of professional learning and support, and thus resources and structures that leverage existing local support systems were developed, tested, and widely implemented. This finding will also be elaborated upon acceptance.

## Conclusion

The organization of the Carnegie Math Pathways as a networked improvement community has facilitated the design, testing, refinement, implementation, and scaling of the professional development supporting first-time Pathways faculty. Specifically, the NIC organization provided the hub with access to faculty from a wide range of institutions and thus insight into their work processes and needs as Pathways instructors. Additionally, the FSP measurement system aided in specifying areas for improvement, examining how colleges adapt program components to better fit their local context, and determining whether those adaptations resulted in improvement. In sum, engaging users and institutions in collective improvement work around specific problems, and then testing changes to the program to address those problems, provided us with key opportunities to learn about what effective professional development can look like across diverse community college campuses and diverse groups of faculty.

Future Middle Grades Teachers' Solution Methods on Proportional Relationship Tasks

Merve Nur Kursav
Michigan State University

Sheri Johnson
University of Georgia

*This study examines the solution methods that future middle grades teachers chose when solving a problem on proportional relationships. The examination of the solution methods was framed by a new perspective on proportional reasoning that connects multiplication, division, and proportional relationships into a coherent framework. This framework places emphasis on multiple batches and variable parts. The data were collected from a sample of 22 future middle grades teachers' exams completed as part of a content course at a large university in the Southeastern United States. Findings revealed that future middle grades teachers utilized strategies involving multiple batches and variable parts after completing a two-semester sequence of mathematics content courses on proportional relationships tasks.*

*Keywords:* Proportional relationship, Proportional reasoning, Variable parts perspective, Multiple batches perspective

## Introduction

Skills of multiplicative and proportional reasoning are important because their development, or lack thereof, can greatly influence success for students in later mathematics (Beckmann & Izsák, 2015). First introduced in middle grades mathematics, reasoning proportionally forms a crucial base for further concepts such as functions, graphing, algebraic equations, and measurements (Karplus, Pulos, & Stage, 1983; Langrall & Swafford, 2000; Lobato & Ellis, 2010; Lobato, Orrill, Druken, & Jacobson, 2011; Thompson & Saldanha, 2003). Proportional reasoning is difficult, teachers are often not more advanced than their students and in order to teach effectively, one's own understanding must be deepened (Lobato et al., 2011). In addition, researchers pointed out that teachers need to be "sensitive to the types of reasoning that are most accessible as entry points for students while pushing them to develop more sophisticated forms of reasoning." (Lobato el al., 2011, p. 1). Despite the growing body of research on proportional reasoning, the studies that have explored future middle grades teachers' understandings of ratios and proportional relationships are rather limited. Thus, there is a need for research on how future middle grades teachers reason with proportional relationships because "teachers are among the most, if not the most, significant factors in children's learning and the linchpins in educational reforms of all kinds" (Cochran-Smith & Zeichner, 2009, p. 1).

## Purpose of the Study

This study investigates the performances of future middle grades teachers in understanding proportional relationships from two distinct perspectives and considers the role of multiplication and division in their reasoning. Mathematics educators need new approaches and perspectives to think about how future middle grades teachers' reasoning about proportional relationships can be supported. With this objective in mind, Beckmann and Izsák (2015) developed a new approach to reasoning about proportional relationships comprising two perspectives and four methods. These methods encompass a coherent understanding of proportional relationships that includes both multiplication and division. Their approach was innovative because they connected multiplication, division, and proportional relationships into a single coherent framework that highlights two complementary perspectives on ratios and proportional relationships. These two perspectives are called variable parts and multiple batches. In line with Beckmann and Izsák's (2015) approach, this study specifically focused on future middle grades teachers' solution methods related to proportional relationships according to the two perspectives and four strategies. This research was guided by the question: What solution methods do future middle grades teachers use when solving a problem at the end of a content course involving two perspectives on proportional relationships?

## Theoretical Framework

This study is framed by Beckmann and Izsák's (2015) perspective on proportional relationships, which integrates multiplication, division, and proportional relationships into a coherent whole.

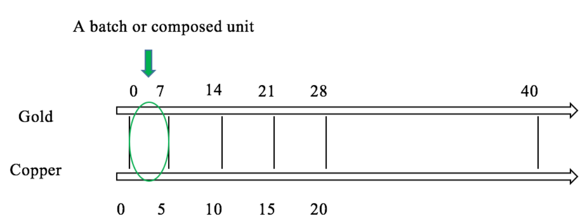
### Equation: M•N= P

Beckmann and Izsák (2015) formalized an equation for multiplication based on equal sized groups as "M • N= P", where M is the number of the groups (multiplier), N is the number of the units (multiplicand) in each whole group, and P is the product amount.

### Perspectives: Multiple Batches and Variable Parts

Beckmann and Izsák (2015) proposed two perspectives, multiple batches and variable parts, by considering the multiplier and multiplicand roles in proportional relationships. In this study, we demonstrate two perspectives by using the following Gold and Copper problem: *To make jewelry, jewelers often mix gold and copper in a 7 to 5 ratio. How much copper should a jeweler mix with 40 grams of gold?*

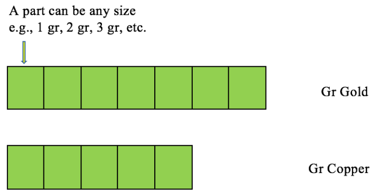
The multiple batches perspective supports at least two solution strategies: multiply-one-batch method and the multiply-unit-rate batch method. For the multiple batches perspective, they stated that "the original batch (A units of the first quantity and B units of the second quantity) are fixed multiplicands, and the multiplier varies; therefore, the proportional relationships can include "all of pairs (rA, rB)", where r > 0 (Beckmann, Izsák, & Olmez., 2015, p. 519). Figure 1 shows one way to represent multiple batches in the Gold and Copper problem.



| Number of Batches | Gr Gold | Gr Copper |
|---|---|---|
| **1** | **1** • 7 | **1** • 5 |
| **2** | **2** • 7 | **2** • 5 |
| **3** | **3** • 7 | **3** • 5 |
| **4** | **4** • 7 | **4** • 5 |

*Figure 1: Multiple Batches Perspective (Beckmann et al., 2015)*

Similarly, the variable-parts perspective supports at least two solution strategies: multiply-one-part method and the multiply-total-amount method. For the variable parts perspective, they considered the two quantities as consisting of A parts and B parts, respectively, where each part contains the same number of units. This time the multipliers are fixed by the numbers of parts, whereas the multiplicand varies with "the number of the measurement units" in every part (see Figure 2). Correspondingly, the multiple-batches perspective, variable-parts proportional relationships include "all of pairs (Ar, Br)" for r > 0 (Beckmann et al., 2015, p. 520). Figure 2 shows one way to represent variable parts in the Gold and Copper problem.



| Gr per part | Gr Gold | Gr Copper |
|---|---|---|
| **1** | 7 • **1** | 5 • **1** |
| **2** | 7 • **2** | 5 • **2** |
| **3** | 7 • **3** | 5 • **3** |
| **4** | 7 • **4** | 5 • **4** |

*Figure 2: Variable Parts Perspective (Beckmann et al., 2015)*

## Methodology

### Research Design

The aim of this study is to explore which solution methods future middle grades teachers used when solving a problem at the end of a content course that introduced two perspectives on proportional relationships. To address the research question, mixed methods were utilized to examine future teachers' solutions. Mixed methods research provides more evidence for studying a research problem than either quantitative or qualitative research alone. Quantitative methods individually provide useful information, however they do not provide an in-depth understanding of the participants approaches and qualitative research makes up for this weakness. Thus, the combination of strength of each approach accounts for the weakness of the other approach. More specifically, we used a sequential explanatory design with a qualitative approach being the first method applied as well as the method of priority (Creswell, Plano Clark, Gutmann & Hanson, 2003). Qualitative research methodologies were used to discover the meanings that participants created in context or in an activity (Wolcott, 2009). When reviewing the student written work qualitatively, we analyzed features of solutions and representations to determine the method they employed. In accordance with sequential explanatory design, it is typical to use qualitative results to reveal additional information and help clarify the primarily quantitative study (Creswell et al., 2003). Thus, we supported our qualitative interpretations with descriptive statistics. This combination of methods provides "multiple ways of seeing and hearing" (Greene, 2007, p. 20). With the priority placed on the qualitative approach, "the researcher builds a complex, holistic picture, analyzes words, reports detailed views of informants, and conducts the study in a natural setting" (Creswell, 2008, p. 15).

### Data Collection

Data for the present study were collected from 22 future middle grades teachers at a large, public university in the Southeastern United States during the Spring 2016 semester of a two-semester mathematics content course. The first semester focused on numbers and operations including multiplication, division, and fractions; the second semester focused on topics related to fraction division, ratio, proportional relationships, and algebra. Both courses emphasized the meaning of multiplication. These courses were intended to help future teachers develop practices outlined in the Common Core State Standards for Mathematics (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010). The same textbook was used for both courses, *Mathematics for Elementary Teachers with Activities* (Beckmann, 2014). It was standard practice in these courses that future middle grades teachers worked in groups during class, however individually completed homework assignments and examinations.

Tasks on the midterm and final exams that addressed proportional relationships were identified. Then items that allowed future middle grades teachers to choose their own methods as opposed to items that directed them to use a particular method were chosen and analyzed. Ultimately, one task from the final exam of the second semester course was selected (see Figure 3).

| | |
|---|---|
| **Task** | To make jewelry, jewelers often mix gold and copper in a 7 to 5 ratio. How much copper should a jeweler mix with 40 grams of gold? Write two different products A•B for the amount of the copper, where A and B are numbers derived from 7, 5, and 40. Explain each product A•B in detail in terms of the situation using our definition of multiplication and using math drawings as support. |

*Figure 3. Task Item*

**Data Analysis**

Drawing on the theoretical framework, we were able to classify the future teachers solutions. This framework is exemplified in Figure 4, which shows solutions for the Gold and Copper problem that illustrate the two perspectives and four methods and how those methods are coordinated with equations following the multiplier (M) • multiplicand (N) convention. Beckmann and Izsák (2015) indicated that double number lines (DNLs) fit well with the multiple-batches perspective and that the strip diagrams fit well with the variable-parts perspective. DNLs represent quantities visually as lengths and afford such operations as iterating, partitioning, or addition. Strip diagrams represent quantities in terms of variable parts.

<table>

<tr><td>Strategy</td><td>Multiply Total Amount</td><td>Multiply One Part</td></tr>
</table>

*Figure 4.* Solutions to the Gold and Copper Problem using two perspectives on proportional relationships and four strategies (Reproduced Kulow, 2017)

The data were sorted based on the perspective future teachers chose (multiple batches or variable parts) and then based on methods that fit with those two perspectives. Task analysis focused on the future teachers' solutions according to their drawings, equations, and explanations.

## Results

Future middle grade teachers who completed the two-semester sequence of content courses emphasizing topics related to ratio, proportional relationships, fraction division, algebra, and the meaning of multiplication were able to appropriately use the multiple-batches and variable parts perspectives. When working on a problem that allowed them to select their own method, future middle grades teachers tended to use the variable-parts perspective as opposed to the multiple batches perspective.

Table 1 shows counts for solution classifications to the Gold and Copper problem. Recall that the task asked for two solutions. The counts in Table 1 show that 44 solutions were provided by 22 future teachers: 19 future teachers used two different methods, two future teachers used one method, and one future teacher used four methods, as shown in Table 1. According to these results, the future teachers used the variable-parts perspective in 29 solutions and the multiple batches perspective in 15 solutions.

*Table 1. Frequency of each method*

| Perspective | Total | Method | Total |
|---|---|---|---|
| Variable Parts Perspective | 29 | Multiply Total Amount | 12 |
| | | Multiply One Part | 17 |
| Multiple Batches Perspective | 15 | Multiply One Batch | 8 |
| | | Multiply Unit-Rate Batch | 7 |
| Total | | | 44 |

The total number of solutions in which future teachers used the variable parts perspective with the multiply-total-amount method was 12, whereas the total number of solutions in which future teachers used the variable parts perspective with multiply-one-part method was 17. Additionally, the total number of solutions in which the future teachers used the multiple batches perspective with multiply one batch method was 8. The total number of the solutions in which future teachers used the multiple-batches perspective with multiply unit-rate batch method was 7. Some future teachers used the multiple batches perspective with multiply-one-batch method logically in combination with a strip diagram instead of a DNL. Some future teachers used the multiple batches perspective with multiply-unit-rate-batch method logically in combination with a strip diagram instead of a DNL.

### Variable-Parts Perspective with the Multiply Total Amount Method

Future teachers who used the variable parts perspective with the multiply-total-amount method included an equation which mainly included appropriate values for M and N (i.e., M is 5/7 and N is 40). For instance, the future teacher LM defined M = 5/7 as “# of groups”, N = 40 as “# of grams in one whole group”, and P = 200/7 is “# grams in 5/7 group”. In addition, LM showed the total amount of gold and copper in the math drawing (see Figure 5).

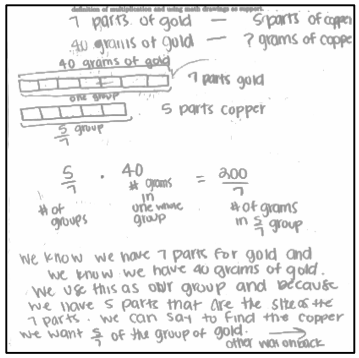

*Figure 5.* LM's solution

## Variable-Parts Perspective with the Multiply One Part Method

Future teachers who used the variable parts perspective with the multiply one-part method included an equation with appropriate values for M and N (i.e., M = 5, N = 40/7, and P = 200/7). The future teacher BM stated M is "# of groups", N is "units per group", and P is "amount of copper needed" (Figure 6).

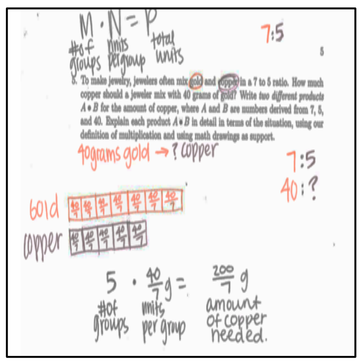

*Figure 6.* BM's solution

## Multiple-Batches Perspective with the Multiply One Batch Method

Future teachers who used the multiple-batches perspective with the multiply one batch method included an equation which mainly included appropriate values for M and N (i.e., M = 40/7, N = 5, and P = 200/7). Figure 7 includes future teacher AH's solution using the one batch method that included explicit descriptions for M, N, and P such as M is "groups gold", N is "grams copper per group", and P is "grams copper per 40 grams gold."

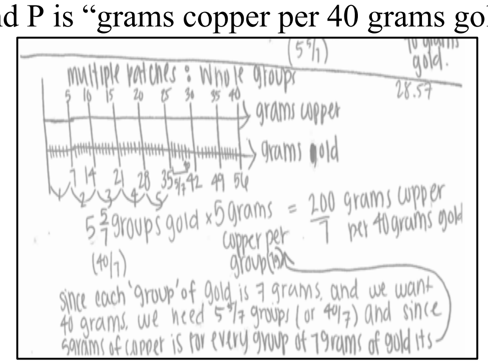

*Figure 7.* AH's solution

**Multiple-Batches Perspective with the Multiply Unit-Rate Batch Method**

Future teachers who used the multiple-batches perspective with the multiply unit-rate batch method included an equation which mainly included appropriate values for M and N (i.e., M is 40, N is 5/7, and P is 200/7). In Figure 8, future teacher KC used the mathematical drawing, showed total amount of gold and copper. More specifically, in KC's solution, DNL indicated target amount (e.g., tick mark for 40 grams of gold) and DNL indicated initial batch (e.g., tick mark for 7 grams of gold and 5 grams of copper) (see Figure 8).

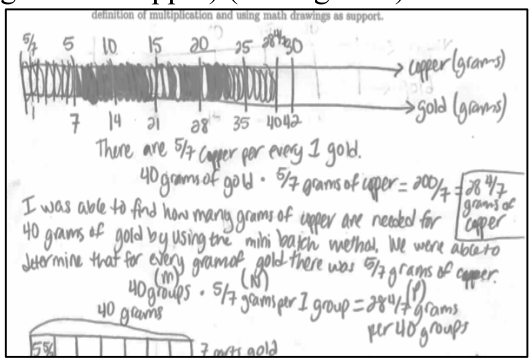

*Figure 8.* KC's solution

## Discussion and Conclusion

Proportional relationships are at the heart of middle grades mathematics, so learning and teaching this concept is crucial. In order to improve learning the concept of proportional relationships, we need to educate future teachers. Thus, there is a need for research on the mathematical training of future middle-grade teachers for better teaching and learning of proportional relationships between co-varying quantities. In order to reach this goal, the education program for future middle grades teachers should be designed to support proportional reasoning. The findings of this study indicated that when topics related to ratio, proportional relationships, fraction division, algebra, and the meaning of multiplication were emphasized in a two-sequence content course, future middle grades teachers were able to use the multiple-batches and variable-parts perspectives and the associated methods in an appropriate way on an exam problem.

This study revealed that two perspectives are important since both have been designed by combining multiplication, division, and proportional relationships. While the sample size of the study is small, more participants are needed in more classes for future work. In addition, studies including interviews are needed to further understand future teachers' solution methods by considering two perspectives.

The instructional approach to topics in the multiplicative conceptual field appeared to support development of future middle grades teachers' understanding of proportional relationships. This approach also supports future teachers' understanding of the meaning of multiplication and division and the use of each perspective's features. According to Beckmann and Izsák (2015), the variable-parts perspective offers students an approach to thinking about variations of quantities in proportional relationship problems. In this study, students used the variable-parts perspective (n = 29) more often than the multiple-batches perspective (n = 15). This result represents the first determination regarding students' tendency when choosing which perspective to work with.

*Because students of color are underrepresented in undergraduate mathematics classes, their experiences are often ignored in studies drawing on large data sets or are inferred based on the experiences of other underrepresented populations, specifically women. This exclusion and misrepresentation of students of color is often attributed to methodological limitations. In this study, we reexamine the data studied for a previous analysis attending to student race and ethnicity rather than to gender. Due to the smaller numbers of non-white students, we utilize different analytic tools, and draw on students' open-ended responses to a survey question asking about their experiences in Calculus I. In addition to adding to the literature on students from marginalized populations in undergraduate mathematics, this paper argues for a reframing of how we value papers with a small N, and what this value indicates about our value of the students making up the small samples.*

*Keywords:* equity, quantitative methods, calculus

A number of recent studies have been published that draw on a large data set to make strong claims about students' gendered experiences in undergraduate mathematics (see e.g., Ellis, Fosdick, & Rasmussen, 2016; Laursen et al., 2011). In each of these studies, the researchers had access to the students' race and ethnicity, but were unable to conduct the same statistical analyses differentiating by race and ethnicity as they did by gender because of the small sample of students from non-white populations. For instance, in discussing learning gains between the active learning courses (specifically Inquiry Based Learning; IBL) and non-active learning courses, Laursen and her colleagues (2011) state: "We could only compare [the learning gains of] white and Asian students, because the number of other students of color in our sample was very low (see Appendix A3)" (p. 55). Similarly, in a recent publication investigating factors related to students' and instructors' experiences in calculus: Hagman, Johnson, and Fosdick (2017) state: "We do not investigate the association between race or ethnicity and [opportunities to learn] due to the small proportion of non-white students and instructors in our study" (p. 5).

Because of the underrepresentation of students of color in undergraduate mathematics courses, their experiences in these courses are made invisible in studies that draw on large data sets, or are inferred based on the experiences of other underpenetrated populations, specifically women. For instance, researchers use Laursen and her colleagues' (2011) paper as evidence that active learning benefits students from "underrepresented" groups. As a prototypical example of this, Webb (2016) states: "Research has shown that undergraduate students who are involved in active learning techniques can learn more effectively in their classes, resulting in increased achievement and dispositions… particularly so for underrepresented groups (Laursen et al., 2011)" (pp. 1-2). While Laursen et al. (2011) are able to make substantive claims about the benefits of IBL for women and typically low-achieving students, which are both underrepresented groups in STEM, these findings are being generalized to make claims about underrepresented students in general, which is often taken to specifically include students from underrepresented racial and ethnic minorities.

While there are some studies about such students' actual experiences in undergraduate mathematics (see Adiredja & Andrews-Larson, 2017 for a review of this literature), such studies are “limited [in] number” (Adiredja & Andrews-Larson, 2017, p. 451) and, due to the underrepresentation of such students in undergraduate mathematics, draw on a smaller data set and often employ qualitative methods. For instance, McGee and Martin (2011) studied the experiences of 23 Black mathematics and engineering college students, Levya (2016) studied the experiences of five Latin@ engineering college students, and Adiredja and Zandieh (2017) studied the experiences of 8 Latina’s in a Linear Algebra course. In comparison, Laursen et al. (2011) drew on survey data from 1,100 students and Ellis, Fosdick, and Rasmussen (2016) analyzed data from 2,266 students, with about 50% identifying as female in each study.

Studies drawing on large data sets are viewed as more reliable and objective than studies drawing on smaller data sets, are able to use statistics to generalize findings, can seek to identify cause and effect relationships, and aid in testing hypotheses (Creswell & Clark, 2007). However, there are a number of issues that arise when considering a quantitative design in the study of race and ethnicity (Adiredja & Andrews-Larson, 2017; Teranishi, 2007). One such issue is simply that the sample size (and the population itself) of non-white populations may be too small in even very large data sets to utilize these benefits. Another issue, as Adiredja and Andrews-Larson (2017) explain, lies in generalizing:

> [G]eneralizability of findings from quantitative studies as a result of a large sample size is always in tension with their reliance on aggregate outcomes and averages. Attending to this tension means being mindful of the reality that the effects on each student in the study are not the same, despite the closing of any gap between groups…The use of averages unfortunately also has the potential to deemphasize any perpetuated inequities. (p. x).

Taken together, these perspectives indicate that both quantitative and qualitative studies can be valuable as we seek to better understand students’ experience in undergraduate mathematics courses, especially understanding experiences of students of color. Qualitative studies are powerful in understanding the nuanced differences of such students, and are able to discuss the experiences of students as individuals rather than as groups. Quantitative studies are powerful in understanding the strength and prevalence of such experiences.

Because students of color are underrepresented and their numbers are small, their experiences are often ignored or are inferred based on the experiences of other underrepresented populations, specifically women. This “exclusion and misrepresentation of [students of color] in education research” is often attributed to methodological limitations (Teranishi, 2007, p. 38). In this study, we reexamine the data studied for a previous analysis (Ellis, Fosdick, & Rasmussen, 2016) attending to student race and ethnicity rather than to gender. Due to the smaller numbers of non-white students, we utilize different analytic tools, and draw on students’ open-ended responses to a survey question asking about their experiences in Calculus I. In addition to adding to the literature on students from marginalized populations in undergraduate mathematics, this paper seeks to argue for a reframing of how we value papers with a small N, and what this value indicates about our value of the students making up the small samples.

## Related Literature and Theoretical Perspective

In K-12 education, African American, Latin@, and Native students continue to be denied equitable access to a high quality mathematics education (Kitchen, Ridder, & Bolz, 2016), including high level mathematics courses (US Department of Education Office for Civil Rights, 2016). This is problematic in higher education due to advanced mathematics courses frequently being used as gateways (pre-requisites) for college credit mathematics and science courses, as well as entrance and continuation in undergraduate mathematics and science courses and majors.

This racialized disparity in K-12 mathematics education access directly and continually negatively impacts the numbers of students of color in higher education mathematics.

Access to resources however represents only part of the marginalized experiences many students of color face in mathematics education. Students of color continue to face systemic racism and racialized negative narratives in mathematics classrooms (Anderson & Tate, 2008; Jackson, Gibbons, & Sharpe, 2017; Spencer & Hand, 2015). Despite the large and still-growing academic research and literature unveiling these disparities and systems of oppression, dominant mathematics education narratives continue to defend the "objectivity" of mathematics as a color-blind discipline (Martin, 2013; Shah, 2017). While this color-blind narrative put forth in defense of the continued practice of marginalization of students of color has been challenged for many years (Gutiérrez, 2007; Martin, 2003; Nasir & Hand, 2006), the issue remains of low concern and priority in higher education, perhaps largely due to the continued low numbers of students of color in college mathematics courses. This underrepresentation, while itself an area of high concern, has set up those students of color who do gain access to college mathematics to have their experiences and even their entire presence often completely erased in research surrounding college/university mathematics education research. One significant contributor to this phenomenon is the practice of removing would-be outliers and/or subgroups within large data sets that have small Ns.

The issue and outcomes of racialized invisibility (Haynes, Stewart, & Allen, 2016) in mathematics education research has been challenged and countered by two notable collectives or research, one housed in the socio-cultural theoretical framework (Boaler, 2008; Hand, 2010; Nasir, 2008; Stinson, 2008) and the other in critical theories (Gutstein, 2006; Leonard & Dantley, 2002; Martin, 2009). Both approaches have made significant contributions toward challenging the dominant narratives and research practices that have worked to erase the presence and experiences of students of color in mathematics education, as well as to elevate the voices and experiences of students of color in mathematics classrooms. While these research endeavors and traditions have elevated the voices, experiences, and presence of students of color in mathematics education, the stigma of the small N remains a significant (albeit socially contrived) barrier for researchers (and their publication reviewers) in quantitative research. Little work has been done to look closely at and provide suggestions and guidance for quantitative researchers whose research involves large data sets and for whom students of color are not an expressed focal point.

Leveraging the notion that the invisibility of students of color in mathematics education research has become a socially acceptable norm, along with the foundational premise of the sociocultural and critical theory research identified above that racial identity, racial experiences, and the presence of students of color in our classrooms are important and they should not be erased by any measures, including a methodological approach. Thus, we take a pragmatic approach to a re-analysis of the data from a previous study focused on persistence in calculus and gender (referred to as the gender-comparison study) with the goal of making an early contribution toward a re-thinking of how the undergraduate mathematics education research community makes its methodological decisions with consideration to students of color.

## Methods

In this study, we conduct three analyses of the data coming from a 2010 survey of Calculus I students, with decreasingly coarse approaches. By doing so we seek to highlight the benefits and drawbacks of each approach, and take all three together to better understand the experiences of students of color in Calculus I.

## Background and Data Collection

The data used for these analyses draws on a national data set made available by the Mathematical Association of America. This data was collected by surveys sent to Calculus I students at the beginning and the end of the course. Data used for this analysis comes from both surveys, focusing on demographic data, persistence data, and a reflective free response question. To determine students' persistence in calculus, we use data from both the beginning and end of term surveys. Students are identified as Persister if they intended to take Calculus II at both the beginning and end of Calculus I, and as Switchers if they originally did intend to and then no longer intended to by the end of Calculus II. For demographics, we rely on three questions: "What is you gender?", with options given only as male and female, "What is your race? (Mark all that apply)" with options given White, Black, Asian, Pacific Islander, American Indian or Alaska Native, and Other (please specify), and "Are you of Hispanic origin?" with responses Yes or No. A new variable was created identifying the students' race and/or ethnicity, where the race and ethnicity questions were combined. Students who wrote in a real race or ethnicity were either grouped with the most aligned category (for example, Puerto Rican students were identified as "Of Hispanic Origin") and students who wrote in something other than a real race or ethnicity category were grouped together with the students who chose not to report their race or ethnicity (for example "human" or "race is a social construct"). Students who identified as multiple non-white races and ethnicities were grouped together. The last question used in this study was a free-response question on the end of term survey, that asked students "Is there anything else you want to tell us about your experience in Calculus I?". Table 1 illustrates the number of students from each race or ethnicity category in the large data set and in the free response data set.

***Table 1.*** *Race and ethnicity for data used*

| | Large Data Set | | FR Data Set | |
|---|---|---|---|---|
| **Race or Ethnicity** | **Number** | **Percentage** | **Number** | **Percentage** |
| White and/or non-Hispanic/Latin@ | 6674 | 68.2 | 348 | 67.0 |
| Non-white and/or Hispanic/Latin@ | 2921 | 29.8 | 157 | 30.2 |
| *Black* | 431 | 4.4 | 28 | 5.4 |
| *Asian* | 1334 | 13.6 | 63 | 12.1 |
| *Pacific Islander* | 70 | 0.7 | 3 | 0.6 |
| *Native American or Alaska Native* | 107 | 1.1 | 11 | 2.1 |
| *Of Hispanic origin* | 844 | 8.6 | 48 | 9.2 |
| *Multiple non-white identities* | 135 | 1.4 | 4 | 0.8 |
| Race or ethnicity identity not listed | 112 | 1.1 | 6 | 1.1 |
| Chose not to report | 86 | 0.9 | 9 | 1.7 |
| Total | 9793 | | 520 | |

## Data Analysis

The first analysis is the coarsest, and attempts to mimic the analysis of the Ellis, Fosdick, & Rasmussen (2016) analysis as much as possible by grouping students into two race and ethnic categories: (a) White and/or non-Hispanic/Latin@ and (b) Non-white and/or Hispanic/Latin@. For this proposal, we conduct chi-square statistics to test if there are significant difference in the persistence in calculus between these binary categories of students. (Note: At the time of submitting this proposal the statistician involved in both studies is on maternity leave and is actually taking a break for work. We honor this break, and thus for this proposal the analyses are not as robust as they were in the initial analysis, nor as robust as they will be for the presentation of this study in February.) The second analysis is similar but disaggregates by race and ethnicity categories. The third analysis is the least coarse and draws on students' free responses on the end of term survey. To analyze these responses, we draw on a thematic analysis conducted for a previous study (Ellis & Cooper, 2016).

## Results

### Analysis 1: Most Coarse

The output variable used for the gender-comparison study was student persistence through the calculus sequence. In that study, we looked at the relationship between gender and student persistence, controlling for a number of factors that may be related, such as career intentions and previous calculus experience. Through that analysis, we found that female students were 50% more likely to be identified as Switchers compared to male students, after controlling for a number of factors. This result was very statistically significant, which we were able to test for because of the large number of students and, more specifically, the large number of students who identified as male (N=1,236) or female (N=1,030).

For the first analysis in this paper, we attempt to mimic the above analysis as much as possible by identifying students as either white, non-Hispanic/Latin@ (N=2213) or not (N=864). In the data set used for this analysis (N=3077), we do not find a significant different between the persistence of white, non-Hispanic/Latin@ students compared to non-white or Hispanic/Latin@ students [$X^2$ (1, $N$ = 3077) = 0, $p$ = .997]. We note that this result holds when students identifying as Asian are included with the white, non-Hispanic/Latin@ students. Among both groups of students, 19.6% of students were identified as Switchers. For reference, 14.5% of all male students and 25.3% of all female students were identified as Switchers. When looking at the intersection between gender and racial and ethnic identity, 26.1% of female, white, non-Hispanic/Latin@ students and 23.8% of female, non-white or Hispanic/Latin@ students were identified as Switchers.

Such a coarse analysis allows us to make claims about statistical significance and compare the findings to the gender-comparison analysis, but this comes at the cost of identifying all non-white, Hispanic/Latin@ students together. However, what this analysis does tell us is that generalizing the experiences of female students as a marginalized population in mathematics to students from racial and ethnic minorities in mathematics does not work, at least in this setting.

### Analysis 2: Less Coarse

In this second analysis, we disaggregate by race and ethnicity identity. As shown in Table 2, while we saw no numerical nor statistical differences in the first analysis, we do see numerical difference in the persistence rates among different race or ethnicity identity groups of students. However, due to the small sample sizes in some groups we cannot make any claims about the significance of these differences.

This analysis shows that there are differences in the persistence rates among students in our sample with different race or ethnicity identities. The most drastic outliers from the general trend are students who identify as Native American or Alaska Native, with 27.9% of the 43 students identified as Switchers, students who reported multiple non-white identities, with 36.4% of the 33 students identified as Switchers, and students who identify as Asian, with 17.3% of the 398 students identified as Switchers. While these results are not statistically significant since we could not test the significance, they convince the authors that students from these populations are likely not persisting through the calculus sequence at the same rates as students from other racial or ethnic groups.

***Table 2.*** *Persistence by race and ethnicity*

| Race or Ethnicity | Persister % | Switcher % | Total N |
|---|---|---|---|
| White and/or non-Hispanic/Latin@ | 80.4 | 19.6 | 2213 |
| Non-white and/or Hispanic/Latin@ | 80.4 | 19.6 | 864 |
| *Black* | 80 | 20 | 95 |
| *Asian* | 82.7 | 17.3 | 398 |
| *Pacific Islander* | 82.4 | 17.6 | 17 |
| *Native American or Alaska Native* | 72.1 | 27.9 | 43 |
| *Of Hispanic origin* | 80.3 | 19.7 | 249 |
| *Multiple non-white identities* | 63.6 | 36.4 | 33 |
| Race or ethnicity identity not listed | 82.8 | 17.2 | 29 |
| Chose not to report | 83.3 | 16.7 | 24 |

While the above analysis does not group all non-white and/or Hispanic/Latin@ together, it still problematically groups all Asian students together (Teranishi, 2007), for example. Also, while this analysis allows us to identify trends between the different racial and ethnic groups of students, we cannot identify the strength of these trends due to the small N.

**Analysis 3: Least Coarse**

In order to take a more nuanced look at students' reports of their experiences in Calculus I and how this may relate to their race or ethnicity identit(ies), we rely on students' free responses to the question "Is there anything else you want to tell us about your experience in Calculus I?". Of the 9,793 students for whom we had race and ethnicity data, 520 provided responses to the open-ended question. These responses were analyzed using thematic analysis (Clarke & Braun, 2006), and was originally studied in order to explore the relationship between persistence and gender (Ellis & Cooper, 2016). The original two authors each coded subsets of 50 student responses to develop and refine codes. Affect was the most frequently used code, and was defined to include statements about "Student's emotions, attitudes, and beliefs about (a) the calculus course, (b) mathematics, (c) themselves as learners." (p. X). Each code was weighted with the values -1, 0, or 1 to indicate a negative, neutral, or positive connotation, respectively, and each student response was coded with as many codes as appropriate.

In this section, we focus on student responses coded with Affect. White, non-Hispanic/Latin@ students have similar frequency of Affect codes and a similar frequency of positive Affect codes when compared to non-white or Hispanic/Latin@ students, with around 45% of responses from each group identified as related to Affect and around 42% of those comments coded as positive. However, among non-white or Hispanic/Latin@ students there are differences within the race or ethnicity identify group – for instance, of the 28 responses from Black students, 57% were coded as related to Affect but only 37.5% of these were coded as positive. While these numbers are too small to make generalizations, they do inspire curiosity among the authors to better understand the experiences of the students in our sample who provided open-ended responses. We highlight a few of the responses from students who identify as Native American or Alaska Native and students who reported multiple non-white identities because of the higher Switcher rates in the second analysis. We also highlight responses from

Black students due to the high number of responses coded as Affect but the low number of those responses identified as positive.

> *This class made me lose my love for math. The teacher was absolutely awful. I had to learn it on my own, and books were not efficient enough to do so. The tutoring program available is a complete and total waste of time unless you wait in there four hours for the two tutors available to help you. Thank you [University] for such a terrible academic standard of professors.* – Male Switcher; Native American or Alaska Native

> *The class was extremely helpful for trying to further investigate modern mathematical applications. The instructor was genuinely concerned with the students' success, and I thought highly of him and his methods of teaching unfamiliar material.* – Male Persister; Native American or Alaska Native

> *Although the material for Calculus 1 was the same in both high school and college, I had much more trouble learning the concepts this year in college than I did in high school. I do not know if that was because my high school teacher taught in a way that I could better understand the concepts; I do know, however, that I did much better in Calculus 1 in high school than in college.* – Female Switcher; Asian and Puerto Rican

> *This Calculus I experience made me dislike Calculus greatly. I found myself confused and lost throughout most of it. My peers had to constantly reiterate what the professor taught in class and I still did not understand.* – Female Switcher; Black

> *I had a great experience. It was much more fulfilling, satisfying, and doable than I had thought it would be.* – Female Persister; Black

The above quotations are presented to help give student voices to the quantitative data. They do not allow us to generalize student voices, to learn how prevalent these voices may be, or how they compare to white voices. Instead, they help to answer the call put forth by Adiredja and Andrews-Larson (2017): "While our ability to conduct quantitative analyses with large sample sizes may be limited, we can still highlight and prioritize the experiences of these students in research" (p. 459). We position these responses as examples of the kinds of powerful differing voices that can be erased when traditional small N decisions are made. In other words, the results are not the trends in what was said, but show that meaningful things were said that indicate racialized experiences exist and should not be erased.

## Brief Discussion

The goal of this paper is to bring attention to the normative practice in our community of ignoring the experiences of students of color in our quantitative studies. While our qualitative colleagues work to richly understand and document the experiences of students of color in our undergraduate classes, and while we eagerly wait for the representation of students of color to increase in our classes and in our data sets, we must challenge and overcome the stigma of a small N. This paper indicates that the experiences of students of color are (a) different from the experiences of women, (b) not all the same, and (c) are more complex that statistics can indicate.

# How Does Problem Context Shape Students' Mathematical Reasoning on Calculus Accumulation Tasks?

William Hall
Washington State University

*Calculus serves many students from myriad fields of study. Investigations into the ways students from these fields of study reason about calculus concepts are vital, yet lacking (Rasmussen, Marrongelle, & Borba, 2014). The biological and life sciences make up 30% of traditional Calculus I students (Bressoud, 2015) and yet we know very little about how these students utilize context as they reason about calculus ideas like the definite integral. In this study, task-based interviews were conducted with 12 undergraduate students majoring in the biological and life sciences. Data were analyzed via open coding from a constructivist grounded theory approach (Charmaz, 2000) and a new analytic tool, local theory diagrams was developed. Results indicate problem context influenced students' assessment of the viability of their solution strategies as well as enabled them to reason through apparent contradictions in their work.*

*Keywords:* Calculus, Integral, Biology

## Framing the Study

Calculus is at the heart of a great many disciplines. Biology, computer science, economics, engineering, and physics are just a few of the undergraduate programs that require at least one semester of calculus. Enrollment in calculus courses at the secondary and post-secondary levels continues to rise (Bressoud, Carlson, Mesa, & Rasmussen, 2013; Kaput, 1997) and so understanding how students reason about calculus concepts is vital to better serve this growing community. Since the 1980s, research in calculus teaching and learning has blossomed into a field unto itself where researchers have explored several areas including the cognitive development of introductory calculus concepts in students and the potential for new digital tools to change calculus instruction (see Rasmussen, Marrongelle, & Borba, 2014 for a review).

Recent studies have highlighted the service nature of introductory calculus at the undergraduate level, since "very few students in Calculus I - between 1% and 3% of those enrolled in this course - intend to major in mathematics" (Bressoud et al., 2013, p. 691). Most students in these classes are majoring in other fields, what are often called the *client disciplines* of calculus. One popular client discipline of calculus is the biological and life sciences. Researchers have identified that 30% of the students in traditional Calculus I courses intend for careers in the biological and life sciences (Bressoud, 2015). However, the traditional Calculus I course "is designed to prepare students for the study of engineering or the mathematical or physical sciences" (Bressoud et al., 2013, p. 691). Which means a great many students in calculus are not seeing many contextually-based tasks catered to their field of study.

This study specifically addresses students' solution strategies on tasks involving the definite integral and accumulation primarily because integration and accumulation serve an important role in differential equations, which are used extensively in modeling within the biological and life sciences. Researchers have investigated student conceptions of the definite integral and have found that calculus students are good at using the standard antiderivative techniques taught in introductory calculus (Ferrini-Mundy & Graham, 1994; Grundmeier, Hansen, & Sousa, 2006; Mahir, 2009; Orton, 1983) and that while area under the curve dominates instruction of the definite integral in calculus, the multiplicative structure of the Riemann sum is a more powerful way to conceive of the definite integral as seen in both mathematics and physics education research (e.g. Jones, 2015a; Sealey, 2014). Unfortunately, researchers have seen that students struggle to make these meaningful connections between rate of change and accumulation in definite integral tasks (Bajrachara & Thompson, 2014; Thompson, 1994). Furthermore, researchers have found that when solving physics-based tasks, students' problem-solving strategies differ in relation to the context presented (e.g., Bajracharya & Thompson, 2014; Jones, 2015b; Sealey, 2014), and that some of these strategies are productive in a physics context when compared to a decontextualized mathematics context (Bajracharya, Wemyss, & Thompson, 2012; Jones, 2015a).

To better serve students from the myriad client disciplines of calculus, we must understand how students solve calculus tasks set in contexts relevant to those fields and whether those contexts play a significant role in their mathematical reasoning. Rasmussen et al. (2014) end their review of the state of research on calculus teaching and learning with a call for "research that closely examines the ways in which calculus ideas are leveraged in the client disciplines, how these ideas are conceptualized and represented in the client disciplines, and what these insights might mean for calculus instruction" (p. 513). The current study was designed to address this gap in the literature. My specific research question is: What role does context play in how undergraduate students majoring in the biological and life sciences solve calculus tasks involving accumulation?

## Theoretical Perspective

The perspective of learning that influenced the construction and analysis of this study is constructivism, specifically a view of knowledge as cognitive adaptation. In a constructivist theory of learning, the fundamental assumption is that learners build up knowledge for themselves instead of being imbued with knowledge by those around them. In other words, the learner must actively participate in the development and organization of the cognitive structures making up their understanding of the world (von Glasersfeld, 1982). To explore an individual's understanding, one must consider the following three factors: "the individual's current state of development, social and cultural influences of a tribe (group), and environmental/physical factors in relation to the task at hand" (Confrey & Kazak, 2006, p. 317). This perspective on learning, while maintaining focus on the individual learner, acknowledges that social and environmental factors must necessarily play a role in that learning. For this study, such a perspective provides the foundation for analyzing individual's approaches to calculus tasks while framing those approaches within the influence of those individual's backgrounds (in this case, as undergraduate students majoring in the biological and life sciences) and the interview setting itself.

One aspect of constructivism that played a key role in the data analysis in this study is a view of knowledge as an adaptive function. Ernst von Glasersfeld, in his interpretation and extension of the work of Jean Piaget, stresses the connection between the mechanisms of evolution by natural selection and how individuals learn. von Glasersfeld (1982) claims "knowledge for Piaget is never (and can never be) a 'representation' of the real world. Instead it is the collection of conceptual structures that turn out to be adapted, or as I would say, viable within the knowing subject's range of experiences" (p. 4). Viability is the crucial idea. Just as with the evolution of an organism in an ecosystem, what students learn is not driven by matching some objectively true reality, but what the student, within their personal "ecosystem," finds viable. Therefore, for learning, as in evolution, there is an emphasis placed on stability and equilibrium. von Glasersfeld states that "in the sphere of cognition, though indirectly linked to survival, equilibrium refers to a state in which an epistemic agent's cognitive structures have yielded and continue to yield expected results, without bringing to the surface conceptual conflicts or contradictions (p. 5). This is the heart of the concept of viability in constructivism, that learning is the development of stable cognitive structures and forms the foundation for the analytical tool developed herein, local theory diagrams, which were designed to highlight this process of students assessing the viability of their mental schemes.

## Methods

To answer the research question posed, qualitative methods were employed. I utilized task-based interviews with twelve undergraduate students majoring in the biological and life sciences at a large public university in the Southeastern United States that I will call South State University (SSU) in the spring of 2016. Task-based interviews allowed me to investigate students reasoning about calculus tasks involving accumulation and to probe their understanding as they solved the problems. Data were open-coded via methods from constructivist grounded theory (Charmaz, 2000) which led to the development of a new analytic tool, local theory diagrams.

### Participants

The population was all undergraduate students majoring in the biological and life sciences at South State University (SSU). SSU is a large, public university serving approximately 24,000 undergraduates. The students at SSU are of high academic caliber; half of all incoming freshman rank in the top ten percent of their high school class with a GPA of at least 3.75. SSU is considered “very selective” with 46% of applications admitted per year (The College Board, 2017). Students majoring in the biological and life sciences at SSU at the time of this study, were required to take at least two semesters of calculus, either the calculus sequence for life and management sciences or Calculus I and II.

Participants were solicited by visiting second semester calculus courses specifically designed for students studying in the biological and life sciences as well as upper-level courses within the biological and life sciences. Twelve students were interviewed, half of which were freshman or sophomores while the other half were juniors or seniors. The students were predominately female (8 of 12) and Caucasian (11 of 12).

### Interview Protocol

In this study, I utilized task-based interviews in which students completed five calculus tasks concerning accumulation (approximately 50 minutes). In each of the five tasks, the students were presented with a rate of change function of some quantity and asked questions about the accumulation of said quantity over various periods of time. To answer the research question: “What role does context play in how undergraduate students majoring in the biological and life sciences solve calculus tasks involving accumulation?”, the contexts for the tasks were chosen to be diverse but relevant for the students’ backgrounds. In this session, I will discuss the results of two of the tasks, which are reproduced below in Figures 1 and 2.

**Task 3**

The greenhouse effect is the rise in temperature that the Earth experiences because certain gases prevent heat from escaping the atmosphere.

According to one study, the temperature is rising at the rate of: $R(t) = 0.014t^{0.4}$ degrees Fahrenheit per year, where $t$ is the number of years since 2000. Given that the average surface temperature of the earth was 57.8 degrees Fahrenheit in 2000, predict the temperature in 2200.

*Figure* 1. *Interview Task 3*

**Task 5**

A new virus has shown up in a small town. The following table gives the estimated rate of change of the number of infected individuals on a given day (measured in people per day). Describe how the number of infected people is changing and use the information in the table to estimate the total change in the infected population over the given time period.

| Days | **0** | **2** | **4** | **6** | **8** | **10** | **12** | **14** | **16** |
|---|---|---|---|---|---|---|---|---|---|
| Rate (Infected per day) | 18 | 25 | 20 | 4 | -5 | -10 | 16 | 17 | 20 |

*Figure 2. Interview Task 5*

## Data Analysis

Analysis of the interview transcripts followed a constructivist grounded theory approach (Charmaz, 2000). Constructivist grounded theory, like other forms of grounded theory (e.g., Glaser & Strauss, 1967; Strauss & Corbin, 1990), allows the researcher to explore the data without a preconceived framework of what results should emerge from the data. Charmaz notes that objectivist grounded theorists "assume that following a systematic set of methods leads them to discover reality and to construct a provisionally true, testable, and ultimately verifiable 'theory' of it" (p. 524) and therefore that the data collection and analysis procedures should aim to minimize the role of the researcher to be able to make claims about an observer-independent reality. For constructivist grounded theory, Charmaz argues, this is not the case. She argues that "the research products do not constitute the reality of the respondents' reality. Rather, each is a rendering, one interpretation among multiple interpretations, of a shared or individual reality" (Charmaz, 2000, p. 523). Charmaz illustrates this succinctly when she says, "data do not provide a window on reality. Rather, the 'discovered' reality arises from the interactive process and its temporal, cultural, and structural contexts" (p. 523-524). This approach to data analysis fits with the theory of learning described earlier, particularly the focus on viability in learning since both perspectives reject the assumption that we are uncovering some objectively true reality.

The open-coding process led to the development of a new analytical tool, local theory diagrams, which visually represent a student's solution strategy and all its mutations for a given task. Local theory diagrams showcase the "core" of the student's current theory concerning the given task and its solution (e.g. how to interpret the given rate of change function) and is then surrounded by all the hypotheses the student generates based on that assumption and ideas the student believes to be true at the time. The local theory diagrams also illustrate how these theories shift as the student interacts with the task and assesses whether their current assumptions and strategies make sense. In this way, the diagrams show the process of students coming to develop more viable theories of the tasks they solve. Examples of the local theory diagrams are given in the next section.

## Results

There were two primary ways the problem context helped shape students' mathematical reasoning. The first was their use of the context partnered with the given information to refine their local theories of the task to increase the perceived viability of their strategies. Secondly, students would occasionally use the problem context to help explain away apparent contradictions within one of their local theories. I will use the results of the open-coding process as well as a few examples of the local theory diagrams to illustrate each of these findings.

### Using Problem Context and Given Information in Theory Refinement

Whenever the students began working through one of the accumulation tasks, they were continuously revising or replacing a local theory concerning the task. For Task 3, there were a few pieces of information students attached to while generating various solution strategies. Primarily, students knew that because the initial temperature was given to be 57.8 degrees Fahrenheit and the problem concerned climate change and the warming Earth, that their answer must be greater than 57.8 degrees Fahrenheit. Seven of the 12 students interviewed initially assumed that the given function would output the average surface temperature in the year 2200. This assumption runs contrary to the actual problem text in which it is stated that "the temperature is rising at the rate of: $R(t) = 0.014t^{0.4}$ degrees Fahrenheit per year." While many of them read the task out loud prior to beginning their work, they neglected this specific description of the function as a rate and instead assumed it represented the average surface temperature.

With this assumption, each of the seven students then evaluated $R(200)$ and were then faced with contradictory evidence since $R(200)$ equals approximately 0.116. Each of the seven students then realized their current theory was no longer viable, their understanding of what the answer to the task should be overwrote their assumption that the function would output the average surface temperature and so a new local theory was developed to explain this new contradictory evidence. As Tom acknowledged after seeing the result of $R(200)$, "and I said that was wrong because I was, wait, that's so small." It is important to note that this realization does not necessarily lead the students to interpret the output of the function as it was intended, as a rate of change. When contradictory evidence is acknowledged, the student adjusts their local theory or abandons it for another local theory that is more viable to them. In five of the seven interviews in which students acknowledged this contradictory evidence, the student then developed a second local theory with the core assumption that the function is outputting the change in the average surface temperature instead of the average surface temperature itself. Thus, the students tend to suggest adding 0.116 to 57.8 to find the new average surface temperature. This new hypothesis is more viable for the students since it fits within the contextual assumptions they have made. This hypothesis is not mathematically accurate. The students are adding a value of the instantaneous rate of change to the initial temperature instead of using the rate of change to approximate or calculate the change in the temperature over the 200 years. However, the students do not tend to perceive any contradiction here, their current local theory is viable to them since the contextually-based assumptions are now not in any perceived contradiction with the evidence. The fact that their solution is mathematically inaccurate is not a factor in the students' assessment of viability.

In Figure 4 below, we see such an example in Anne's local theory diagram for her work on Task 3. We see in Anne's first local theory that her core assumption is $R(t)$ outputs the average surface temperature. While she describes the function as the "rate of change for the temperature" she then claims that by plugging in 200 into the equation she will get the average surface temperature in the year 2200. After calculating $R(200)$ she notes that this is a very small value and after I ask her what the function tells her about the context she drops her current theory for a more viable one, one with a core assumption that the function outputs the change in the average surface temperature. This theory is more viable for Anne since she is now able to explain her formerly contradictory information that $R(200)$ is a small number. I ask Anne specifically what the units on $R(t)$ are with the intention of seeing if this will cause her to acknowledge another contradiction but she is content in stating the units are degrees Fahrenheit per year without acknowledging any contradiction in her theory. Later in the interview, after she had completed all the other tasks, I again direct her attention to the units and ask her if she can add degrees per year to degrees. Now, based on this question and my desire to return to this task, Anne shifts to another local theory with the core assumption that the function outputs the rate of change of the average surface temperature instead of the actual temperature or the temperature change. Anne now reasons that the rate of change would vary each year and so she would have to add the value each year to the starting temperature of 57.8 degrees. Anne has now utilized the context of the task, the given information from the task, and the interview setting to continually revise her local theory about the task and so her final local theory would be considered the most viable for her at the end of the interview.

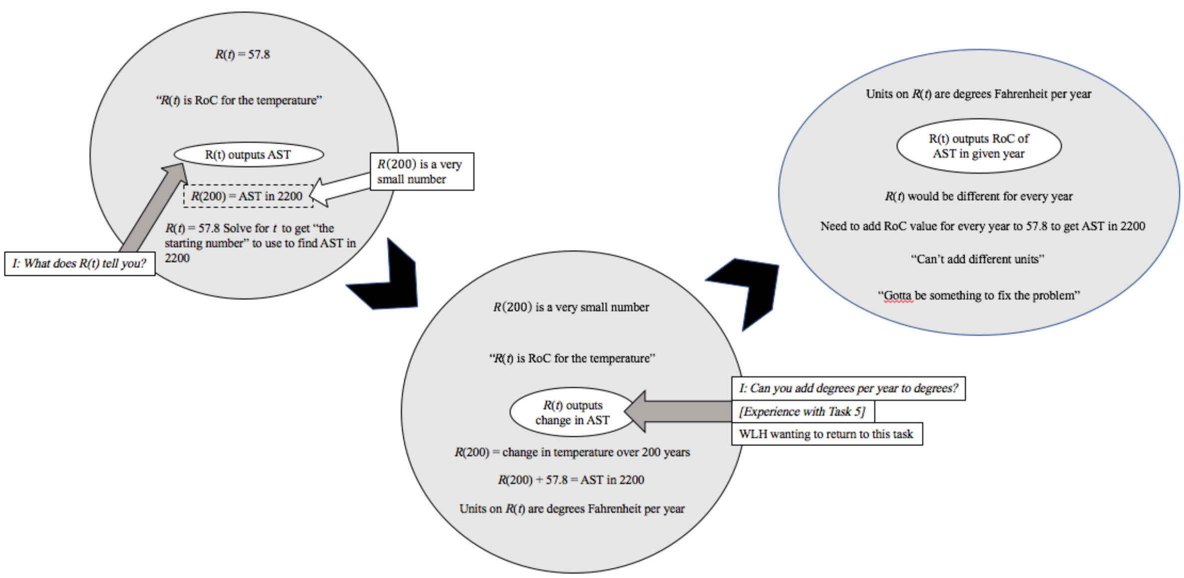

*Figure 3. Local theory diagram for Anne's work on Task 3*

## Reasoning About Contradictions via Problem Context

Another way students utilized the context in reasoning about Task 5 was how they interpreted the negative table values. For some students, like Jake, they could shrug off a potential contradiction. Jake interpreted the table values as representing the number of infected individuals. This means that a negative table value could have served as a contradiction, leading to a theory shift. However, Jake waves away the contradiction by claiming that the negative table values must imply, “there’s like a negative amount of people infected I guess. Um, let’s see, I don’t know just, dropped below the line of infected individuals, I guess maybe they were infected and they died? And they’re still… or maybe they’re people immune.” Jake does not have to settle on any one idea here to disregard the apparent issue. It appears he assumes he must not fully understand the problem and so this allows him to continue with his core assumption that the table values represent the number of infected individuals instead of having to generate a new local theory. This may be related to the difficulties other researchers have identified with how students reason about area under the curve when a function is not strictly positive (e.g., Orton, 1983).

Anne similarly reasons her way through a potential contradiction but instead of attributing the discrepancy to a lack of understanding, she adjusts the problem context entirely to fit within her current theory therefore preserving the viability of her assumption that the table values represent the number of infected individuals. Anne acknowledges that negative people is not a viable interpretation, “so I mean obviously, you don’t have like negative people but, like it’s saying on day zero there was eighteen people…” but instead of altering her theory to increase viability, she alters the problem itself. She claims that the negative five in the table must represent five people who should have been included in the original figures but were not, “I guess if like if they had these people as the original eighteen then they found five people who were sick who weren’t sick anymore they would be like oh, that was five people hadn’t included in the original number that were sick and, but now they’re not sick.” This is a rather sophisticated approach to maintain the consistency of her theory and I believe this creative alteration of the given data is only possible for her because of her confidence with and understanding of the context.

## Implications

There is ample evidence in the current study that problem context influenced how the students reasoned about the tasks. For educators, this means that we need to give students ample opportunities to solve accumulation tasks within various contexts. The results of this study indicate that students may only reason about the accumulation in specific ways when given a specific representation. Additionally, we need to be cautious about what kinds of tasks we use in summative assessments in calculus. Assuming a student’s performance on a contextually-based test question accurately models that student’s ability to solve similar tasks in different contexts may not be warranted. Their experiences in their chosen major and their educational history has given them specific tools they will utilize to reason about these tasks.

Viewing students’ work on calculus tasks through the lens of viability is a meaningful way to approach the data analysis. The local theory diagrams were immensely helpful in my attempt to better understand how the students were solving the tasks by developing and revising local theories concerning the tasks. Creating these diagrams provided me the opportunity to view the data through a different lens and thus I came to understand more about how students interpret calculus tasks and what it takes for them to notice a mathematical contradiction. I believe there is merit in the continued development and use of the local theory diagrams in qualitative data analysis both in calculus and more broadly in mathematics education research.

Implementation and Impact of a Web-based Activity and Testing System in Community College Algebra

Shandy Hauk
WestEd

Bryan Matlen
WestEd

*Most community college students in the U.S. must complete at least one developmental class, such as elementary algebra, before they can enroll in a college-level mathematics course. Increasingly common in such courses is the use of a web-based activity and testing system (WATS). This report presents initial results of a mixed-methods study of elementary algebra learning among 510 students in the classes of 29 instructors across 18 community colleges. Instructors were randomly assigned to use a particular WATS (treatment condition) or their usual approach (control condition). The focal WATS had adaptive problem sets, hints, and videos. Treatment group instructors had access to online support for implementation. For the study, students completed common pre- and post-tests and instructors regularly provided information about their teaching practices. The early results reported here indicate that greater instructor fidelity to developer intentions regarding frequency of assignments are positively associated with greater student learning.*

*Key words:* College Algebra, Multi-site Cluster Randomized Controlled Trial, Fidelity of Implementation

More than 14 million students are enrolled in community college in the United States. Each is seeking an educational path to a better life. Community college students are more likely to be low-income, the first in their family to attend college, from a group under-served by status quo K-12 education (e.g., from an ethnic, racial, or linguistic minority group; Bailey, Jeong, & Cho, 2012). Most must take at least one developmental class, such as elementary algebra, before they can enroll in a college-level course (Porter & Polikoff, 2012). When it comes to technology and early algebra learning in college, what works? For whom? Under what conditions? When instructors implement technology tools, how are they used? In ways aligned with developer intentions? To what degree? Several web-based activity and testing system (WATS) have emerged for use in college developmental mathematics (e.g., ALEKS®, Khan Academy). Some WATS, like the one at the heart of this study, include adaptive problem sets, videos, and tools for instructors to monitor student learning. Though some research on the efficacy of WATS exists (e.g., Gardenhire, Diamond, Headlam, &Weiss, 2016 and references therein), the study reported here is the first large scale, multi-institution, mixed-methods experimental study of a WATS in community college developmental algebra of which we are aware.

## Research Questions

Funded by the U.S. Department of Education, we are conducting a multi-year large-scale mixed methods study in over 30 community colleges in one U.S. state. We report here on the first year. The study is driven by two research questions:

Research Question 1: What is the impact of a particular WATS learning platform on students' algebraic knowledge after instructors have implemented the platform for two semesters?

Research Question 2: What challenges to use-as-intended (by developers) are faculty encountering and how are they responding to the challenges as they implement the learning tool?

## Background and Conceptual Framing

Regardless of how they might be used, WATS environments vary along at least two dimensions: (1) the extent to which they adaptively respond to user behavior (e.g., static vs. dynamic) and (2) how they are informed by a model of cognition or learning. Static WATS are non-adaptive – they deliver content in a fixed order and contain scaffolds or feedback that are identical for all users. The design may be based on intuition, convenience, and/or a hypothesized common learning trajectory. An example of this type of environment might be online problem sets from a textbook that give immediate feedback on accuracy (e.g., "Correct" or "Incorrect").

Dynamic WATS environments keep track of learner behavior (e.g., errors, error rates, time-on-problem) and use this information in a programmed decision tree that selects problem sets or feedback based on estimates of student learning. An example of a dynamic environment might be a system such as ALEKS® or the approach now used in Khan Academy Missions. For example, at khanacadmy.org, a behind-the-scenes data analyzer captures student performance on a "mastery challenge" set of items. Once a student gets six items in a row correct, the next level set of items in a target learning trajectory is offered. Depending on the number and type of items the particular user answers correctly (e.g., on the path to six in a row correct), the analyzer program identifies and assembles the next "mastery challenge" set of items.

Above and beyond responsive assignment generation, programming in a dynamic environment that is also cognitively-based is informed by a theoretical model that asserts the cognitive processing necessary for acquiring skills (Anderson, Corbett, Koedinger, & Pelletier, 1995; Koedinger & Corbett, 2006). For example, instead of specifying only that graphing should be practiced, a cognitively-based environment also will specify skills needed to comprehend graphing (e.g., connecting spatial and verbal information), and provide feedback and scaffolds that support these (e.g., visuo-spatial feedback and graphics that are integrated with text). In cognitively-based environments, scaffolds themselves can be adaptive (e.g., more scaffolding through examples can be provided early in learning and scaffolding faded as a student acquires expertise; Ritter, Anderson, Koedinger, & Corbett, 2007). Like other dynamic WATS, such systems can provide summaries of student progress. No fully operational cognitively-based WATS currently exists for college students learning algebra. Several dynamic systems do exist (e.g., ALEKS®, Khan Academy Missions). The particular WATS investigated as the treatment condition in our study was designed primarily for use by learners as replacement or supplement to homework or in-class individual seatwork.

The theoretical basis for our approach to examining the instructional implementation of a WATS lies in program theory, "the construction of a plausible and sensible model of how a program is supposed to work" (Bickman, 1987, p. 5). As in many curricular projects, developers of the WATS in our study paid attention to learning theory inasmuch as it shaped the content in standard algebra texts upon which the WATS content was based. Developers articulated their assumptions about what students learned in completing WATS activities, but the roles of specific components, including the instructor role in the mediation of learning, were not clearly defined.

Munter and colleagues (2014) have pointed out that there is no agreement on how to assess fidelity of implementation (how close implementers come to realizing developer intentions; Dusenbury, Brannigan, Falco, & Hansen, 2003). However, there is a growing consensus on a component-based approach to measuring the structure and processes of implementation (Century & Cassata, 2014). Five core components are key in examining implementation: Diagnostic, Procedural, Educative, Pedagogical, and Engagement (see Table 1).

*Table 1. Components and focus in examining implementation.*

| *Components* | *Focus* |
|---|---|
| Diagnostic | These factors say what the "it" is that is being implemented (e.g., what makes this particular WATS distinct from other activities). |
| Structural-Procedural | These components tell the user (in this case, the instructor) what to do (e.g., assign intervention *x* times/week, *y* minutes/use). These are aspects of the *expected* curriculum. |
| Structural-Educative | These state the developers' expectations for what the user needs to know relative to the intervention (e.g., types of technological, content, pedagogical knowledge needed by an instructor). |
| Interaction-Pedagogical | These capture the actions, behaviors, and interactions users are expected to engage in when using the intervention (e.g., intervention is at least *x* % of assignments, counts for at least *y* % of student grade). These are aspects of the *intended* curriculum. |
| Interaction-Engagement | These components delineate the actions, behaviors, and interactions that students are expected to engage in for successful implementation. These are aspects of the *achieved* curriculum. |

## Method

The study we report here used a mixed methods approach combining a multi-site cluster randomized trial with an exploration of instructor and student experiences. Half of instructors at each community college site were assigned to use a particular WATS (treatment condition), the other half taught as they usually would, barring the use of the treatment group's focal WATS tool, though other WATS might be used (control condition). Faculty participated for two semesters so treatment instructors could familiarize themselves with implementing the WATS with their local algebra curriculum. ***Note***: We report here on data collected from the first of two years. Hence, we purposefully under-report some details.

### Sample for this Report

Initial enrollment in the study included 89 instructors across 38 college sites. Attrition of instructors by the end of the year was significant (68%). In the end, 29 instructors at 18 colleges finished the study (i.e., we had sufficient data from them to include them in analyses). This report is based on data from these instructors and their 510 students (see Table 2).

*Table 2. Counts of teachers, students, and colleges in the study.*

| *Condition* | *Teachers* | *Students* | *Colleges* |
|---|---|---|---|
| Control | 17 | 328 | 13 |
| Treatment | 12 | 182 | 11 |
| *Total* | *29* | *510* | *18* |

### Measures

A great deal of textual, observational, and interview data were gathered. These data allow analysis of impact (Research Question 1) and an examination of implementation structures and processes (Research Question 2). Initial indices of implementation fidelity were based on instructor weekly self-reports of WATS use and, for the treatment group, on the WATS audit trail of student use. The primary outcome measure for students' performance was an assessment from the Mathematics Diagnostic Testing Program (MDTP), a valid and reliable test of students' algebraic knowledge (Gerachis & Manaster, 1995).

**Student Mathematics Performance.** One way to estimate student achievement on the MDTP tests is the *raw* score (i.e., proportion of correct answers as a percentage). However, such a calculation does not take into consideration other parameters of interest, such as item difficulty. To address this, in a second analysis we used a multilevel extension of two-parameter logistic item response theory to compute student pre- and post-test *scale* scores (Birnbaum, 1968). Specifically, we computed response-pattern *expected a posteriori* estimates (EAP scores; Thissen & Orlando, 2001) for each student. Also, we created EAP average scores for each classroom (a teacher-level score).

**Instructor Implementation Processes.** The components in Table 1 were operationalized through a rubric, a guide for collecting and reporting data on implementation. Each component has several factors. The research team developed a rubric for fidelity of implementation that identified measurable attributes for each component (Hauk, Salguero, & Kaser, 2016). For this report, we focus on the first element in the "procedural" component (see Table 3). The values and proportions (e.g., at least 2/3 of weeks) were specified by the developer. Data on the aspects in Table 3 was collected from weekly logs in which instructors indicated (a) WATS assignments made, (b) encouragement to students to complete assignments, (c) use of recommended mindset lessons, and (d) nature of attention in-class to student experiences with the WATS.

*Table 3. Example of rubric descriptors for levels of fidelity, Structural-Procedural component.*

| ***Procedural:*** These components tell the user (instructor) what to do regarding instruction. Scaling within unit of instructor.. | | | |
|---|---|---|---|
| | **Low Level of Fidelity** | **Moderate Fidelity** | **High Level of Fidelity** |
| **Assigned WATS** | Instructor rarely or never assigns WATS activities (2 or fewer times per semester). | Instructor sometimes assigns WATS activities (between 3 and 8 times per semester). | Instructor regularly assigns WATS activities (at least 8 times per semester). |
| **Value of WATS** | Instructor rarely or never encourages students to complete assignments (less than 1/3 of weeks/term). | Instructor sometimes encourages students to complete assignments (1/3 to 2/3 of weeks/term). | Instructor regularly encourages students to complete assignments (at least 2/3 of weeks/term). |
| **Effort-based mindset** | Instructor conducts at most 1 session of mindset training. | Instructor conducts 2 sessions of mindset training. | Instructor conducts recommended 3 sessions of mindset training. |
| **Intensity of in-class supports for WATS use** | Explicit mention or attention in class to content in WATS in fewer than 50% of weeks in term. | Explicit mention or attention in class to content in WATS from 50% to 80% of weeks in term. | Explicit mention or attention in class to content in/from WATS at least 80% of weeks in term. |

## Results

The study employed Hierarchical Linear Modeling (HLM), controlling for students' pre-test MDTP scores, to estimate the impact of WATS use on student achievement. The hierarchical modeling approach accounts for the nested structure of the sample (Raudenbush & Bryk, 2002), specifically the nesting of students within instructors. Preliminary analysis indicated that such a hierarchical model was justified: the intra-class correlation in the unconditional model was 0.36, suggesting that the observations were not independent (i.e., scores varied based on classroom – statistically, the teacher mattered – so single-level regression was not appropriate). The exact model and random and fixed effects for it are reported elsewhere (Hauk & Matlen, 2017).

## Intervention Impact

**Baseline equivalence.** The What Works Clearinghouse (2014) considers baseline differences with a Hedges $g > .25$ not to be amenable to statistical correction. The raw pre-test scores were higher in the treatment group, with a marginal effect size ($g = 0.25$) for the difference between groups; however, the difference between treatment and control student pre-test EAP scores was substantive ($g = 0.30$). The EAP pre-test difference is large enough that the analytic sample might be considered non-equivalent at baseline on this variable (below, we discuss this fact).

**Impact analysis.** The aim of impact analysis was to address the question: What is the impact of the WATS intervention on students' elementary algebra knowledge, as measured by the MDTP? Controlling for students' pre-test scores, we found that using WATS corresponded to, on average, treatment student post-test scores 5 percentage points higher than the control group ($p < .05$). The Hedges $g$ value for this effect is 0.32, which is considered a small but noteworthy effect in educational research for studies of this size (Cheung & Slavin, 2015; Hill et al., 2008). The 95% confidence interval of the Hedges $g$ value is .14 - .50 (i.e., entirely above zero). Using EAP instead of raw scores, we obtained similar results. Since baseline differences between treatment and control group student raw scores were within the range of statistical correction, the similarity between the two *models* (raw score and EAP score models) is important, offering more confidence in the estimates of positive impact.

## Implementation Fidelity and Student Learning

Of the 12 treatment instructors, 9 provided sufficient weekly information about the amount of instruction using WATS to determine a level of implementation. Three instructors were coded as high fidelity, 3 as moderate, and 3 as low. We explored whether the level of this category of procedural implementation fidelity in the treatment group correlated with student learning. To estimate *learning* we computed a normalized gain score, calculating $z$-scores for the pre- and post-test EAPs separately, and then subtracting the post-test $z$-scores from the pre-test $z$-scores for every student. These gains represent a difference between a student's relative position on the distribution of pre-test scores to their relative position on the distribution of post-test scores. Thus, a negative gain does not mean that a person (or in the case of Figure 2, a group of people) know less by the end of the course. Rather, it means that students are lower in the standardized distribution at post- than at pre-test. Figure 1 shows the average gain for treatment group students at each of the different fidelity of implementation levels for "Assigned WATS." We report here on this Procedural factor because it had the most notable differences across levels of fidelity.

The results in Figure 1 (next page) suggest that the more regularly instructors assigned WATS lessons, the larger the student gain. However, sample sizes at present are small, so results are not definitive. Nevertheless, these results are consistent with the developer's expectations (and an addition of a second cohort will allow us to examine whether these associations persist).

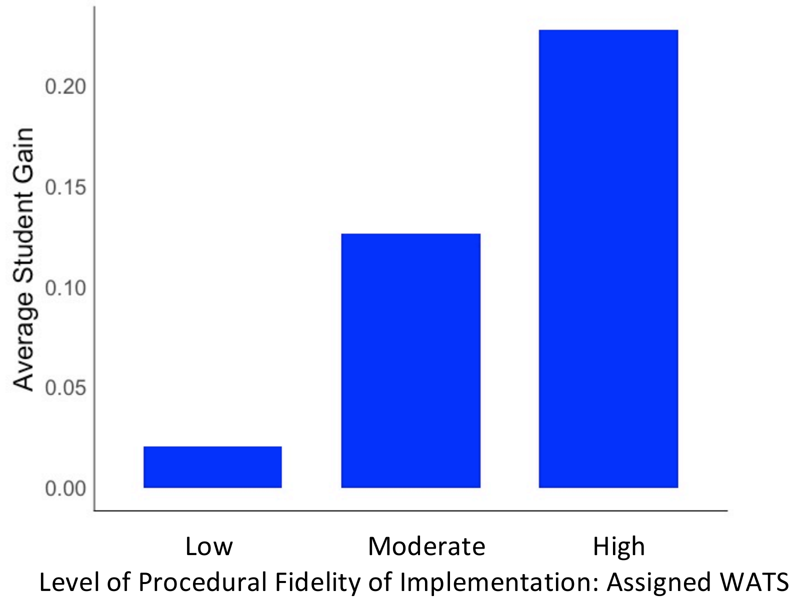

*Figure 1. Average student gains in treatment classrooms according to instructor's level of procedural fidelity of implementation in the factor "Assigned WATS."*

Control group instructors might use a WATS, but were restricted from using the focal WATS under study. Thus, one question was whether use of *any* WATS, regardless of whether it was the focal one, correlated with student learning. To explore this possibility, we examined average student gains for instructors using the treatment WATS ($n$ = 9) compared to those in the control group who used a different WATS ($n$ = 8). Figure 2 suggests that use of the study's focal WATS in particular, not just any WATS, had a positive relationship with student learning.

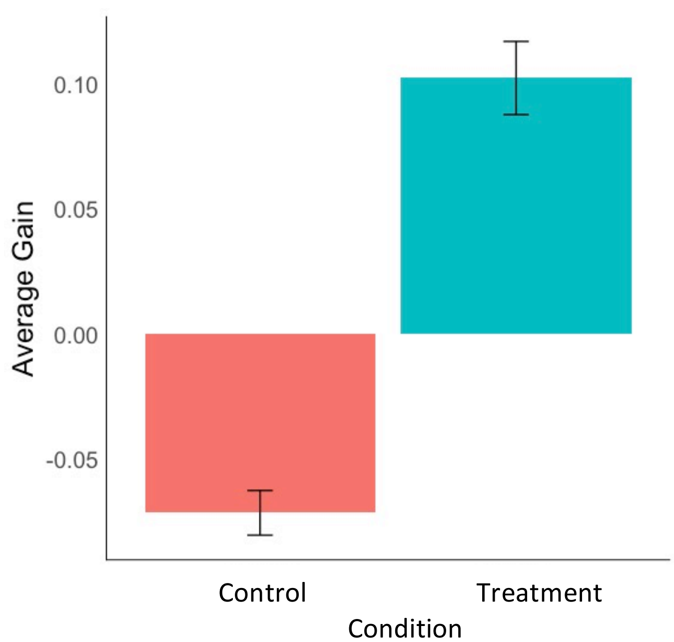

*Figure 2. Average student gains for control group classes using a WATS vs. treatment WATS.*

## Discussion

We continue to explore relationships between fidelity of implementation and student success. While the results to date suggest that the focal WATS had a positive impact on students' elementary algebra achievement, recall there was high instructor attrition. This fact, coupled with moderate to large baseline differences at pre-test, warrant caution in interpreting the results. Still to do is a systematic consideration and testing of alternative explanations for Figures 1 and 2. For example, differential attrition may mean that treatment instructors who stayed in the study were better at incorporating the focal WATS into instruction. Mitigating against this explanation are the exit surveys completed by instructors who left the study in which course reassignment was the primary reason for treatment instructor attrition. Also, while we know the types of WATS used by control group instructors, we do not have a developer-validated fidelity of implementation rubric for each of those other WATS.

The ultimate purpose of a fidelity of implementation rubric is to articulate how to determine what works, for whom, under what conditions. In addition to allowing identification of alignment between developer expectations and classroom enactment, it provides the opportunity to discover where productive adaptations may be made by instructors, adaptations that boost student achievement beyond that associated with an implementation faithful to the developers' view. As we move forward with modeling, implementation indices (or vectors of values, one for each factor) will be used at the instructor level in statistical modeling of the impact of the intervention as part of a "specific fidelity index" (Hulleman & Cordray, 2009).

## Conclusion

As indicated above, we have repeated the study with a second cohort of participants in the 2016-17 academic year. The new data, combined with the first study reported here, may provide additional results and insights by the time of the RUME conference.

**Implications for practice.** For the question: Should faculty use a WATS? The answer is a cautious: It depends. We know that treatment instructors had supports for WATS use in the form of video-based professional development and access to a project consultant who was experienced with the focal WATS in community college algebra. The implementation supports for control group teachers who used another WATS were varied. Taking into account the potentially biased statistical impact results and the exploration of variation in instructor implementation, there is still an open question about what might be the minimal supports needed for an instructor to have high fidelity on procedural components (e.g., Assigns WATS).

**Implications for research.** There were significant challenges in recruiting and retaining community college mathematics instructors for the study. To build community and assist in future research efforts in two-year colleges, we are sharing the processes and results of this work in materials read by community college faculty and administrators (e.g., *MathAMATYC Educator* – a journal of the American Mathematical Association of Two Year Colleges). It is important for potential faculty participants in research and their chairs/deans to be aware of the enormous contributions faculty can make to research. A second pragmatic implication for research is in how to manage the data generated by such projects (Hubbard, 2017)

Early Undergraduates' Emerging Conceptions of Proof and Conviction

Alison Lynch and Ryan Pugh
California State University, Monterey Bay

*Before enrolling in an introduction-to-proof course, undergraduates often hold conceptions of mathematical proof that do not align with those accepted by the mathematics community. These conceptions are informed, in part, by past experiences with proof in mathematics and science courses. In this study, we sought to investigate the influence of these past experiences on students' conceptions of proof. We conducted interviews with nine undergraduates in their first or second year in which we asked them to solve number theory tasks and determine the validity of provided number theory statements. In this paper, we report on the various conceptions of proof these students conveyed and the influence of past experiences on these conceptions.*

*Keywords:* Proof, Conceptions, Student Thinking

## Introduction and Motivation

It has been well-established in the literature that undergraduate students struggle to learn to prove. One challenge that students face is that many of them enter university mathematics courses with conceptions of proof that differ from those accepted in the mathematics community. These conceptions include what constitutes a mathematical proof, what purposes a mathematical proof can serve, and how one constructs a mathematical proof. Students develop these conceptions through their past experiences in mathematics, as well as through experience with the idea of proof in non-mathematical settings. Notably, most students in the United States encounter proofs in high school when studying geometry. They also may encounter proofs in a Calculus course, constructing proofs (e.g. epsilon-delta proofs) or making sense of instructor-provided proofs (e.g. the Mean Value Theorem). These experiences influence the way that students conceive of proof in mathematics.

In order to help students develop more robust conceptions of proof, we need to understand the conceptions they bring in with them. In this paper, we explore these emerging conceptions, the factors that influence these conceptions, and the strategies students already employ when determining the truth of a mathematical statement. We ask the following questions:

- How do early undergraduate students' past experiences in math and science influence their conceptions of proof?
- How are early undergraduate students' conceptions of proof related to their strategies for gaining conviction?

## Relevant Literature and Theoretical Perspective

Following Thompson's (1992) definition of conceptions of mathematics, we use conceptions of proof to refer to one's "conscious or subconscious beliefs, concepts, meaning, rules, mental images, and preferences" concerning mathematical proof. Conceptions of proof have been studied across populations including high school students (Chazan, 1993; Healy & Hoyles, 2000), undergraduate mathematics majors (Harel & Sowder, 1998; Weber, 2010), and mathematics teachers (Knuth, 2002). In recent years, researchers have also investigated the conceptions of proof held by early undergraduate students - students who have enrolled in at least one college-level mathematics course, but have not yet enrolled in an introduction to proofs course or other proof-based mathematics course (Janelle, 2014; Raman, 2001; Stylianou, Blanton, & Rotou, 2015; Stylianou, Chae, & Blanton, 2006). In the largest of these studies, Stylianou, Blanton, and Rotou (2015) conducted a survey of over 500 early undergraduates about their conceptions of proof, including questions about beliefs and past experiences and multiple-choice proof evaluation tasks. They found that most of the students surveyed selected deductive arguments as the *most rigorous*, but that the proofs students selected as *most explanatory* were the arguments they identified as closest to their own approach (split between deductive, empirical, and narrative). They also found that only a quarter of the students reported having past classroom experiences that "emphasized the importance of developing proofs" (p. 112) and more than half of the students reported past instructors using examples to prove mathematical statements. In this paper, we investigate further the influence of these past experiences on students' beliefs about proof.

When identifying students' strategies for gaining conviction, we focus on *ascertaining*, which Harel and Sowder (1998) define as "the process an individual employs to remove her or his own doubts about the truth of an observation" (p. 241). Much of the existing literature focuses on conviction in terms of what participants identify as convincing in the arguments of others (e.g. Janelle, 2014; Knuth, 2002; Healy & Hoyles, 2000; Chazan, 1993) as opposed to how students construct arguments to convince themselves. Each of these studies found that the majority of participants accepted both deductive and empirical arguments as convincing. However, Stylianou et al. (2015) found that the proofs that students identify as the most convincing and the most like their own approach don't always match their actual proof construction. They gave the same four mathematical statements to 60 students first as proof construction tasks, then as proof evaluation tasks two weeks later. They found that the majority of students constructed empirical arguments, but then reported two weeks later that a narrative or deductive argument was most like what they would construct. Considering this finding, we look at conviction in this paper in the context of students' generated arguments.

## Methods

In this study, we conducted hour-long interviews with nine undergraduate students. The participants were all freshman or sophomore students at a small, Hispanic-serving university in the Western United States. The participants were selected because they were enrolled in a college-level mathematics course but had not yet taken an introduction to proof course. Of the nine participants, four were enrolled in Calculus I, three were enrolled in Calculus II, and two were enrolled in Discrete Math. Four of the participants were biology majors, three were marine science majors, and two were computer science majors.

Each student participated in an individual, hour-long, semi-structured interview. During the interview, they were presented with five number theory tasks to explore one at a time. Participants were asked to think aloud as they worked; their speech and writing were recorded using LiveScribe pens, and each interview was videotaped.

On each task, participants were asked if they were convinced by the work they had done and if they considered their work to be a mathematical proof. Depending on their answers, the interviewer asked relevant follow-up questions (e.g. What is missing that would make this a proof? What would you need to do or see to be fully convinced?). After the first task, participants were asked what they believe it means for something to be a mathematical proof. At the end of each interview, participants were asked about their experiences with mathematical proofs in the context of their mathematical careers. Specifically, they were asked if their professors ever show proofs of theorems in class, if they have ever written proofs in their classes or for homework, and what they thought the purpose of proofs in mathematics is.

## Tasks

Each participant was asked to work on five number theory tasks, including the three tasks in Table 1. We chose number theory as the content area because it is one of the first topics that students typically encounter in an introduction to proof class. The five tasks were chosen to be easily accessible to the students, requiring only knowledge of divisibility, factors, and even/odd numbers. Some tasks asked students to determine whether a statement was true or false, while others were more exploratory in nature, asking students to create a conjecture.

*Table 1. Three of the five number theory tasks used in the study*

| Task Number | Task Statement |
|---|---|
| Task 1 | Consider the statement: The sum of any 5 consecutive whole numbers is divisible by 5. Is this statement true or false? Would this statement still be true if 5 was replaced with any other number? |
| Task 3 | A factor of a number is a whole number that divides it evenly. For example, the factors of 10 are 1, 2, 5, and 10. Which numbers have an odd number of factors? |
| Task 4 | If $a$, $b$, and $c$ are whole numbers, is $a$ times $b$ plus $a$ times $c$ always even, always odd, or can it be either? If $b$ and $c$ are required to be odd, will $a$ times $b$ plus $a$ times $c$ always be even, always be odd, or can it be even or odd? |

## Data Analysis

For analysis, each interview was transcribed and images of student work from the Livescribe PDFs were added to each transcript. The transcripts were analyzed using a grounded theory approach (Strauss & Corbin, 1994). The two researchers independently coded each transcript using open coding and then discussed themes arising from the generated codes. Codes capturing aspects of participants' conceptions of proof were refined and a modifier was added to capture whether the code was something the participant was convinced by, not convinced by, considered to be necessary/sufficient for proof, or considered not to be necessary/sufficient for proof. Codes were also developed to capture the references participants made to past experiences when discussing proof and conviction. Once the coding scheme was refined, the second author recoded each of the transcripts and wrote a descriptive narrative for each participant. These narratives outlined each participant's ideas surrounding proof and conviction, providing examples and direct quotes from the transcripts to illustrate what they found convincing and what they believed a proof to be.

# Results

We report on two aspects of students' emerging conceptions of mathematical proof: the sources they draw upon when forming and articulating these conceptions and the implications for their view of the definitiveness of proof. We also highlight one participant, Rosa, to illustrate the relationship we observed between students' conceptions and the strategies they use to gain conviction.

**Influence of Math and Science Experiences on Conceptions of Proof**

While the students in our study discussed the concept of proof in mathematics in diverse ways, they drew upon common themes and past experiences as sources for their understanding and reasoning. The three most common themes participants referred to were *Science, High School Geometry,* and *Discrete Mathematics*.

Among the seven science majors (biology, marine science), five drew connections to the study of science in their discussions of mathematical proof. Rosa, José, and Alicia (all Biology majors) described a mathematical proof as only needing evidence – examples or explanations. José described a proof as *"Evidence. Any kind of evidence. Material, biological, any kind of evidence is proof."* Alicia's description of proof was similar: she shared that a mathematical proof is *"show[ing] evidence that it works."* She also talked about more examples being valuable because they served as replication. On Task 4, she gave two confirming examples of the statement, and when asked why two examples were necessary, she explained it as, *"I guess, like, the ability to reproduce the results. Because [the second example] kind of justifies the prior one."* Unlike Rosa and José, Alicia and the two Marine Science majors, Gabriela and Cecilia, described mathematical proof in contrast with ideas from science. Gabriela drew a distinction between the definitiveness of proof in mathematics and in science:

*Interviewer*: So, in mathematics, what is a proof? What is necessary for something to be a proof?

*Gabriela*: I would say that it's like an absolute thing. And it's been tested many, many times to make sure that there aren't any aren't any exceptions to that one rule. Kind of like how- like it's like a law in science would be.

Alicia drew a similar contrast when comparing proving in mathematics and biology, saying that *"Math is like- I don't know, I feel like once you have it on paper it's pretty much irrefutable, but bio and pretty much it's just, at one point it can be proven wrong."*

Another common theme among the science majors were references to proofs in high school geometry. Four of the seven science majors referred to the two-column proofs they learned in high school, but their interpretations of these proofs differed considerably. Cecilia interpreted the steps in a two-column proof as steps in a deductive argument, describing the second column in terms of logical arguments:

> Well, it's really to prove your logic to get from A to B. It's to show and explain in ways that another person who understands math can look at it, see your work, read that explanation whether it's just, you know, explaining the logic in that one step or actually citing some theorem.

In contrast, Rosa used two-column proofs as justification for why examples and informal arguments were sufficient for proof:

*Rosa*: Proofs, I get them. I think of geometry. We would get the proofs on one side and, like, have to show that it's true. So proof is making a statement and showing through examples or other like rules that this is a true statement.

*Interviewer*: Oh okay, so you're thinking back to your high school geometry when you were proving properties of triangles and circles.

*Rosa*: Yeah, you'd have like all the true statements on one side and then your work and your explanations on the other side.

The two computer science majors in our study, Antonio and Ana, were enrolled in a discrete mathematics course at the time, and both drew primarily from the content of the course when discussing proof. This is unsurprising since the course contains a week-long unit on mathematical proof, but what was interesting were the features of proof that were most salient to these students. Both students described a proof as a deductive argument which shows that a mathematical statement is always true, but they also emphasized the need for formal language, symbols, and certain structure. For instance, on Task 1, Antonio was fairly convinced that the statement was true from patterns he observed in his examples, but to be totally convinced, he would need to write it the "fancy way":

*Antonio*: So, if I did it in the fancy way, with Discrete Math, that's a way to prove how you got the answer.

*Interviewer*: Yeah?

*Antonio*: Pretty much. Uh, cause sometimes proving, you need to require some, like, kind of Discrete Math symbols, I say.

The requirement of formal language was restrictive for Ana on Task 3. She had generated a conjecture and articulated an argument in support of her conjecture, but she felt like she lacked the language necessary to write a proof:

*Interviewer*: Do you think, at this point, based on what you know about this problem, that you would be able to write a proof?

*Ana*: Probably not. [Laughs]

*Interviewer*: Why not?

*Ana*: Because like, I'm just assuming this. I don't know how I would formally write a formal proof. Well, like, when I think proof, it has to be formal, so like, there would have to be, like, if this, then this. And then suppose this. And then you show your proof.

These quotes are representative of a phenomenon we saw broadly in our study of participants using key past experiences as reference points when describing and conceptualizing proof. These references also played a role in how students thought about obtaining conviction, as we discuss more below.

**Conceptions of Proof and Strategies for Conviction**

Although many of the students in our study described conceptions of proof that differ from the accepted norm in mathematics, there was general consistency between students' conceptions of proof and how they sought to convince themselves.

**The case of Rosa.** To illustrate this notion of consistency, we highlight the work of Rosa, a freshman Biology major. As referenced above, Rosa accepted examples and informal explanations as a proof. She described proofs as making a claim and supporting that claim with some evidence. For Rosa, proofs are not definitive:

> Proof is kind of like, I have this idea that, like, you know. […] It would be like [on Task 4], "I think that, you know, when we do the same *a* term with two different *b* and *c* terms, I think we'll always get even" and it could've been true. Like if they were to say I think it's always even and we did these 2 examples right here, we'd be like "Oh, okay." But then I would prove them wrong by saying "Well this one's odd."

For more definitive arguments, she assigned the terms *theory* or *law*. Generalizing from the scientific definitions of the words, Rosa defined theories as, *"things they've experimented and it's been true for the most part. Like, not always, but almost all the time,"* and defined laws as, *"something like gravity, yeah, there's no proving that it's not true."*

Rosa's beliefs about proof, theory, and law were consistent with what she viewed as convincing. Since proof was not definitive for Rosa, a proof was not necessarily convincing. On Task 1, she tried two examples that both worked and she described her two examples as a proof of the statement. However, she wasn't convinced that it would always be true:

*Interviewer*: Okay, are you convinced that it's going to be true for any 5 consecutive numbers?

*Rosa*: I don't think, um...There's not a lot of absolutes in math, like you know? So I don't know. I'm not convinced that this will always be true, but like for right here it was true.

Rosa was more convinced when she could articulate why a statement was true. On Task 3, she formed a conjecture that the numbers with an odd number of factors were the perfect squares, and she checked her conjecture with three confirming examples (16, 4, and 64). She then explained the rationale behind her conjecture, that the numbers with an odd number of factors are *"the ones where you don't have to list the extra factor"* because the *factors "partner up"*. Rosa was quick to describe this as a proof (since *she "made a statement and then showed examples to why [she] made that statement"*), but later upgraded it to a theory, bordering on a law:

> I would go to say that this one is, like, I did theory on this one because it would be different if I said like you know, I gave a couple of examples but I'm saying like specifically the squares, like the perfect square ones, so I'm already going more in depth and, um, if it was the, yeah theory. See, it's almost on the border of a law.

From her work on these two tasks, we see that Rosa is more convinced by arguments that are more deductive and explanatory in nature, classifying these arguments as theory or law. Since Rosa's *law* is closest to what mathematicians would call *proof*, her reasoning is significantly more mathematically sound than her definition of proof would suggest.

**Definitiveness of Proof.** We observed another area of consistency between students' conceptions of proof and whether they viewed proofs to be definitive. Of the nine students in our study, four described mathematical proofs as non-definitive (i.e. a proof does not guarantee that a mathematical statement is always true). However, as we saw with Rosa, all but one of the students' views of the definitiveness of proof were consistent with their conceptions of proof. All four of the students who viewed a proof as non-definitive also accepted examples and informal explanations as a proof, whereas four of the five remaining students required a formal deductive argument as a proof.

## Implications

In this study, we observed students drawing upon common past experiences in math and science when thinking about and describing mathematical proof. However, despite these experiences being common in a broad sense, different students had internalized different meanings from the experiences. For instance, two students used two-column proofs from high school geometry to support the claim that proofs are deductive, but two other students used the same proofs to claim that examples were sufficient. As a result, it seems that identifying the sources students draw upon in their conceptions is too coarse of a unit of analysis for making sense of those conceptions.

We also observed that, while some students classified empirical arguments as proofs, this does not necessarily mean they viewed those arguments as definitive. In fact, the students' notions regarding what made an argument convincing were far more mathematically accurate than their notions of what constitutes a proof. In future studies, researchers should take care not to conflate these two separate sets of conceptions.

Gestures as Evidence of Assimilation When Learning Optimization

Keith Gallagher and Nicole Engelke Infante
West Virginia University

*Teachers and students often produce gestures during communication about mathematical concepts and processes. Our goal in this study was to determine whether students would produce gestures similar to those used by the teacher. Each of five students in a first semester calculus course was asked to solve two optimization problems based on a video lesson in which the teacher used primarily pointing, primarily depictive gestures, or no gestures at all. Though our data do not show the students' gestures directly imitating the teacher's, they provide support for the claim that frequent gesture use during communication may indicate assimilation of new concepts and that assimilation improves student performance on optimization tasks.*

*Keywords:* gesture, calculus, optimization, assimilation, accommodation

## Background

Optimization problems are frequently difficult for students in first semester calculus. These problems often require the drawing of figures, definition of several variables, coordination of multiple equations, algebraic substitutions, application of derivatives, and ultimately interpretation of the final results. LaRue and Engelke Infante (2015) studied student responses to optimization problems and determined that students have the most difficulty during the early, "set up" parts of the problem. This part of the problem solving process is referred to as the *orienting phase* (Carlson & Bloom, 2005). During this early phase of problem solving, the student "deciphers the problem and assembles the tools he or she thinks may be required" (LaRue & Engelke Infante, 2015, p. 2).

Deciphering the problem may evoke for the student certain *concept images*. The notion of *concept image*, as defined by Tall and Vinner (1981), is "the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes. It is built up over the years through experiences of all kinds, changing as the individual meets new stimuli and matures." For instance, one's concept image of the derivative might include things like a prototypical example curve, tangent lines, slope, rate of change, "prime" notation, and processes like the power rule, product rule, and chain rule. Note that the concept image is *dynamic*: it changes in response to new experiences. Prior to learning about optimization, students in calculus will almost certainly have learned about derivatives, maxima and minima (in relation to curve sketching), and the second derivative test for concavity. When optimization is introduced, however, it may become a part of the student's concept image for any or all of these concepts.

A student's concept image may incorporate gesture. Gestures are a naturally occurring part of communication; as such, teachers frequently gesture when teaching. For example, it is not uncommon for teachers to trace the shape of a parabola in the air, or to point to an equation written on the board for reference. Students may internalize these gestures as part of their concept image, and in turn, they may produce these or similar gestures during communication. It has been shown that thinking about an object or an event activates the same regions of the brain that become activated during the actual physical perception of those objects or events, and thus regions of the brain responsible for reacting to these stimuli are also activated (Hostetter & Alibali, 2008). Hostetter and Alibali's (2008) *Gesture as Simulated Action* framework posits that the activation of these regions of the brain in response to simulated (mental) actions will sometimes result in the realization of an overt movement: a gesture.

Studies suggest that students are more likely to produce gestures when communicating difficult information (McNeill, 1992; Radford, 2009; Roth, 2000). Roth (2000) specifically noted, "This and other research documents a high incidence of gestures when individuals deal with unfamiliar situations" (p. 1711). In light of the results of LaRue and Engelke Infante (2015), we expect that when solving an optimization problem, students might produce more gestures during the orienting phase of solving the problem. This study aimed to answer the following question: Do students mimic the teacher's gestures when solving problems similar to what the teacher presented? While we did not see evidence of this, we did observe evidence that students were more likely to produce gestures if they are *assimilating* new information, rather than *accommodating* it.

## Theoretical Perspective

We frame our research using Piaget's (1985) notions of *assimilation* and *accommodation*. *Assimilation* is "the cognitive *process* by which the person integrates new perceptual matter or stimulus events into existing schemata or patterns of behavior" (Wadsworth, 1975, p. 15). During the learning process, an individual is said to have assimilated new knowledge when they have made cognitive connections between the new information and their pre-existing knowledge. However, assimilation may not be possible: the individual may not possess an existing schema into which the new information fits. Under this circumstance, accommodation may take place. *Accommodation* is "the creation of new schemata or the modification of old schemata" (Wadsworth, 1975, p. 16). Piaget posits that cognitive systems exist in a state of dynamic equilibrium involving both processes of assimilation and accommodation (Piaget, 1985).

Piaget's concepts of assimilation and accommodation describe two ways in which learners attempt to reconcile new information with their pre-existing knowledge. This includes the incorporation of sensorimotor input like gestures (Piaget, 1985). As evidence of the assimilation of perceived gestures into existing schemata, we observe the repetition of these or similar gestures during communication. Here, we adopt Sfard's (2001) communicational approach to cognition, which views thinking as a special case of communication, "as one's communication with oneself" (p. 26). With this perspective, gestures that are realized during interpersonal communication, as well as those performed during individualized thought, are taken as evidence of assimilation.

## Methods

The goal of our study was to determine how student understanding is affected by the instructor's gesture use in the classroom. We prepared a lesson on optimization for a first semester calculus course, and three scripts were prepared: one in which the instructor used only *pointing* gestures, one in which the instructor used only *depictive* gestures, and one in which the instructor made no gestures. Using the definitions in Alibali et al. (2014), a *pointing gesture* is one which "indicate[s] objects or locations in the physical world," and a *depictive gesture* is a simulated action or a conceptual action grounded in a physical action, such as simulating the action of collecting objects as a metaphor for the conceptual action of adding numbers. Apart from the differences in gestures, these three scripts were identical. One member of the research team was filmed presenting each script, and three videos were prepared. It should be noted that this lesson used the second derivative to confirm that the answer that was obtained was a maximum/minimum instead of the first derivative.

Interview subjects were assigned one of the above videos to watch based upon the order in which they arrived for interviews. Students were permitted to take notes while watching their video. Immediately after watching the video, students were asked to solve two optimization problems:

*Problem 1: If the perimeter of a rectangle must be 84 inches, what are the dimensions of the rectangle that has the largest possible area?*

*Problem 2: A company wishes to manufacture a rectangular box with an open top whose base length is twice as long as its base width. If the box must contain a volume of 32 $ft^3$, what are the dimensions of the box that will minimize its surface area?*

Students were encouraged to speak aloud as they worked so as to ascertain why they took the steps they did to solve the problem. Interviewers prompted the students when they were quiet for long periods of time and after they had completed certain steps in their solutions. Interviews were filmed to capture students' thoughts and gestures during this process. Students were compensated for their time with a $10 gift card.

There were a total of five interview subjects who were assigned pseudonyms: Ben, Andrew, Eric, Lisa, and Mary. Ben and Lisa watched the "Pointing" video, Andrew and Mary watched the "Depictive" video, and Eric watched the "No Gesture" video. All five students were enrolled in first semester calculus at the time of their interviews. Students Ben and Mary reported having taken a first semester calculus course in the past, while Andrew and Lisa reported that they had not. Ben and Eric self-reported that they were international students.

We employed a thematic approach to the data set (Braun & Clarke, 2006). Each video was watched several times by each member of the research team who made notes about the students' problem solving activity, paying particular attention to the gestures being made. From these notes, it became evident that two of the participants were actively seeking to make connections between the new information that had been presented to them and their existing knowledge of functions and calculus. Hence, complete transcripts (all speech and gesture production) for Lisa and Mary were made and further analyzed to examine how they were assimilating the new ideas.

## Data

Ben, Andrew, and Eric all displayed superficial understandings of the lesson presented in the videos. Evidence of accommodation was present in the form of utterances referring to the instructor's words in the videos, but little evidence of assimilation was demonstrated by any of these three subjects. Most of the actions performed by these subjects during their solution attempts were simply appealing to memorized rules they had learned either from the video or from some other source; little evidence of true understanding manifested. For these reasons, we focus on the results of interviewing Lisa and Mary, which we present here as case studies.

### Lisa

Lisa began the explanation of her solution to Problem 1 with several pointing gestures referring to her written perimeter and area formulas. When asked to explain how she knew she had the correct formulas for area and perimeter, she initially stated that "Teachers have beat those into my brain," and "That's just what I've always been told." However, when asked if these formulas have meaning for her, Lisa immediately explained that the perimeter is the sum of the lengths of the sides of the rectangle she had drawn, and that the area was the product of the side lengths, pointing to the relevant sides of her figure as she spoke about them. She elaborated that she thinks of the area as “tiny squares everywhere, so how many squares on this side [points to one side of rectangle] times how many squares on this side [points to a perpendicular side] will give you how many squares in total [mimes shading in the figure].”

To determine the length needed to obtain the maximum area, Lisa found the derivative of her area function and set it equal to zero. When asked why she chose to do that, Lisa explained that, on the graph of the area function, this would be where the graph changed from increasing to decreasing. While explaining this, Lisa traced a “concave down” shape in the air. While continuing her explanation, Lisa also drew a rough sketch of the curve she pictured in her mind, then also quickly sketched the graph of the derivative of this curve to explain that a maximum would occur when the values of the derivative changed from positive to negative.

Before beginning Problem 2, Lisa indicated that she did not know the formula for the surface area of the shape in question. However, she began to think aloud as she reasoned through what the formula should be. She vocalized that the figure had five faces, and initially suggested “5 times length times width.” At the interviewer’s prompt, Lisa drew and labeled a picture of the figure. She stated that surface area is “kinda the area-perimeter of everything on the outside… all the material on the outside.” When asked to elaborate on what she meant by the term *area-perimeter*, she explained, “It’s kinda both in a way. ‘Cause it’s all around [moves her hand in a circle around an imaginary object] the object, but it’s the area of each face as well [mimes touching the five faces of the box by holding her hands in parallel then rotating them 90 degrees to indicate the next pair of parallel sides].” She was then able to determine the area formula for each face, pointing to the appropriate faces on her figure as she did so, and add them together to obtain the surface area formula for her figure.

Continuing, Lisa used the volume formula and the constraint that the base length is twice the base width to rewrite her surface area function in terms of one variable. After staring quietly at her formula for about 30 seconds, Lisa said, “Well, I’m thinking about taking the derivative of this, but I don’t want to.” She explained that she didn’t like the quotient rule, but then she acknowledged that she could avoid using it by rewriting her formula using negative exponents, and she then differentiated her function:

> *Interviewer:* And why do we take the derivative?
>
> *Lisa:* So that we can find the critical point, which will be our, hopefully our minimum. I mean, it’ll likely be concave up, but…
>
> *Interviewer:* OK, and so, you’re hoping that it’s concave up. Why are you hoping that it’s concave up?
>
> *Lisa:* If it’s concave up, then it will be like a U [puts her thumbs together and extends her index fingers into a U-shape], and then it’ll have a minimum value [puts a fist at the bottom of the U-shape and points at it with her other hand] at the critical point where the slope is zero.

She then set her derivative equal to zero and found the critical number to be the cube root of 24. Initially, she wrote “$\pm\sqrt[3]{24}$,” but she decided that her answer must be positive because it defines a width. After another moment, however, she concluded that her solution must be positive, as 24 is positive, and “negative times negative times negative would be a negative number.”

When asked how she knew that the dimensions she obtained would minimize the surface area, Lisa answered, “’Cause I’m gonna take the second derivative, and if it’s a positive number then I’ll know it’s concave up.” She talked briefly about testing the function for points of inflection, but then decided against it. She then spoke about substituting a value into the second derivative, but she was unsure what value to use. She concluded that she could choose any number in the domain, so she chose to substitute $w=1$ into the second derivative. Lisa seemed unconvinced by her result, so she then used the first derivative test to confirm that the graph of her surface area function was concave up at the critical number. With this information in mind, she then returned to the second derivative and substituted $w=3$ to again confirm that the graph was concave up, as she expected it to be.

Throughout her interview, Lisa utilized a variety of gestures to express various notions relating to work she had done on her paper. When explaining written parts of her work, she used pointing to refer to the relevant portions of her work; when describing more general concepts like slope or maximum and minimum, she often used depictive gestures, as exemplified in the following excerpt:

> *Lisa*: The derivative will be zero when L is 21.
> *Interviewer*: OK, so why, why do we care about that?
> *Lisa*: Um, because that is, uh, that'll be the critical point. So that'll be [traces a concave down arc in the air] when it's changing directions from, um, from increasing to decreasing on the graph, and we care about that because we want the maximum area.

In addition, she frequently referenced the notes she had taken while watching the video any time she felt unsure as to how to proceed.

**Mary**

When Mary began working through Problem 1, she generated the correct formulas for area and perimeter. When asked how she knew that her formulas were correct, she replied in similar fashion to Lisa, initially citing memorization but elaborating a clear conceptual understanding via similar gestures to those used by Lisa.

Throughout solving Problem 1, Mary referred to her notes on the video to confirm her procedure as she worked. Mary expressed frankly that she was unsure what the significance of the second derivative was in solving these problems. Despite this, Mary worked quickly through most of Problem 1, and used her notes on the second derivative to confirm that her solution would yield the maximum area for the rectangle. Like Lisa, Mary utilized a combination of pointing and depictive gestures.

Mary began Problem 2 by sketching a box with an open top and labeling its dimensions with *l*, *w*, and *h*. Similar to the other interview subjects, Mary said "I don't even know the surface area of a cube to be perfectly honest." However, she knew that the surface area represents "the area of, like, all of the outside… let's say rectangles, added together [uses her hands to depict the parallel pairs of faces of a box]." After a brief conversation about this idea, Mary was able to determine the correct formula for the surface area of her open-topped box. She then proceeded to solve Problem 2 using the same method she employed to solve Problem 1. She continued to express doubt about her use of the second derivative, but she followed the rules stated in the video.

Prior to stating that "If it is a max or a min, then the derivative has to be zero," Mary said that if the derivative is equal to zero, "it either has to be a max or a min… well – no, not necessarily." Following the exchange in the previous paragraph, the interviewer returned to this comment to ask Mary how she convinced herself that this original statement was false. She answered, "I was just, um… Because, like, in cubic functions, [sketches a graph similar to that of $y=x^3$] um, you can have a point where the derivative right here [draws a point at the point of inflection] would equal zero, but it's not necessarily an absolute max or a min."

At the conclusion of the interview, Mary asked if it was necessary to test the endpoints in addition to the critical number by substituting them into the original surface area equation, apparently thinking about the test for absolute extrema on a closed interval (the domains for both Problems 1 and 2 are open intervals). However, she correctly identified that, if she were to do this, the input value which yielded the smallest surface area would give the location of the function's minimum.

## Discussion and Conclusions

In response to our research question, we did not observe that students consistently mimicked the instructor's gestures when solving similar problems. However, we argue that assimilation of new information increased the frequency of gesture production and increased subjects' degrees of success in solving the problems in this study. In the data, it is clear that Lisa and Mary performed a significant number of gestures, while Ben, Andrew, and Eric did not. We now discuss evidence of Lisa and Mary's assimilation and its correlation to their success on Problems 1 and 2.

The new information presented in the videos in this study is twofold: the context of the problems (optimization), and the use of the second derivative in the determination of extrema. Data collected from interviews with Ben, Andrew, and Eric are minimally discussed here, as we observed little evidence of assimilation of this new information. These subjects showed some evidence of accommodation. For Ben, Andrew, and Eric, the use of the second derivative in this way appeared to be detached from their prior knowledge of calculus. Rather than assimilating this knowledge, they appear to have simply accommodated it by adding it to a collection of disconnected procedures. For example, Eric initially claimed that both the first and second derivative tests were necessary to confirm the location of the maximum in Problem 1. However, he concluded that the second derivative test alone was sufficient, as the instructor in the video had said this, and because "The second derivative is negative two; negative number is concave down… uh, concave down. The first derivative is equals to a positive number, so that's why we got, like, a maximum value." Eric's response is typical of these three students. While often incorrect, each of these students used what they believed to be appropriate rules in an algorithmic manner with no evidence of attempting to make connections between concepts. These three subjects were largely unsuccessful in their solutions of both Problems 1 and 2. Correspondingly, Ben, Andrew, and Eric gestured minimally when discussing their solutions.

Lisa and Mary both demonstrated significant evidence of assimilation, and we observed significantly more gesture from these subjects, so we focus on the results of their interviews. First, we note that Lisa and Mary were the only two subjects who were able to articulate a conceptual understanding of the perimeter and the area formulas. From their oral descriptions, one has the sense that both of them have a clear concept image of perimeter and area, at least for rectangles. This knowledge assisted them in determining the formula for the surface area of a box. By using gesture to help them visualize the sides of the box in a manner similar to perimeter, both were able to construct an appropriate formula.

Furthermore, both subjects demonstrated a rich concept image of the first derivative as it relates to maxima and minima. Lisa's explanation in Problem 1 for setting the first derivative equal to zero rested on the idea that the function should be increasing to the left and decreasing to the right of this point, and her gesture of drawing a concave down arc in the air is further evidence of her understanding. Moreover, without prompting, she was able to quickly sketch an example curve and its first derivative to support her claim that the derivative should be equal to zero. Mary's concept image of the first derivative as it relates to maxima and minima contains counterexamples to erroneous claims. Solving Problem 2, when trying to explain why she set the first derivative equal to zero, she said that if the first derivative is equal to zero, then "it either has to be a max or a min…" but quickly corrected herself, as she appeared to have internally convinced herself that this statement was false. When probed about this later, Mary was able to provide the example $y=x^3$, a function which she explained contains a point where the first derivative is equal to zero but that point is not an extremum of the function. In these and other examples in the data, we see evidence of very detailed concept images of the first derivative.

The data suggests that Lisa readily assimilated the new information about the second derivative into her existing schema for finding maxima and minima. In solving Problem 2, Lisa expressed not only an intention to find the second derivative of her surface area function, but also her expectation that her calculation should yield a positive result: "If it's concave up, then it will be like a U [puts her thumbs together and extends her index fingers into a U-shape], and then it'll have a minimum value [puts a fist at the bottom of the U-shape and points at it with her other hand] at the critical point where the slope is zero."

Despite Mary's expressed lack of confidence in the use of the second derivative to solve these problems, she tried to use this method. When she did so, her comments reflected an internal struggle in which she sought to reconcile this new knowledge with her existing schema for extrema: "this is… where she took the second derivative, which I didn't really understand the purpose, but… [writing] So A double-prime of l is 2… which means that it's going to be a min… at 2. Um… [looking at her work] … we're trying to maximize the area, yeah, I don't know. This is where I get a little confused," and later, "Is it because of taking the second derivative and getting that max that you know that those are the dimensions that give you the largest possible area?" Though it doesn't appear that Mary had fully assimilated this use of the second derivative during her interview, there is evidence to suggest that she was making a concerted effort to do so.

Ben, Andrew, and Eric showed little evidence of assimilation; rather, we observe only the most basic accommodation. They appear to remember snippets from the videos they watched, but none of them appears to have a complete picture. Of these three students, only one of them obtained the correct solution to Problem 1 via a logically valid procedure, and none of these students obtained a correct solution for Problem 2. None of these students attempted to justify their solution without being prompted to do so, and none of them provided an accurate explanation for how to do so. Lisa and Mary both demonstrated evidence of at least an attempt at assimilation, if not success. Not only were these two the only subjects to obtain complete solutions to both Problems 1 and 2, but they were also the only subjects to attempt to justify their solutions without prompting. They were the only subjects to use logically sound reasoning about the second derivative in their justifications.

The results of this study point to frequent gesture use as a potential indicator of assimilation of knowledge. Future research might investigate: Does student gesture use facilitate assimilation, or might it simply indicate that assimilation has occurred? More research needs to be done to better understand the role gesture plays in assimilation of new concepts.

## Acknowledgments

We thank Jennifer Glaspell for being our video-recorded instructor, as well as Tim McCarty, Joshua Case, and Cody Hood for assistance in project design, data collection, and initial analyses.

*Considerable learning is entailed in adopting an inquiry-oriented approach to teaching a class. In this analysis, we examine classroom video data of three instructors' initial implementation of an inquiry-oriented instructional unit and their implementation of the same unit one year later. We document consistent increases in instances of eliciting and building on student contributions across tasks and instructors, and use Toulmin's argumentation scheme to offer an illustration of how classroom discussions became more mathematically robust and student-centered from initial to subsequent implementations. Implications for instructor learning are discussed.*

*Key words:* inquiry-oriented instruction, instructor learning, instructional practice

Enrollments in science, technology, engineering, and mathematics (STEM) programs in the United States must grow to meet projected workforce demands in coming years (PCAST, 2012). Following a growing body of research documenting the positive outcomes related to student-centered approaches to instruction in undergraduate STEM (e.g. Freeman et al., 2014), there is increased institutional and financial support for initiatives that promote this kind of teaching. Student-centered approaches range widely, from approaches that provide opportunities for students to practice things demonstrated by their instructor with groups of peers during class time, to inquiry-oriented approaches that aim to provide students with opportunities to participate in the reinvention of important mathematical ideas by working with peers to solve non-standard problems with many possible solution paths. Inquiry-oriented approaches are instructionally complex in that as students are inquiring into the mathematics, instructors inquire into students' mathematical thinking so it can be leveraged as a resource for moving forward the development of the class's mathematics (Kwon & Rasmussen, 2007).

The difficulties experienced by instructors attempting to implement research-based, inquiry-oriented instructional materials developed by others have been documented to include struggles in making sense of and building on student reasoning (Johnson & Larsen, 2012; Speer & Wagner, 2009; Wagner, Speer, & Rossa, 2007). While these findings suggest it is challenging to teach in an inquiry-oriented way for the first time, there is little work at the undergraduate level that examines what one learns as a result of teaching in this way. In this analysis, we draw on video data of three instructors' initial implementation of an inquiry-oriented instructional unit in linear algebra and their implementation of that same unit one year later. The research question is: How does instructors' facilitation of whole-class discussions shift from initial to subsequent implementations of inquiry-oriented instructional materials?

## Literature Review & Theoretical Framework

To conceptualize the kind of knowledge needed for teaching mathematics, Hill, Ball, and Schilling (2008) developed a model of mathematical knowledge for teaching (MKT) which is split into two major domains: subject matter knowledge (SMK) and pedagogical content knowledge (PCK). This distinction builds on Shulman's (1986) argument that there is a distinction between knowledge of mathematics and the specific knowledge about mathematics that is needed to teach it effectively. In this work, we are particularly interested in how PCK might develop as a result of implementing inquiry-oriented instructional materials so we focus on that part of Hill and colleagues' framework. Hill et al. (2008) divide PCK into three subdomains. First, Knowledge of Content and Students (KCS) refers to the knowledge a teacher has about their students' prior knowledge of specific content and how student learn that content. Second, Knowledge of Content and Teaching (KCT) has to do with instructional decisions that require "coordination between the mathematics at stake and the instructional options and purposes at play" (Ball, Thames, & Phelps, 2008, p. 401). Third, Knowledge of Curriculum (KOC) refers to what teachers know about how ideas build in the context of a particular set of curricular materials.

At the elementary level, Remillard (2000) found that instructors can learn from curricular materials when materials focus on mathematical problem solving and analysis of student reasoning. Sherin (2002) conducted an analysis of two high school algebra teachers' work with a reform-oriented unit on linear functions, noting three kinds of learning: their subject matter knowledge, their views of curricular materials, and their ideas about student reasoning. However, little work at the undergraduate level has explored what teachers learn by engaging in inquiry-oriented approaches to instruction. Inquiry-oriented approaches require careful attention to student reasoning as well as skill at facilitating classroom discussion and argumentation, so we seek to document teacher learning by examining shifts in instructional practice as evidenced by shifts in classroom mathematical argumentation.

We draw on Toulmin's (2003) model of argumentation that was originally used to examine how individuals supported claims in front of an audience. Krummheuer (1995) extended the model to examine mathematical argumentation in classroom discussions that involved input from multiple individuals. Others have used this framework as a tool of analysis for both individual mathematical argumentation (e.g. Wawro, 2015), and collective mathematical discussion (Ramussen, Wawro, & Zandhieh, 2014; Conner, Singletary, Smith, Wagner, & Francisco, 2014). In this study, we draw on four core components of Toulmin's argumentation model: claims, data, warrants, and backings. Wawro describes a claim as "the conclusion that is being justified" whereas data is the evidence that supports the claim (Wawro, 2014, p. 320). Warrants are "statements that connect data with claims" (Conner et al., 2014, p. 404) or alternatively "clarification [statements] that connects the data to the claim" (Rasmussen et al., 2015, p. 263). On occasions when a backing is given, it can be defined as the support that gives a warrant authority (Rasmussen et al., 2015). Claims and data can also be a pair; once a claim has been established in a discussion, it can be used as data for a subsequent argument (Conner et al., 2014).

## Study Design (Study Context, Participants, Data Sources, Methods of Analysis)

This work is part of a broader NSF-funded project aimed at developing shareable, research-based resources for instructors interested in using teaching inquiry-oriented linear algebra. The primary data used in this analysis consists of video-recordings of three instructors who implemented a 4-6 day instructional unit on span and linear independence two years in a row. The instructional approach is detailed in Wawro, Rasmussen, Zandieh, Sweeney, & Larson (2012). The instructional sequence consists of four tasks, starting in a context where students are given two "modes" of transportation (a magic carpet and a hoverboard that can travel in particular directions that are represented as vectors) and start at home (the origin). Students work to figure out if they can reach a particular location (to introduce ideas related to linear combinations of vectors), determine if there is anywhere they can't reach (to introduce span), and explore when they can take "non-trivial" journeys that start and end at home (to introduce linear in/dependence). In the final task, which we examine in greater detail, students work to generate examples of linearly dependent and independent sets of specified numbers of vectors in $R^2$ and $R^3$, as well as generalizations that emerged from their efforts to generate these examples.

The instructors participating in this study were 'best case' implementers in many ways: they all expressed interest in implementing the materials and all were situated in departments that were supportive of these efforts. The instructors represent a variety of institutional contexts including two small, private teaching-focused institutions (one religious, one not) and one large research institution. One instructor was a mathematician interested in RUME research, one was a RUME researcher, and one was teaching faculty in a mathematics department at a large research-focused institution. Class sizes ranged from 8-35 students.

Our analysis had four phases: content logging, development of codes for whole class discussions, coding of whole class discussions, and a comparative case study. We began distilling the data by generating a content log for each day of classroom instruction that was video recorded as part of the instructional unit for each instructor for both the first and second year of implementation. The content log was organized in four columns: time stamp and discourse structure (whole group, small group), key events, new language or notation introduced, and other notes. A new row was created when there was a change of discourse structure or shift in topic.

In our second phase of analysis, we drew on data from the analysis of the first year's data to identify four levels of eliciting and building on student ideas: 1. Getting students to talk, 2. Getting students to explain, 3. Using student ideas to explain or formalize, and 4. Using student ideas as the basis for a new mathematical question or task. In our third phase of analysis, two coders separately coded each whole class discussion according to the highest level of eliciting and building on student ideas that was observed. There was difficulty coming to agreement about when one whole class discussion ended and another began based on the criteria of "topical shifts," but by aggregating all scores to the "maximum" score observed in all whole class discussions that took place after students worked on each task in the instructional sequence, agreement was reached.

We noted that in the second year implementation, whole class discussions felt "smoother" in that they seemed to have a clearer mathematical direction, but this distinction was difficult to operationalize. In order to better understand shifts in discussion from the first to the second implementation, we decided to closely examine the mathematics that emerged in whole class discussions following the final task in the sequence in the first and second year. We selected mathematically analogous ten-minute segments from the same instructor, transcribed them, and used Toulmin's (2003) argumentation model to examine the mathematical arguments that emerged, who contributed what to these arguments, and the role of the instructor in the construction of these arguments.

For our final phase of analysis, we transcribed the selected segments, noted important gestures, such as writing on the board or pointing to work, and identified the role group of the speaker (teacher or student). We analyzed the transcripts to identify core claims being argued and from there identified the data and warrants that supported these claims. When they occurred, backings were also noted. Argument components were numbered according to the order in which they occurred in the transcript. Once we had identified and numbered the components of argumentation, we constructed diagrams of the mathematical discussion. We adapted Conner et al.'s (2014) convention of using solid and dotted line in these diagrams to distinguish the primary contributor of the statement. The Toulmin mappings allowed us to count the types of contributions by role to quantify shifts in argumentation relative to who made contributions.

## Findings

To show how instructors' facilitation of whole class discussions shifted from their initial implementation of inquiry-oriented instructional materials, we leverage our coding scheme for eliciting and building on student reasoning to show consistent, quantifiable growth. Table 1 shows the maximum score each instructor received in all whole class discussion after students had worked in small groups on each of task 1 through 4 in year 1 and year 2. Every instructor elicited and built on student reasoning in whole class discussion as much or more in the second year's implementation. However, this does not capture the way in which year 2 discussions seemed to generally hold a clearer sense of direction and seem more mathematically rich while also building on student ideas. To explore this, we examine two mathematically similar ten-minute segments of discussion for instructor A in year 1 and year 2 through a Toulmin analysis.

Table 1: Instructors' Eliciting and Building on Student Reasoning

| | Year 1 | | | | | Year 2 | | | | | Year 1 to 2 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| **Task:** | **1** | **2** | **3** | **4** | **mean** | **1** | **2** | **3** | **4** | **mean** | **Mean change** |
| Instr A | 3 | 4 | 2 | 3 | 3 | 3 | 4 | 3 | 4 | 3.5 | +0.5 |
| Instr B | 3 | 3 | 3 | 2 | 2.75 | 3 | 3 | 4 | 4 | 3.5 | +0.75 |
| Instr C | 2 | 2 | 3 | 2 | 2.25 | 4 | 3 | 3 | 3 | 3.25 | +1.0 |
| **Mean** | **2.67** | **3** | **2.67** | **2.33** | **2.67** | **3.33** | **3.33** | **3.33** | **3.67** | **3.42** | **+0.75** |

### Toulmin Analysis of Selected Exchange: Year 1

Figure 1 shows a Toulmin mapping of a whole group discussion in instructor A's class in year 1 related to the claim that any three vectors in $R^2$ must form a linearly dependent set. The class had already concluded (in previous discussion) that two vectors in $R^2$ are linearly dependent when they are scalar multiples of one another or point in the same direction (note the zero vector case had not been teased out). The instructor then pointed out one group's example of a linearly dependent set of three vectors in $R^2$ (marked as Claim 1). Upon the teacher's request, students offered somewhat vague data (2) that alluded to scaling vectors to get a non-trivial solution (without specifying *what* equation would have such a non-trivial solution), supported by the warrant (3) that this was possible because the three vectors were not parallel.

The instructor built on students' ideas by writing the equation $a\begin{bmatrix}1\\2\end{bmatrix} + b\begin{bmatrix}3\\4\end{bmatrix} = \begin{bmatrix}5\\6\end{bmatrix}$ on the board and asking "how are you sure of that without finding the coefficients?" (Data 4). When the students seemed unsure of how to answer, the instructor asked, "What if we just had these two? [*pointing to two of the three vectors in the original set of vectors*] Is this an independent set?" Students agreed with a choral response (Warrant 5). The instructor continued, "they're not multiples of each other, easy to check with two vectors, throw the third in, now I might be able to write a linear combination of two that gets me the third, that's our triangle… um pretend this is your magic carpet and your hover board cause I claim this is no different from that situation. They look different directions, they're not in the same line, they're an independent set. Where can you get on your magic carpet and hover board?" Students chorally responded, "Everywhere"

(Data/Claim 6 and Warrant 5). The instructor then rearranged the equation in Data (4) to point out that the homogeneous vector equation corresponding to the set of vectors proposed by the students has a non-trivial solution, so that the set is linearly dependent by definition (Warrant 7 and Backing 8).

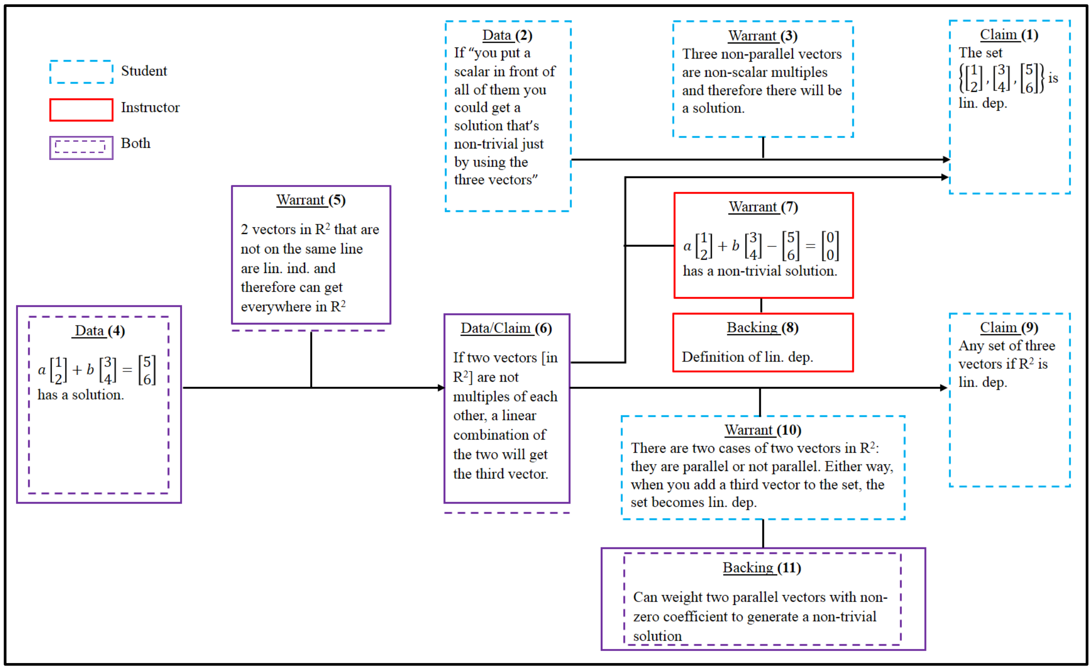

*Figure 1*: Year 1 Toulmin Mapping of Selected Episode for Instructor A

The instructor then asked, "Say I didn't take (1,2) and (3,4) say I take any two vectors that didn't lie on the same line, I throw a vector into that set. What's true about it?" A student suggested, "You can get back to the start… because you can get to that point using those two non-parallel vectors." After the instructor rephrased this idea in terms of span, a student observed, "We just showed that if we have the two [vectors] that are not parallel and then a third one, we can get anywhere. So if we have two that are parallel, then we can just go out one and come back the other. So either they're parallel or not parallel; there's no third case. So in every case they're going to be dependent" (Claim 9 and Warrant 10). The instructor then acknowledged that she set students up to make this observation, and a student asked, "If we have two parallel vectors and the third one, are we allowed to throw a zero on that third one?" The instructor confirmed that that is still considered a non-trivial solution and offered an example (backing 11) linking this case to the definition.

Overall, the two core claims in this exchange (1 and 9) came from students, though the instructor offered significant support that build toward the formulation of claim 9. Specifically, an incomplete data and warrant (2 and 3) were initially offered by students. The instructor added information to these by formulating them as an equation (data 4). She then built those into a new claim (6) and warrant (5), with students contributing to these in the form of choral responses. The instructor then used claim 6 as data to support claim 1, also providing the warrant (7) and backing (8). As such, we argue that the instructor provided the majority of the justification for claim 1 that built on student ideas while making clear efforts to involve students in the development of that justification. On the other hand, claim 9 and warrant 10 were fully articulated by a student after an initial question from the instructor that the instructor later explicitly acknowledged was intended to lead students in this direction.

**Toulmin Analysis of Selected Exchange: Year 2**

In year 2, the conclusion that three vectors in $R^2$ cannot form a linearly independent set was arrived at rather differently (see Figure 2). The class had previously established, as suggested by a student, that two vectors in $R^2$ are linearly dependent when "they are scalar multiples of one another." The discussion began with one group's (incorrect) claim (1) that the set of vectors $\left\{\begin{bmatrix}1\\2\end{bmatrix},\begin{bmatrix}7\\2\end{bmatrix},\begin{bmatrix}8\\5\end{bmatrix}\right\}$ is linearly independent[1]. The instructor did not correct the students but asked them how they checked they were independent. One student from the group explained, "you can't add vector one and vector two to create…vector three" (marked as Data 2). The instructor then offered what we refer to as an "empathetic" warrant (3): "Because you can't generate uh, by sort of observation, a dependence relation between those, they're independent." Another student then (correctly) noted that any pair of vectors from this set "can reach anywhere in the plane…" (Claim 4) because they are linearly independent (Data 5). The instructor provided the warrant (6) that any two of these vectors are not multiples of each other and "point in different directions". The student continued, noting that you "can reach eight, five" (Warrant 7), so the set is linearly dependent (Claim 8).

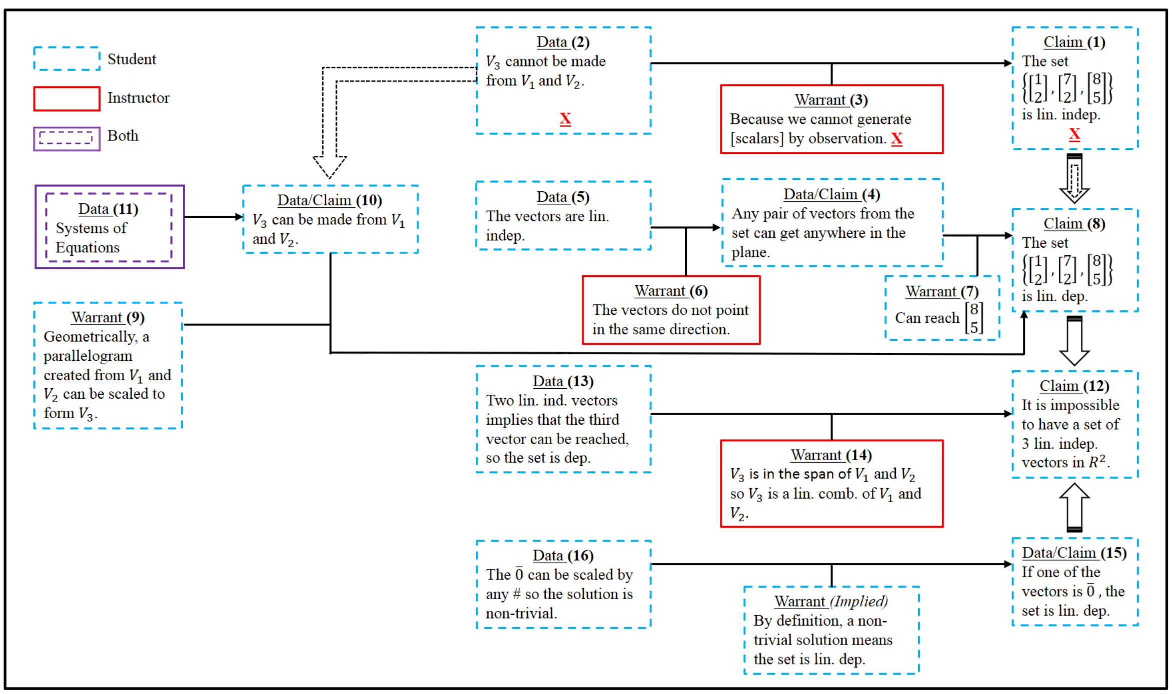

*Figure 2*: Year 2 Toulmin Mapping of Selected Episode for Instructor A

The instructor then revisited the question of how one can tell if the third vector $\begin{bmatrix}8\\5\end{bmatrix}$ can be made from a combination of the other two vectors. A student rectified the previous reasoning from Data 2, arguing that a parallelogram created from the other two vectors could be scaled to

[1] In the Toulmin mapping, statements that are not mathematically correct are marked with an X. Incorrect statements that resolve to correct statements are marked with dotted arrows.

make the third vector (Warrant 9 and Data/Claim 10). Another student suggested you could make a system of equations (Data 11), which the instructor elaborated somewhat extensively.

The instructor then said, "So this isn't an example of an independent set. Can we come up with three [vectors] that are? Who came up with a different example? Back corner, you guys have something written for that." A student claimed that it's "impossible" to create a set of three linearly independent vectors in $R^2$ (marked as Claim 12) because two linearly independent vectors in $R^2$ "can reach wherever the third is going which by definition makes it to become dependent" (marked as Data 13). The instructor elaborated, "Whatever third vector you pick it's already in the span of these. It's a linear combination of these. It's dependent on the previous two" (Warrant 14).

A student-to-student exchange about making the third vector the zero vector follows. A student suggested that if one vector is the zero vector, then the set is linearly dependent (Data/Claim 15), with another student noting "you could scale the zero vector by any number you want, then it's not trivial" (Data 16). The warrant remained implicit, as the instructor confirmed the second student's reasoning that "you can always put something non-trivial there" and ended the class period.

**Comparing Argumentation in Year 1 to Year 2**

In comparing these two exchanges, we noted a shift in the interconnectedness of mathematical ideas discussed, as well as a shift toward students taking authority and contributing more claims and data in year 2. Table 2 identifies how many claims, data, warrants, data/claims, and backings were articulated primarily by the teacher, and primarily by students.

Table 2: Count of Components of Arguments by Primary Contributor

| | Claim | | Data | | Warrant | | Data/Claim | | Backing | |
|---|---|---|---|---|---|---|---|---|---|---|
| | T | S | T | S | T | S | T | S | T | S |
| Y1 | 0 | 2 | 0 | 1 | 2 | 2 | 1 | 0 | 2 | 0 |
| Y2 | 0 | 4 | 1 | 4 | 3 | 3 | 0 | 2 | 0 | 0 |

We argue that in year 1, the teacher elicited correct student ideas, built on, and reshaped them so as to achieve her mathematical goals. In order to accomplish this, the teacher ended up formulating a larger portion of the mathematical argumentation as compared with the following year. In year 2, the instructor made space for students to explore their ideas in a supported way, even when those were incorrect. By engaging an incorrect response as a starting point, and allowing students to articulate and explore the ambiguity and their own uncertainty (supported by both the instructor's empathetic warrant and her invitation to discuss their uncertainty), the students were able to correct their reasoning and provide a larger portion of the mathematical argumentation.

## Discussion

Our analysis offers insight into the shifts that take place between initial and subsequent implementations of inquiry-oriented instructional sequences among instructors with interest in implementing (and some access to conversations with curriculum developers). Our analysis suggests that teachers' knowledge of curriculum, content and students, and content and teaching all increased. Our study also functions to contribute a potential methodological approach of using Toulmin's argumentation model for investigating shifts in instructional practice, an important form of instructor learning.

Johnna Bolyard
West Virginia University

Matthew Campbell
West Virginia University

*In this paper, we analyze video data of five instructors teaching the Mean Value Theorem in a first-semester calculus course. Throughout the lessons, graphical examples were provided by the instructors and/or the students of functions that satisfied or did not satisfy the conclusion of the Mean Value Theorem. Through the use of thematic analysis, we identified four themes related to emergence and use of examples: who generated the example, who evaluated the example, for what purpose the example was used, and the richness of the example. We emphasize that instruction that leverages student generated examples can provide a great deal of richness in a mathematics lesson and create opportunities to engage students in authentic mathematical activity. This work contributes to an evolving notion of what is entailed in students' active learning of mathematics and the role of the instructor.*

*Keywords:* Example space, Calculus, Mean Value Theorem, Active Learning, Graphical Representations

Although educational research has shown that students develop deeper understanding of mathematics in classrooms where they are actively engaged, lecture is still the primary (and often only) mode of instruction in many collegiate level mathematics courses (Freeman et al., 2014). In this project, we studied five instructors of first semester calculus who were committed to increasing the amount of active learning in their classes. We analyze data from instruction covering the Mean Value Theorem, which provided many graphical examples. While many themes emerged from this data, in this paper we describe instructors' use of graphical examples in covering the Mean Value Theorem. Specifically, we seek to answer the research questions: In what ways are examples generated and used in instruction? What role do these examples play in contributing to an active learning environment?

## Literature Review

While many students view examples provided by teachers and texts as templates for solving homework exercises (Lithner, 2003, 2004), examples can play an important role in developing understanding of concepts. Watson and Mason (2005) introduced the notion of learner generated examples (LGEs) and advocated for their power as a tool for deeper learning. Mason and Watson (2008) elaborated:

> ...when a teacher offers an example and works it through, it is the teacher's example. Learners mostly assent to what is asserted. … When learners construct their own examples, they take a completely different stance towards the concept. They 'assert'; they actively seek to make sense of underlying relationships, properties, and structure which form the substance of the theorem or concept. (p. 200)

Mason and Watson (2008) noted "Learners who are encouraged to be creative and to exercise choice respond by becoming more committed to understanding rather than merely automating behavioural practices" (p. 192). To promote creativity in LGEs, students should be encouraged to consider variation. That is, students need to be comfortable asking and exploring questions such as: “What can vary in this problem?” and “To what extent can this aspect of the problem vary?” Watson and Shipman (2008) note that “if students generate examples, reflection on those examples could, through perceiving the effects of the variations they have made, lead to awareness of underlying mathematical structure. ‘Structure’ here means how elements and properties of mathematical expressions are related to each other.” (p. 98) They further indicated that directed example generation, rather than “directionless exploration,” can be a good way to begin understanding concepts.

Through LGEs, a personal example space (PES) is constructed and developed. A PES is defined to be the set of available examples and methods of example construction a learner has at their disposal for solving problems. Sinclair, Watson, Zazkis, and Mason (2011) examined how personal example spaces are structured, paying attention to the varying degrees of “connectedness” such PESs may have. The more connected one’s example space, the greater the likelihood of having a stronger understanding of the concept. They indicate that slightly different prompts may trigger the use of different examples.

## Theoretical Perspective

We frame our work considering active learning and the role of examples in the undergraduate mathematics classroom from a communities of practice perspective (Wenger, 1998). The mathematics classroom, as a community, should be a microcosm of the broader mathematics community—engaging in similar disciplinary practices such as proof and justification, seeing structure in mathematics, and the collaborative pursuit of mathematical discovery. What makes the mathematics classroom, whether in K-12 or at the undergraduate level, different from the academic discipline of mathematics is that most of the participants (students) are often newcomers to the taken-as-shared practices, norms, and habits of mind of doing mathematics. However, the classroom community does not (or at least should not) exist in a vacuum—the goal should not only be for students to become more central participants in the classroom (for the sake of the classroom itself) but also in the broader discipline of mathematics, specifically the ways of thinking and reasoning about and communicating with mathematics. Viewing the mathematics classroom as a community of practice, as defined by Wenger (1998), has implications for considering what learning consists of and the role the instructor plays in supporting learning. For our purposes, this perspective also helps clarify some of the structural elements and characteristics of supporting “active learning” in the undergraduate mathematics classroom.

As a social theory of learning, learning from the communities of practice perspective integrates four components: meaning, practice, community, and identity (Wenger, 1998). A productive mathematics classroom is one in which students have the opportunity to learn mathematics. From this communities of practice perspective, this means that students have opportunities to: experience meaningful ways of doing and constructing mathematics (meaning), to then engage in those authentic practices (practice), to be positioned in the classroom community as competent participants in mathematical activity (community), and to come to see themselves (and be seen by others) as one who does mathematics (identity). This multi-faceted process by which newcomers learn and become included in a community of practice is referred to by Lave and Wenger (1991) as “legitimate peripheral participation.” This raises questions about conceptions of active learning that only focus on “participation”—such as opportunities for working in small groups or monitoring air time in whole group contexts. The substance of that participation and how students are ultimately positioned in the midst of that participation is equally important. A focus only on participation may support students coming into the community of the classroom from a purely social standpoint, but be divorced from engaging meaningfully in mathematical ways of working and from being positioned as someone whose ideas are worthwhile, worth building on, and contributing to a collective effort. In our work, we have come to focus on students' opportunities to reason about, offer, and make connections among mathematical examples, and how students have a clear sense of the way in which examples serve a collective effort to build mathematical ideas.

## Methods

Subjects in this study were five instructors of first-semester calculus at a large public research university. One of the authors served as the coordinator of the course as well as one of the instructors in the data set. To help preserve confidentiality, we use the term *instructor* to describe the instructor of record of the course, regardless of whether the instructor was a tenured faculty member, a full-time teaching instructor, or a graduate student. We use the pronouns *she, her, and hers* to describe all five instructors, referred to in this paper as Instructor A, Instructor B, etc. All subjects consented to the study, and all but the author received a $500 stipend for their participation at the completion of each semester of the project. Additionally, students in each class signed a media release form granting permission to use their image or voices in our data.

During the first semester of the project, we videotaped class sessions of all five instructors, starting in week three of classes. All sessions that covered new material were recorded, but we did not record sessions when students were reviewing for an exam or taking a quiz or an exam. In each classroom, a video camera was placed in the back corner and was focused on the instructor during the class period. During the second semester, the same five instructors were video recorded when teaching two units, one on the Mean Value Theorem (MVT) which was not coordinated and one on definite integrals, which was highly coordinated. In this paper, we discuss data from the MVT during the second semester. We purposefully selected data from the uncoordinated sessions because this provides an authentic example of instruction in these classrooms without the influence of the coordinated lessons. Three of the instructors covered the material in one day of class, and two of the instructors used two partial days of class.

As part of a larger project, we used thematic analysis, which is a "method for identifying, analysing, and reporting patterns (themes) within data" (Braun & Clark, 2006, p. 79). We employed both theoretical and inductive thematic analysis. Theoretical thematic analysis is "driven by the researcher's theoretical or analytic interest in the area, and is thus more explicitly analyst-driven" (Braun & Clark, 2006, p. 84). Initially, our focus of the analysis was on ways in which active learning was being used in the classroom. As such, we were using theoretical thematic analysis to code for times when students were working in groups or were actively participating in doing mathematics. Moreover, the communities of practice perspective requires that we look not only at the ways in which students are participating, but in the ways that they were meaningfully engaging in mathematics. Thus, we employed theoretical thematic analysis to identify these instances. Additionally, we employed inductive thematic analysis (similar to Strauss and Corbin's (1998) grounded theory) to identify additional themes that were not driven by our own interests. Using both of these techniques, we found instructors' use of examples to be of particular significance. From this, we focused on instances of an example emerging across the five instructors' MVT lessons. Multiple passes through these instances yielded several themes regarding the generation and use of examples—both in isolation and in the context of the full instructional episode.

## Data

Recall that the Mean Value Theorem (MVT) says "If $f$ is continuous on the closed interval $[a, b]$ and differentiable on the open interval $(a\ b)$, then there exists a number $c$ in $(a, b)$ such that $f'(c) = \frac{f(b)-f(a)}{b-a}$" (Larson & Edwards, 2015). A special case of the MVT where $f(a) = f(b)$ is stated in Rolle's Theorem, resulting in the existence of a $c$ value where $f'(c) = 0$. In this section, we first provide a general overview of the five lessons. We then summarize the four themes centered around examples that emerged from our data. Finally, we provide a detailed description of two of the classrooms to illustrate these themes.

During the instruction on the MVT, only Instructor A required students to work in groups during the development of the MVT. Instructors B, C, and D asked their students to work in groups to solve problems related to the MVT after lecturing on the topic. The nature of the worksheets was practicing problems similar to what had been done by the instructor and did not introduce any new material. During all of the lectures, there were many times where the instructors asked students to participate in some way, usually by answering a simple question or verifying that they understood something that was said. Instructors B, C, and E chose to introduce Rolle's Theorem prior to the MVT, while Instructors A and D presented the MVT first, with Rolle's Theorem given as a special case of the MVT. In every lesson, at least five graphical examples were utilized.

### Who Generated an Example

The first theme evident in our data relates to *who* generated an example. In all of the classrooms, there were times during a lecture when the instructor would provide an example for the class and write it on the board. We will refer to these instances as *Instructor Generated Examples.* At other times, the instructor asked students to provide an example. In these instances, typically, one or two students provided a response, which tended to be a short one or two-word response. The instructor would then interpret the response and sketch a graph on the board. As such, we call these *Instructor Interpreted Examples.* For example, during Instructor B's lecture, the instructor asked the students if it was possible to draw a graph that was continuous but did not have a horizontal tangent. A student responded with "points," and the instructor drew a graph on the board that resembled $f(x) = |x|$. Often times, *Instructor Interpreted Examples* were in response to questions asked by the instructor that had a very small response space. By this, we mean that the set of possible correct answers is relatively small, and thus, one correct answer often suffices to move the lecture forward. Moreover, it often seemed that the instructors were expecting a specific response to these types of questions and, once the response was given, the instruction proceeded.

Finally, we discuss *Student Generated Examples,* which as the name indicates, are examples that are created by the students. These examples were typically given in response to questions that had a broader response space where there existed several possible correct answers. Most often, these examples were generated when students were given a prompt by the instructor, followed by time to work in groups or to work independently at their seats. For example, during Instructor A's lesson, students worked in groups to create several examples of graphs that did or did not satisfy a list of properties. The students then placed these examples on the board. However, we also saw one case of a *Student Generated Example* given during a lecture, when the instructor asked for an example, and a student responded with $y = x$. While this is still a short response, we claim that the instructor did not need to interpret the meaning of this example, and instead was able to sketch on the board the student's desired graph.

**Who Evaluated an Example**

A second theme centers around whether the instructor or the students were engaged in evaluating the validity of an example. When an example was presented (by a student or an instructor), it seemed to be assumed that if the instructor put the example on the board, then it was a valid example. One can certainly argue that students should always be evaluating the validity of the examples, and that no audible response from the students does not necessarily indicate that students did not do so. There were certainly times when the instructors asked the students, "Does this work?" or "Does this make sense?" However, in our data, we only saw one chunk of video when students audibly discussed whether or not a graph was a valid example. This happened in Instructor A's class. After the students put their own examples on the board, they were given an opportunity to critique each other's examples and argue whether or not they were valid. However, even in this case, the instructor settled the disagreement and explained why the graph was a valid example.

**For What Purpose the Example was Used**

We saw two main ways that an example was used. One was to demonstrate an idea or a property. These examples tended to be along the lines of "existence proofs" where one example was enough to demonstrate that something was possible. Another way an example was used was to build an idea and/or to have students discover a concept. In these cases, there seemed to be several examples that were generated, and connections were made across examples. Or, sometimes a specific example was used to address a common misconception. For example, students often mistakenly thought that a linear function did not satisfy the conclusion of the Mean Value Theorem, and both Instructors A and B used a linear example to address this misconception.

**The Richness of the Examples**

Finally, we note the importance of the richness of the examples that were used in a lesson. Here we consider first if there were any errors in the examples. Instructor D had multiple mathematical errors in her lesson. One small error occurred when a graph she provided did not pass the vertical line test, and thus did not satisfy the basic condition that $f(x)$ be a function. This particular error was not commented on in the class. We also evaluate here examples that may be correct, but perhaps are limited in scope. A deeper discussion of the theme of richness will be provided in the next section.

**Classroom Vignette: Instructor A**

We discuss Instructor A's classroom, as this lesson demonstrates all of the themes discussed previously. At the beginning of the instruction on the MVT, the graph in Figure 1 was provided to the students as an *Instructor Generated Example*. She then asked her students to tell her what a secant line was (several students responded), and she drew the secant line on the graph between the two endpoints. Next, she told her students to work at their seats to see if there was any place on the graph where there was a tangent line with the same slope as the secant line, and if so, to sketch the tangent line at that point on their own paper. For just over two minutes, the instructor walked around the room, looking at the work done by the students and clarifying directions for students who had questions. We noticed that it seemed to be expected that every student would participate. This is in contrast to the lectures of the other instructors, where one or two students would provide an answer, but the rest of the students would not actively contribute.

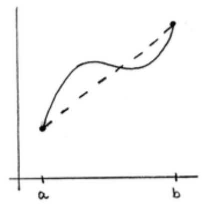

*Figure 1: Instructor Generated Initial Example*

After a brief class discussion about the previous graph, Instructor A told the class to work in groups to see if they could find examples of other graphs where there was or was not a tangent line with the same slope as the secant line between the two endpoints. She instructed her students by saying, "Your next job is to make sure you find some graphs that do have this property and some graphs that don't have the property." Students spent approximately 16 minutes working in groups to create several *Student Generated Examples* that satisfied the property and several that did not satisfy the property. At one point, the instructor put one of the student's examples on the board (a linear function) and told the class to make sure they discussed an example like this one, if they hadn't already done so. She did not tell them whether or not that graph satisfied the conditions, but expected the students to decide on their own.

After it was clear that every group had several *Student Generated Examples*, she instructed each group to send at least one person to the board to sketch an example of a graph that did not have this property (i.e. a graph where there was no tangent line with the same slope as the secant line between the endpoints). Nine graphs were drawn on the board by the students, and Instructor A added one more graph that was used by one of the groups, but was not the one they chose to put on the board. Thus, there were ten *Student Generated Examples* on the board, a few of which are shown in Figure 2. Next, the class was instructed to look at all of the graphs to see if there were any graphs that should not have been on the board, so in other words, to see if any of the graphs on the board had a place where the slope of the tangent line was equal to the slope of the secant line. This created an opportunity for the students to evaluate the validity of the examples.

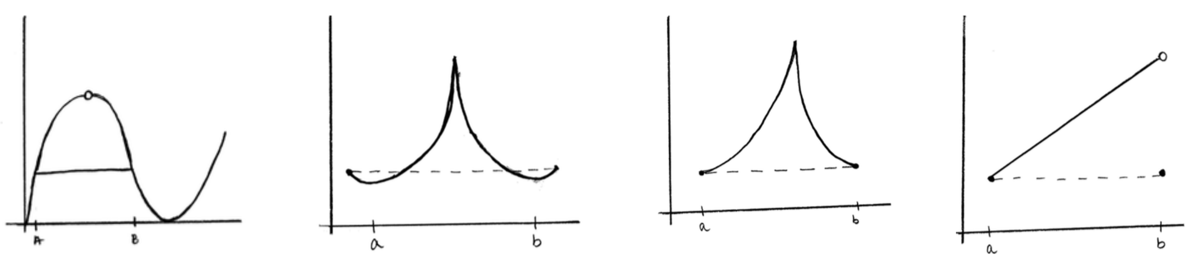

*Figure 2a* *Figure 2b* *Figure 2c* *Figure 2d*

*Figure 2: Student Generated Examples*

When discussing the *Student Generated Examples*, three interesting things happened. First, one student argued that the graph shown in Figure 2a was wrong because there is a place outside of the interval with a horizontal tangent line. The instructor clarified that the task was only to attend to whether or not the property held *on* the interval from *a* to *b*. Next, another student questioned the graph in Figure 2a because he recognized that even though the function was not defined at one point, it looked like the limit would still exist. At this point, the instructor led the class in a nice discussion about the definition of the derivative and why tangent lines do not exist at places where there is a removable discontinuity. Third, Instructor A pointed out that the graph shown in Figure 2b was not quite accurate, even though the students' intent was correct. She cautioned the students to be careful with their graphs and make sure that their examples clearly illustrated the intended properties, then modified the graph to form the example in Figure 2c.

Next, the instructor led the class in a discussion about what the ten graphs on the board had in common. First, she highlighted the seven graphs that had some sort of discontinuity, and asked the students what the other three graphs had in common. At least one student responded that those graphs had a point or a cusp, and Instructor A introduced the term *differentiable* and emphasized that all of the graphs that were drawn without a tangent line parallel to the secant line were either not continuous or not differentiable. Then, the instructor gave the class a short period of time to think about graphs that are both continuous and differentiable on the interval to decide if those graphs had to have a place where the tangent and secant lines were parallel.

The purpose of the examples that had been generated was illustrated as the instructor wrote the MVT on the board and related it to what the students had created. For example, when stating that the function must be continuous on the closed interval [*a, b*], she referred to the example in Figure 2d to illustrate that an open interval would not have guaranteed that the property held. This example was a rich example that nicely illustrated this concept. In contrast, Instructor B had an *Instructor Generated Example* on the board that was extremely similar to Figure 2d, but she did not discuss why this example illustrated the need for the function to be continuous on a closed interval. Furthermore, Instructor D, claimed that a closed interval was required so that it would be possible to compute the average rate of change. As indicated by Figure 2d, Instructor D's statement does not justify the need for continuity on a closed interval.

## Discussion and Teaching Implications

In a classroom that supports students' mathematical learning in a way consistent with the communities of practice perspective, the instructor is also tasked with supporting newcomers in engaging with and becoming more skilled with disciplinary practices. This has implications for the way in which the instructor represents mathematics (for example, the role of examples in developing mathematical ideas) and how the instructor engages students meaningfully in that effort as well. We want to emphasize that this does not simply mean that students should have more opportunity to work in groups or that students should talk more during class; instead, we emphasize that the nature of the task must provide students with the opportunity to *deeply* explore mathematical concepts. In our data, a simple prompt from Instructor A afforded her students the opportunity to deeply engage in developing the Mean Value Theorem. Watson and Shipman (2008) sum this up as:

> ...significant learning can result from the process [of generating examples] because learners generate and explore example spaces related to the ideas, in particular spaces of relations between objects. The importance of normal classroom expectations and teacher guidance cannot be overestimated here. (p. 108)

We also emphasize that the task of generating the examples, while extremely important for student learning, is not all that is necessary. The instructor also needs to be skilled in leading a discussion about the examples in a way that moves the lesson forward. He or she needs to know which examples to highlight in order to provide richness as well as to demonstrate concepts. Our focus on the generation and use of examples contributes to a sense of what is entailed in students' active learning in mathematics. These findings have implications for how instructors can be supported—through materials, coordination, or instructional support—to create classroom environments that actively engage students in doing mathematics.

**Peter's Evoked Concept Images for Absolute Value Inequalities in Calculus Contexts**

Erika J. David
Arizona State University

*Statements involving absolute value inequalities, such as the definition of continuity at a point, abound in Advanced Calculus. In textbooks, such statements are frequently illustrated with graphical representations. Despite their abundance, how students think about absolute value inequalities and their representations in these contexts is not widely known. This study examines one undergraduate mathematics student's evoked concept images (Tall & Vinner, 1981) for absolute value inequalities in various contexts, including those from Advanced Calculus. The student's evoked concept image differed based on the context of the statements involving absolute value inequalities. Notably, the student's evoked concept image did not support his understanding of the visual representation of the formal definition of continuity. The results of this study suggest that some students may not conceive of absolute value inequalities in ways that are productive for understanding the formal definitions of Advanced Calculus concepts.*

*Keywords:* Absolute Value Inequalities, Calculus, Visual Representations

Absolute value inequalities are used in numerous formal definitions and theorems central to advanced Calculus, including statements involving limits, continuity, and sequence convergence. For example, the formal definition of continuity at a point, historically attributed to Weierstrass, may be stated as: "A function $f$ is continuous at a point $c$ in its domain if, for each real number $\varepsilon > 0$, there exists a real number $\delta > 0$ such that, for all $x$ in the domain of $f$ with $|x - c| < \delta$, $|f(x) - f(c)| < \varepsilon$." Not much is known about how students conceive of absolute value inequalities in such statements from advanced Calculus. While research has examined students' understanding of absolute value inequalities, most studies have addressed students' procedural fluency and their common errors at lower levels (Almog & Ilany, 2012). Additionally, many high school algebra textbooks that introduce absolute value inequalities treat them procedurally, instructing students to consider cases of inequalities (Boero & Bazzini, 2004). Conceiving of absolute value inequalities primarily in terms of the algebraic procedure for finding a solution may be insufficient for making conclusions from statements involving absolute value inequalities, such as those commonly used in Advanced Calculus. Furthermore, a procedurally-oriented conception may not be sufficient to support students in understanding graphical representations of statements such as the definition of continuity at a point. For example, several Analysis texts introduce the formal definition of continuity of a function at a point along with an image like the one shown in Figure 1 (Gaughan, 1997).

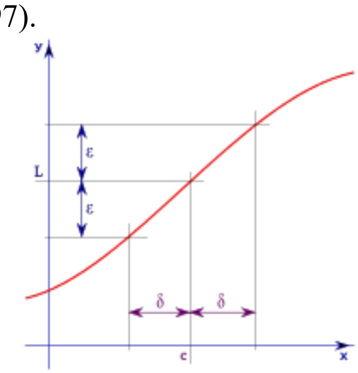

*Figure 1. A visual representation of continuity at a point*

A student that only has a procedural meaning for absolute value inequalities, such as $|x - c| < \delta$, may not necessarily associate the values of $x$ that satisfy this inequality, with the values of $x$ within a distance of $\delta$ from $c$ on the $x$-axis in Figure 1. In graphical representations of advanced Calculus statements, solutions to absolute value inequalities typically refer to a region of space in the rectangular coordinate system with points whose coordinates are within a certain distance from a point. Several studies have found that conceptualizing an absolute value as a distance on a number lines helps students visualize the solutions of an absolute value inequality, thus developing a critical conception of absolute value statements at lower levels (Curtis, 2016; Sierpinska, Bobos, & Pruncut, 2011). The aim of this study is to extend the research in this area by characterizing students' meanings for absolute value inequalities like those found in statements from advanced Calculus, particularly with regard to associated visual representations.

Specifically, the research question for this study is as follows: *What meanings for absolute value inequalities are elicited for students in the context of advanced calculus statements?*

## Theoretical Perspective

In this report, I adopt a constructivist perspective, consistent with von Glasersfeld's (1995) view that students' knowledge consists of a set of action schemes that are increasingly viable given their experience. In this view, students construct knowledge for themselves, and words and images do not inherently contain meaning. This viewpoint also implies that I, as a researcher, do not have direct access to students' knowledge and can only model student thinking based upon their observable actions and behaviors. To characterize student meanings for absolute value inequalities in this study, I also adopt Tall and Vinner (1981)'s constructs of *concept image* and *evoked concept image*. By *concept image*, Tall and Vinner (1981) refer to "the entire cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes" (p. 152). Thus, a student's concept image for absolute value inequalities may include numerous cognitive processes and images built on various experiences with the topic over time. While a student may have a concept image that contains many properties and processes for absolute value inequalities, in a given context, only parts of this concept image are activated at a given time. Tall and Vinner (1981) thus define *evoked concept image* to refer to the aspects of the concept image accessed within a particular context. They also note that different aspects of a students' concept image may be in conflict with one another, without the student's awareness.

### Hypothesized Productive Meanings for Solutions to Absolute Value Inequalities in Advanced Calculus Statements

Based on how absolute value inequalities and their solutions are currently utilized in communicating ideas of advanced Calculus, such as the definition of continuity at a point, one productive way of thinking about absolute value inequalities is in terms of bounded distances. For instance, students may understand that solutions to an absolute value inequality of the form $|x - c| < \delta$ can be determined by finding all values of $x$ that are within a distance of $\delta$ from $c$ on a number line. In two dimensions, this set of solutions is a region of points whose $x$ values are within a distance of $\delta$ from $c$ on the $x$-axis. Coming to such an understanding involves connections between a relationship represented algebraically and a set of solutions represented geometrically. Acquiring this level of understanding can be complex, requiring understandings of many foundational ideas, such as variable and difference.

The solution to $|x–c| < \delta$ can be represented analytically as $c–\delta< x < c+\delta$ or geometrically as all $x$ values within a distance of $\delta$ from $c$. Connecting this inequality successfully to the graphical representation involves students viewing both the algebraic inequality and graph as representing an upper bound on how much $x$ can differ from $c$. That is, they must see that the solutions can be represented by an interval on a number line that includes all values (represented by the letter $x$) within $\delta$ of a value represented by $c$. They must conceptualize the letter $c$ as representing a central value, and the $\delta$ symbol as representing an upper limit on the solutions' distance away from $c$. For example, the solution set to an inequality like $|x –(–1)| < 3$ can be represented as follows:

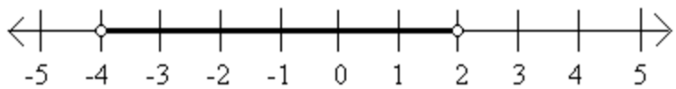

*Figure 2. One-dimension representation of solutions to $|x –(–1)| < 3$*

In this representation, values within a distance of 3 from –1 are included in the set of solutions to the inequality.

In the Cartesian plane, rather than an interval on a number line, this solution set is represented by a region marked by vertical lines representing the boundaries of this solution set. Thus, the region would include all points whose $x$-coordinate is at most a distance of 3 away from –1. Similarly, with inequalities of the form $|f(x)–f(c)| < \varepsilon$, the two-dimensional representation of $f(x)$ values (represented on the vertical axis) that satisfy this inequality can be represented by a horizontal region. This solution set is represented by a region marked by horizontal lines representing the boundaries of this solution set. Thus, the region would include all points whose $y$-coordinate is at most a length of 1 away from 3.

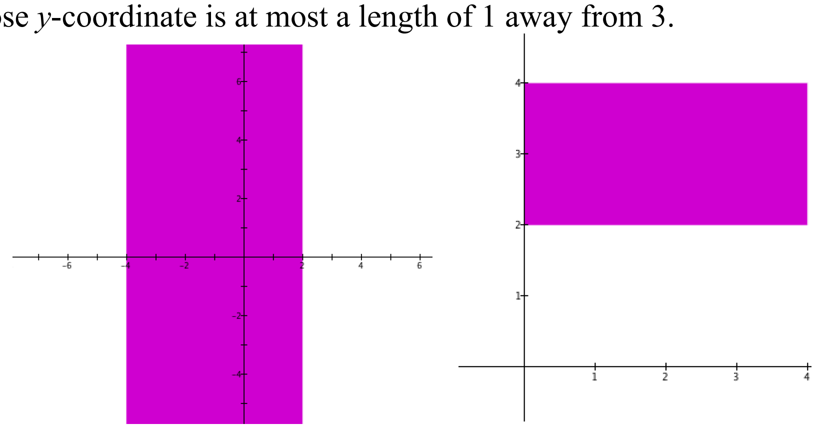

*Figure 3. Two-dimensional representation of solutions to $|x +1| < 3$ and $|f(x)–3| < 1$*

## Methods

For this study, I conducted one 120-minute clinical interview (Clement, 2000) with an undergraduate mathematics student, Peter. Peter was a math major who had completed the Calculus sequence and an Introduction to Proof course, but had not yet taken an Advanced Calculus course.

In the interview, Peter was given tasks that were designed to elicit his meanings for absolute value, absolute value equations, absolute value inequalities, including associated visual representations, such as representing solutions on a number line. Because of the hypothesized evoked concept images for each task, the tasks were ordered in such a way that earlier tasks would not be influenced by later ones. One of the earlier tasks involved a statement about a function $f$ that was the formal definition for continuity at the point $x = 1$ as shown below:

> For each real number $\varepsilon > 0$, there exists a real number $\delta > 0$ such that, for all $x$ in the domain of $f$ with $|x - 1| < \delta$, $|f(x) - f(1)| < \varepsilon$.

After asking the student to explain the statement in his own words, as well as each portion of the statement, I presented him with two graphs, first Figure 4 (left) and then Figure 4 (right). After presenting each graph, the student was asked to evaluate whether the statement was true or false for the function $f$ shown in each graph and explain his reasoning.

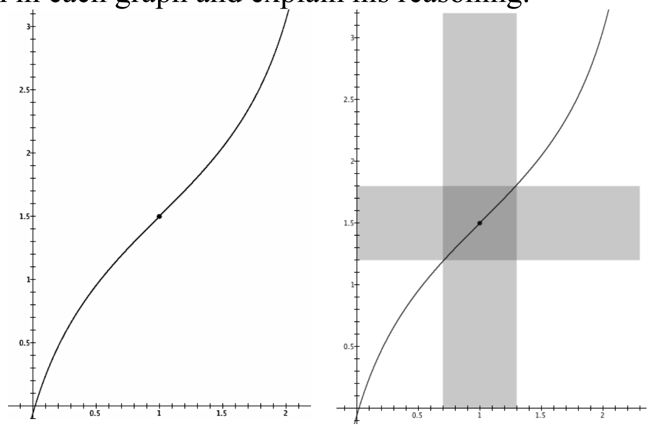

*Figure 4. Graphs used with statement of continuity at x=1*

The final task given to the student is shown in Figure 5.

> a. Find a pair of values, $a$, $b$ such that $|a - b| = 3$.
> b. Find another pair of values $a$, $b$ with $a < 0$ such that $|a - b| = 3$.
> c. Find another pair of values $a$, $b$ with $a < b$ such that $|a - b| = 3$.
> d. If $a = 1$, how many possible values of $b$ satisfy the statement?
> e. What must be true about these pairs of values?
> f. Can you use a number line to explain what $|a - b|$ represents?
> g. Can you use a number line to explain what $|a|$ represents?

*Figure 5. Final task presented to student in interview*

The purpose of this task (Figure 5) was to examine how the student solves absolute value equations, and how he explains the meaning of solutions to absolute value equations involving multiple variables. After the interview, I analyzed the data by modeling Peter's evoked concept image of absolute value (inequality) in each task, especially looking for distinctions in the types of images evoked between contexts.

## Results

In this section, I report several key responses to tasks that revealed Peter's evoked concept image for absolute value and absolute value inequalities. Early in the interview, Peter's written work and utterances suggested that his initial evoked meaning for absolute value was "that a value is positive." When presented with the formal definition of continuity at a point, Peter expressed some confusion, and acknowledged that he was not sure what the statement meant. When presented with the first associated graph (see Figure 4, left), he labeled the graph as shown in Figure 6 below. Peter's procedural meaning for absolute value, that is, making values positive, led to him representing the absolute value of a difference on each axis as a single value.

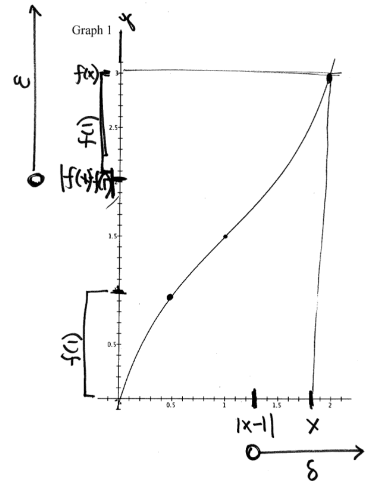

*Figure 6. Peter's labels on the graph of a function related to the formal definition of continuity at a point*

When the interviewer asked Peter to explain "$|x–1|<\delta$," on this graph, Peter responded by saying,

> "So let's say I just chose some value of $x$ here (*labels x on the x-axis as shown in Figure 6*), then $x$–1 (*labels |x–1| on the x-axis to the left of x*), (*pauses*) then δ would have to be larger than that (*draws ray with open circle and labels it "δ"*), so uhh all the values…delta could possibly be any value along this interval (*points to ray he just drew*)."

Peter's words and labels suggest that he was conceptualizing $|x–1|$ as a value on the $x$-axis to the right of zero and one unit to the left of $x$. When prompted to explain what the inequality "$|x–1|<\delta$" represented graphically, Peter provided a literal interpretation of the symbols in his response, stating that δ had a value greater than the value of $|x–1|$. He illustrated this on the number line by constructing a ray with an open circle at $|x–1|$ extending to the right on the $x$-axis. Notably, when shown the graph in Figure 4 (right) and asked to explain the statement relative to the image, Peter paused for a long period of time and acknowledged that he was not quite sure how the statement related to the graph of the function and the shaded regions.

Later in the interview, working on Task 8, Peter's work indicated a different evoked concept image for absolute value that included a distance from zero. In this task, Peter was asked to compare the values of "$|a+b|$" and "$|a|+|b|$" using a number line. Peter produced the following illustration:

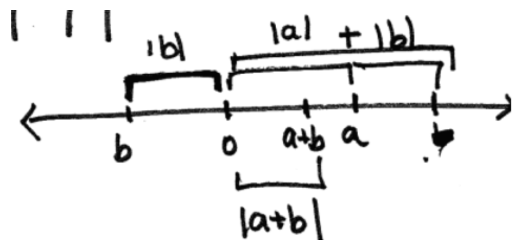

*Figure 7. Peter's work on Task 8*

In Peter's work (Figure 7), he label *a, b,*and *a*+*b* at different locations on the number line, and then labeled line segments from 0 to respective places on the number line with absolute values. Peter placed $|a+b|$ on the segment starting at 0 and ending at $a+b$. The labeling suggests that he considered $|a+b|$ as the distance $a+b$ was from 0 on the number line. Additionally, Peter's work on this task shows his attention to distances. Peter independently chose $b$ to be to the left of 0, and $a$ to be to the right of 0, farther away than $b$ was from 0. When considering $a+b$, Peter attended to the placement of this value relative to the distance $a$ and $b$ were from 0. That is, since $a$ is farther to the right of 0 than $b$ is to the left of 0, $a+b$ would have a positive value less than the value of $a$, and Peter placed $a+b$ to the left of $a$ but to the right of 0. Peter's work on this task was the first indication that he was using absolute value to represent a distance from 0 on a number line.

In the final task, Peter's meaning for absolute value of a difference shifted from his previous meaning. Earlier (as shown in Figure 6), Peter labeled the absolute value of a difference at a location on the number line, indicating he was thinking of a single value that was the result of taking the absolute value of a difference. In the final task, in answering part e) "What must be true about these pairs of values [that satisfy $|a–b|=3$]," Peter's evoked concept image shifted.

To answer this question, Peter first wrote out two equations, "$a–b = 3$" and "$a–b = –3$" and solved them in terms of $b$ and then in terms of $a$. Peter then explained "If I were to choose $a$, then $b$ would be either 3 away from $a$ or 3 on the other side of $a$" and drew a number line to illustrate his idea, as shown below in Figure 8.

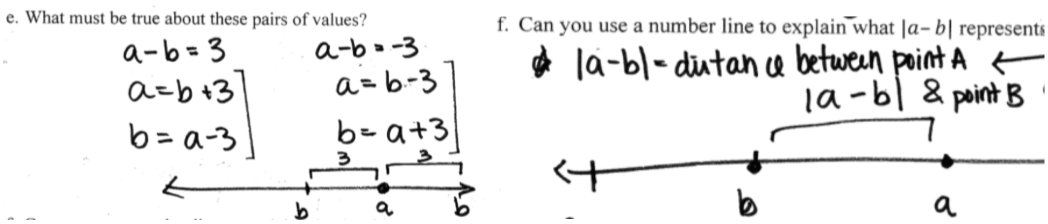

*Figure 8. Peter's work showing what must be true about a and b when |a–b|=3*

Peter illustrated his algebraic interpretation of the relationship between $a$ and $b$ using a number line. He labeled the segment he drew between $a$ and $b$ in either direction with "3," indicating that he recognized the distance between $a$ and $b$ was 3 units. This was the first time that Peter interpreted a difference as a distance between two points, neither of which were 0. When Peter encountered absolute values of differences when responding to earlier tasks, he considered them to be single values on the $x$-axis, or measuring a distance from 0. Rather than treat an absolute value of a difference as a single value whose reference point is 0, Peter treated an absolute value of a difference as a distance between the two values, without reference to 0. In the next sub-question in the final task, Peter confirmed that he was conceptualizing the absolute value of a difference $|a–b|$ as the distance between point $a$ and point $b$ (Figure 8, right).

To check to see if his image for absolute value inequality that had been evoked in the task above influenced his understanding of continuity at a point, I again showed Peter the formal definition of continuity at a point, and associated graph, and asked him to re-label the graph.

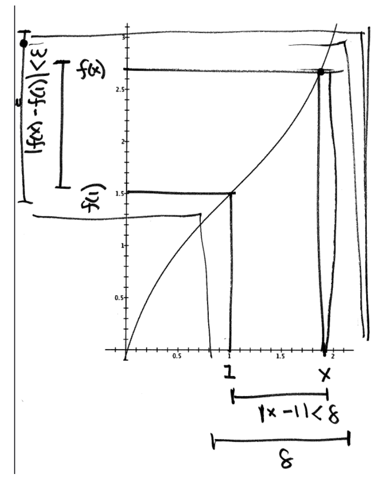

*Figure 9. Peter's updated labels on graph after completing final task*

This time, Peter labeled the distance between $x$ and 1 on the $x$-axis with the label $|x–1|$ rather than labeling $|x–1|$ as a value on the $x$-axis itself. He recognized that the statement "$|x–1|<\delta$" was a statement about a comparison of a distance between two values, and a value $\delta$. While Peter did not attend to $x$ values to the left of 1, his evoked image for absolute value of a difference as measuring a distance (Figure 8) supported Peter in connecting the image of a graph with the definition of continuity at a point.

## Conclusion & Discussion

Peter's work suggests his concept image for absolute value and absolute value of a difference contains several distinct meanings and processes. In different contexts throughout the interview, Peter's work indicated different evoked concept images for absolute value, consistent with findings by Tall and Vinner (1981). In the beginning of the interview, Peter's meaning for absolute value inequalities elicited by the initial tasks included a procedure of making a value positive. Later in the interview, Peter's evoked concept image for absolute value included a meaning of distance from zero on a number line. In the final task, Peter's evoked concept image for absolute value of a difference was a distance between two points.

Most notably, Peter's initial meaning for absolute value elicited by the continuity at a point statement and associated graphs did not include a difference between two points on axes, but rather were of absolute value as an operator that makes values positive. Peter's initial evoked image is consistent with the way absolute value inequalities are introduced in high school textbooks (Boero & Bazzini, 2004). Due to his evoked meaning for absolute value as an operator, Peter was unable to explain the continuity statement relative to the graphs in Figure 4. However, through other various tasks, different aspects of Peter's concept image for absolute value were evoked, which allowed Peter to conceptualize the absolute values in the continuity statement differently than he had previously. The findings from this study suggest that students entering advanced Calculus courses may interpret absolute value inequalities and their visual representations differently than intended. Specifically, their evoked concept image for absolute value may not support their attempts to connect such statements to associated graphs. Instructors of courses utilizing statements involving absolute value inequalities may consider including tasks to evoke different meanings for absolute value. Instructors and curriculum developers should not assume that students' evoked concept image for absolute value inequalities will align with how their solutions are represented in illustrations on graphs.

# A Preservice Mathematics Teacher's Covariational Reasoning as Mediator for Understanding of Global Warming

Dario A. Gonzalez
University of Georgia

*I examine one preservice mathematics teacher's (PST's) covariational reasoning in relation to two functions involved in modeling global warming. I also discuss how her covariational reasoning mediates her understanding of important concepts related to global warming. Jodi, the PST, completed a mathematical task I created for the study during an individual, task-based interview. The analysis of Jodi's responses revealed that: (a) the level of covariational reasoning and conceptions regarding quantities can constrain/facilitate the understanding of concepts related to global warming, (b) overreliance on discrete variation can led to conflicting notions regarding global warming, and (c) reasoning about rate of change is necessary to make sense of mathematical models for global warming based on energy balance.*

*Keywords:* Covariational Reasoning, Global Warming, Preservice Teachers, Modeling

## Introduction

In recent years, there have been several calls to include global warming in school and college instruction (McKeown & Hopkins, 2010; UNESCO, 2012). Global warming is a contemporary and pressing issue affecting different people around the globe (Intergovernmental Panel on Climate Change [IPCC], 2013). Moreover, global warming provides a motivating scientific context to study important scientific and mathematical concepts. Mathematics teachers, however, are likely not prepared to incorporate global warming into their instruction. Researchers have demonstrated that the public have many problematic conceptions about important concepts related to global warming (Leiserowitz, Smith, & Marlon, 2010; Pruneau, Khattabi, & Demers, 2010). Also, teachers and students without sufficient scientific and mathematical literacy can have difficulties understanding concepts related to global warming (Barwell, 2013; Lambert & Bleicher, 2013). Therefore, there are both societal and cognitive needs for studies regarding global warming and mathematical reasoning.

In my research, I investigated how preservice mathematics teachers (PSTs) make sense of introductory mathematical models for global warming. By introductory models, I mean those for which the mathematics can be accessible to high-school students. The models require PSTs to think about a dynamic situation in terms co-variation between quantities. Existing research in mathematics education has demonstrated that students and future mathematics teachers can have persistent difficulties comprehending and mathematically expressing co-variation between quantities (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Johnson, 2012; Oehrtman, Carlson, Thompson, 2008; Thompson, 2011). In this paper, I focus on one PST's covariational reasoning in relation to two functions: *the planetary energy imbalance function*, N(t), and *the planet's mean surface temperature function*, T(t). I also discuss how her covariational reasoning mediates her understanding of important concepts related to global warming.

## Background Information

Earth's climate system is powered by the sun and there is a continuous flow of energy between the sun, the planet's surface, and the atmosphere. This continuous flow of energy is known as the *Earth's energy budget* (Figure 1). The sun warms the planet's surface (S). As the surface warms up, it radiates (infrared) energy to the atmosphere (R), the majority of which is absorbed by *greenhouse gases* (GHG) such as water vapor ($H_2O$), carbon dioxide ($CO_2$), and methane ($CH_4$) (B). The atmosphere re-radiates the absorbed energy in both directions toward space and toward the surface (A). This continuous energy exchange between the surface and the atmosphere is known as the *greenhouse effect* and influences the planet's mean surface temperature. The energy flows S, R, B, L, and A (Figure 1) are all magnitudes of energy flux density, while the abundance of GHG is a magnitude of concentration. *Energy flux density* is a flow of energy per unit of area per unit of time incident to a surface, usually measured in Joules per square meter per second ($J/m^2/s$). *Concentration* is the volume of a gas relative to the total volume of the mixture in which the gas is contained, usually measured in the same units of volume (e.g., $m^3/m^3$) or in parts per million by volume (ppmv). The parameter $0 < g < 1$ (Figure 1) is related to the greenhouse effect. Quantifying changes in the energy flows due to changes in the abundance of GHG is central to accurately model global warming. My study focuses on how variation in the atmospheric concentration of $CO_2$ produces variation in the energy flows over time, and how that variation affects the planet's mean surface temperature.

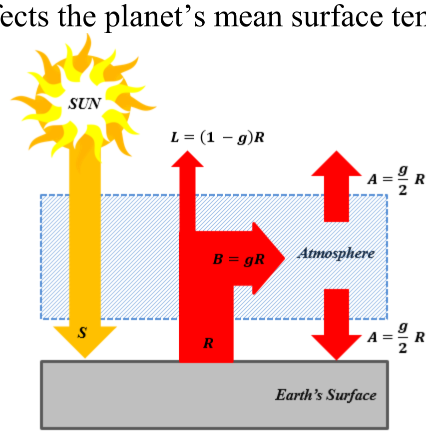

*Figure 1: The Earth's energy budget, assuming a one-layered atmosphere*

The *planetary energy imbalance function* N(t) is a measure of the energy imbalance in the Earth's energy budget over time. In particular, N(t) can be defined as a difference between the downward radiation and the upward radiation at the planet's surface, or mathematically $N(t) = (S + A(t)) - R(t)$. The Earth's energy budget is said to be in radiative equilibrium when $N(t) = 0$ (downward radiation equals upward radiation), which implies that the *planet's mean surface temperature function* T(t) remains constant. However, there are factors or *forcing agents* that can push the energy budget out of equilibrium, producing $N(t) \neq 0$. The present study focuses on how N(t) and T(t) vary over time after a *positive forcing by $CO_2$* occurs at $t = 0$. An instantaneous increase in the concentration of $CO_2$ results in an atmosphere with more capacity to absorb surface radiation R(t). This translates into a value for A(0) such that $N(0) = (S + A(0)) - R(0) > 0$, which means that the downward radiation exceeds the upward radiation. As a result, the planet's surface starts warming up (i.e., an increasing T(t)); a hotter surface produces more radiation (i.e., an increasing R(t)). The atmosphere absorbs even more radiation, increasing its own radiation back to the surface (i.e., an increasing A(t)), further warming the surface. The expression $N(t) = (S + A(t)) - R(t) = S - \beta R(t)$, where S is the solar constant and $\beta = 1 - g/2$, indicates that R(t) continues to increase until the upward radiation equals the downward radiation since $N(t) \to 0$ as $t \to \infty$. This in turn indicates that T(t) increases at a decreasing rate as it approaches to a new equilibrium temperature. In fact, mathematical models for global warming commonly known as Energy Balance Models (EBMs) rest on the idea that $\frac{dT}{dt} = \alpha N(t)$ for a constant $\alpha > 0$ (Widiasih, 2013).

## Conceptual Framework

Carlson et al. (2002) defined covariational reasoning as "the cognitive activities involved in coordinating two varying quantities while attending to the ways in which they change in relation to each other" (p. 354). Based on this definition, Carlson and colleagues developed the Covariation Framework as a theoretical instrument to examine and assess a student's covariational reasoning abilities relative to a mathematical task showing two co-varying quantities. Their framework describes five mental actions involve in reasoning about quantities that vary together. *Mental Action 1 (MA1)* involves coordinating the value of one variable with changes in the other (e.g., labeling the axes with verbal indications of coordinating the two variables such as "y changes with changes in x"). *Mental Action 2 (MA2)* involves coordinating the direction of change of one variable with changes in the other variable (e.g., constructing an increasing straight line or verbalizing an awareness of the direction of change of output while considering changes in the input). *Mental Action 3 (MA3)* involves coordinating the amounts of change in one variable with changes in the other (e.g., plotting points, constructing secant lines, or verbalizing an awareness of the amount of change of the output while considering changes in the input). *Mental Action 4 (MA4)* involves coordinating the average rate of change of the function with uniform increments in the input variable (e.g., constructing contiguous secant lines or verbalizing an awareness of the rate of change of the output while considering uniform increments of the input). *Mental Action 5 (MA5)* involves coordinating the instantaneous rate of change of the function with continuous changes in the independent variable for the entire domain of the function (e.g., constructing smooth curve with clear indications of concavity changes, verbalizing an awareness of the instantaneous changes in the rate of change for the entire domain of the function, or correctly interpreting concavities and inflexion points). The collection of mental actions inferred from the student's responses is examined to determine the student's overall level of covariation reasoning relative to the task. There are five levels of development, each more sophisticated than and built upon the previous one: *dependency of change* (L1: *y* changes when *x* changes), *direction of change* (L2: *y* increases as *x* increases), *amounts of change* (L3: a change $\Delta y$ in *y* correspond to a change of $\Delta x$ in *x*), *average rate of change* (L4: *y* increases more rapidly for successive changes $\Delta x$ in *x*), and *instantaneous rate of change* (L5: *y* increases more rapidly as *x* continuously increases). If a student's covariational reasoning is classified at a particular level, then it is implied that the student's covariational reasoning supports the mental action associated with that level *and* the mental actions associated to all previous levels.

## Methods

This paper is part of a larger study that investigated how PSTs make sense of introductory mathematical models for global warming. That larger study consisted of two parts: (1) exploring PSTs' conceptions of intensive quantities commonly used to model global warming, and (2) examining PSTs' covariational reasoning relative functions commonly used to model global warming. To address these goals, I created an original sequence of six mathematical tasks involving intensive quantities, functions, and concepts related to global warming.

Three secondary PSTs enrolled in a mathematics education program at a large Southeastern university participated in the larger study. The PSTs have completed three mathematics content courses (calculus I, calculus II, and introduction to higher mathematics) and were completing a mathematics education content course (connections in secondary mathematics). In this paper, I focus on the case of Jodi, one of the three PSTs who participated in the larger study. Specifically, I focus on Jodi's responses to the sixth mathematical task in my sequence. Her case is interesting for two reasons. First, Jodi's responses were markedly different from her peers, which represent a unique case for discussion. Second, her case shows clear examples of how covariational reasoning can mediate the understanding of scientific concepts related to global warming.

I started by showing Jodi a 7-minute long video introducing the *Earth's energy budget*, *radiative equilibrium*, and *greenhouse effect*. The video was retrieve from the NASA YouTube channel *NASAEarthObservatory*. Then, I answered any questions she may have had concerning the concepts discussed in the video. Next, I presented her with a diagram of the energy budget (Figure 2a) and the following task:

> *An increase in the atmospheric concentration of $CO_2$ results in an energy imbalance in the Earth's energy budget. This initial imbalance is known as forcing by $CO_2$. We want to examine how the planetary energy imbalance N(t) and the planet's mean surface temperature T(t) vary over time after the forcing. Use what you learned about the Earth's energy budget, the greenhouse effect, and the definition $N(t) = (S(t) + A(t)) – R(t)$ to determine: (a) how N(t) varies over time and sketch its graph and (b) how T(t) varies over time and sketch its graph.*

Jodi completed the mathematical task during a 60-minute, semi-structured, task-based interview (Goldin, 2000). The interview was video recorded and transcribed for analysis. All of Jodi's work on paper was collected as well.

Videos and transcripts were analyzed through Framework Analysis (FA) method; this method five inter-related stages of data analysis: familiarization with data, developing an analytic framework, indexing and pilot charting, summarizing data in analytic framework, and synthesizing data by mapping and interpreting (Ward, Furber, Tierney, & Swallow, 2013). Through these stages, the researcher creates and refines framework analysis' distinctive feature: the *matrix output*, a table arrangement into which the researcher systematically reduces, summarizes, and analyzes the data. I utilized the mental actions in the Covariation Framework (Carlson et al., 2002) as themes for coding interview transcripts. Then, I re-read all transcript texts categorized under a particular mental action. I selected and summarized those transcript texts that were more representative of that particular mental action. I repeated this process until I selected representative texts for each mental action. Then, I organized the selected texts into a matrix output containing five columns (one for each mental action) and two rows: one for N(t) and another for T(t). The matrix output allowed me to develop an idea of Jodi's: (a) overall level of covariational reasoning, (b) understanding of N(t) and T(t), and (c) conceptions of the energy budget and radiative equilibrium.

## Results

Jodi's responses to the first part of the task suggest covariational reasoning abilities at the direction of change level (L2) when her object of reasoning was the situation (i.e., how the energy budget evolves after a positive forcing). When her object of reasoning was the graph of N(t), she demonstrated abilities at the amounts of change level (L3). To start the task, I told Jodi to imagine that an instantaneous increase in the atmospheric concentration of $CO_2$ produces an imbalance of energy equal to $N(0) = 5$ J/m$^2$/s (positive forcing by $CO_2$). Jodi is then given a diagram of the Earth's energy budget showing the initial values: $S = 240$ J/m$^2$/s, $R(0) = 390$

J/m$^2$/s, B(0) = 310 J/m$^2$/s, L(0) = 80 J/m$^2$/s, and A(0) = 155 J/m$^2$/s (Figure 2a). Notice that N(0) = (S + A(0)) – R(0) = (240 + 155) – 390 = 5. Jodi was expected to visualize how N(t) varies as time t increases. Jodi imagined energy moving from R to B, then to A, and finally back to R, what she labeled as *cycles*. Using these cycles, Jodi determined the following values for the energy flows R, B, and A: R($C_1$) = 395 J/m$^2$/s; B($C_1$) = 313 J/m$^2$/s, and A($C_1$) = 157 J/m$^2$/s, and R($C_2$) = 397 J/m$^2$/s; B($C_2$) = 315 J/m$^2$/s, and A($C_2$) = 158 J/m$^2$/s (Figure 2a), where $C_i$ represents *cycle i* after the positive forcing. When I asked Jodi whether N(t) was increasing or decreasing, she stated "I guess it would increase? [*Pauses*] but, I don't see an argument for why it wouldn't stay the same." I then asked her to determine the values of N(t) for each one of her cycles. Jodi determined the values N($C_0$) = 5 J/m$^2$/s, N($C_1$) = 2 J/m$^2$/s, and N($C_2$) = 1 J/m$^2$/s, where $C_i$ represents *cycle i* after the positive forcing. Jodi stated that she was not expecting N(t) to decrease over time ("I though N would be larger"). When I asked her to interpret this decreasing N(t), Jodi replied "[it means] that we are going back to an equilibrium, or we are not as far from equilibrium as we were." When Jodi was able to establish the direction of change of N(t), she began to conceive N(t) as a measure of the energy imbalance. Also, the direction of change helped her develop the idea that the energy budget moves towards (radiative) equilibrium after a positive forcing. These represent foundational concepts to understand introductory mathematical models for global warming.

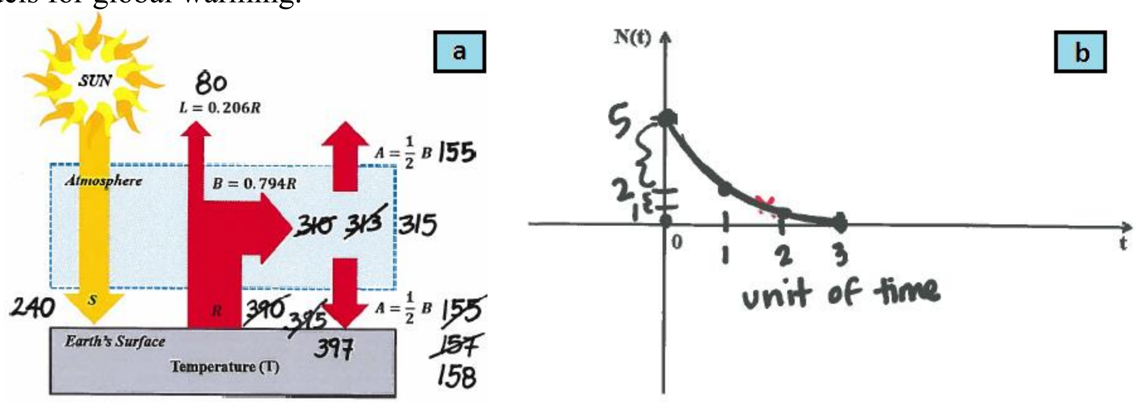

*Figure 2: (a) Jodi's work on the diagram of the energy budget. (b) Jodi's final graph of N(t).*

Jodi constructed the graph of N(t) by plotting the points ($C_i$ , N($C_i$)), and then joining them by a concave-up, decreasing curve (Figure 2b). Jodi looked at the curve and stated that "we are decreasing at a decreasing rate." When asked to elaborate, Jodi said

> Each time we are increasing t, we are decreasing N by smaller amounts. Like here, we decrease 3 [curly brackets on Figure 2b], and then we decrease 1 … I am trying to make sure I know what the graph looks like. OK, when you have a graph and you do like this [*draws a concave-up, decreasing curve*], this is one and this is two [*makes two equally-spaced marks on the horizontal axis*]; you would be decreasing by smaller amounts each time. The same thing what we are doing here [*draws the curly brackets on Figure 2b*], so I want to say that the graph looks like this: decreasing at a decreasing rate

Jodi's responses regarding the rate of change of N(t) and how N(t) decreases by smaller and smaller amounts were a result of reasoning about the graph of N(t). Jodi did draw a concave-up curve, but the concavity was the result of joining all points by a curve. Notice that she need not reason beyond L2 to accomplish that. Jodi did not notice that R, B, and A were also increasing at a decreasing rate. This suggests that she was not attending to the situation when thinking about amounts of change. It was by using the graph as her object of reasoning that Jodi attended to the variation in amounts of change in N with respect to changes in time. This appears as a version of L3 covariational reasoning, a version that makes use of the graph as an object of reasoning. It did not seem that this version of L3 helped Jodi understand the energy budget since the latter was not the object of reasoning. Also, Jodi's verbalization regarding the rate of change of N(t) must be taken with caution. Jodi's responses suggest that she was reasoning in terms of amounts of change rather than rate of change. It is, therefore, unlikely Jodi's covariational reasoning was at the rate of change levels L4 or L5.

Jodi provided an interesting interpretation of N(t) in relation to the variation in energy (or heat) in the surface. Jodi stated that the surface was losing heat because N(t) was decreasing. When asked to elaborate, Jodi stated that "we would need to be losing energy so that we can go back to equilibrium." For Jodi, a decreasing N(t) represented an energy budget moving towards equilibrium, but in the sense that *thing were going back to their original state* (i.e., a budget before the positive forcing). Jodi conceive N(t) as a measure of energy imbalance as in measuring *how far* the budget was from its *original radiative equilibrium*. Jodi's conception of energy imbalance did not involve N(t) as a difference between downward radiation and upward radiation. Jodi's conception of N(t) shaped her understanding of radiative equilibrium.

Jodi's responses to the second part of the task suggest covariational reasoning abilities at a discrete version of the amounts of change level (L3) when her object of reasoning was the situation (i.e., how the energy budget evolves after a positive forcing). For this task, Jodi attended to the way R and A were changing between cycles as shown in Figure 2a. Specifically, Jodi attended to the amounts of change in R and A with respect to changes in time.

> It increased by two (A changes from 155 J/m$^2$/s to 157 J/m$^2$/s), and then it decreased by two (R changes from 395 J/m$^2$/s to 397 J/m$^2$/s) [*pauses*]. So, it is almost as if there was no change in temperature because I associate energy as kind of having a relationship with temperature. So, if the energy increases, then the temperature increases. But, in this scenario an equal change in energy was an equal change in output [*simultaneously points at A and R*]

Jodi saw that any increase in A, or radiation from the atmosphere towards the surface, was match by the same increase in R, or radiation from the surface towards the atmosphere. She interpreted it in the following way: "the Earth would heat up because it got more energy [*points at A*], but then it would release it within the same cycle [*points at R*]." This suggests that the discrete approach to estimate the values of R, B, and A was shaping Jodi's thinking about the situation. Jodi conceived time varying in discrete units, or *cycles*. For *cycle i*, A instantaneously increased by an amount $\Delta_i A$ (at the beginning of *cycle i*), while R instantaneously increased by an amount $\Delta_i R = \Delta_i A$ at the end of *cycle i*. Following this reasoning, Jodi concluded that the surface energy was oscillating over time, which led her to conclude that T(t) was also oscillating over time. She represented this oscillatory variation by two periodic curves (Figure 3). Jodi drew two different periodic curves (*arcs* curve and *dashes* curve) because she was not sure whether the energy, and consequently the temperature, was increasing and decreasing within each cycle (*arcs* curve) or increasing within a cycle and instantaneously decreasing at the end of it (*dashes* curve). Her responses showed evidence of L2 covariational reasoning since she described the direction in which T(t) was changing over time (i.e., as t increases, T(t) increases and decreases).

Interestingly, Jodi constructed a third graph for T(t) by attending to the variation in the amounts of change in the energy flows in the budget. She attended to the variation in the amounts of change in B with respect to changes in time (Figure 2a). Since B was increasing by smaller and smaller amounts, Jodi thought that T(t) was still oscillating, but its *amplitude* was decreasing between *cycles*. Jodi probably saw the decreasing increments in B as consistent with her idea of a budget returning to the original radiative equilibrium. She represented this quasi-periodic variation by drawing a quasi-periodic curve whose *arcs* were decreasing in size (Figure 3). Her response and graph suggest that Jodi, in a way, was reasoning about how T(t) was changing in relation to time. Since she attended to the variation in amounts of change, I consider Jodi's covariational reasoning a version of L3, which was shaped by a discrete conception of time variation. Notice that her L3 covariational reasoning led her to conclude that T(t) was decreasing over time (i.e., the planet's surface was cooling down). This may become an obstacle to understand the link between $CO_2$ pollution and global warming.

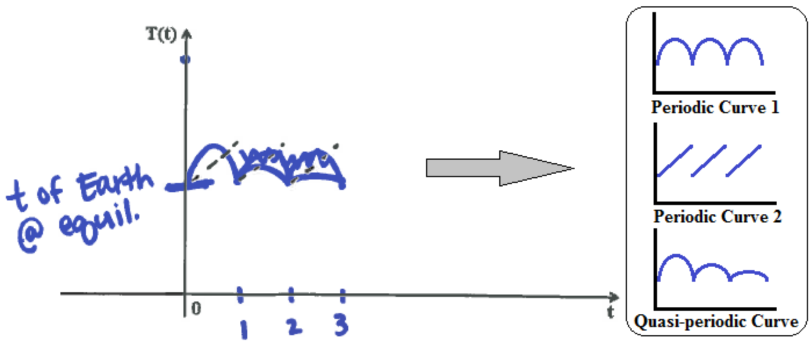

*Figure 3. Jodi drew three different curves for T(t): two periodic curves and one quasi-periodic curve*

## Conclusions

The study's findings suggest that Jodi's covariational reasoning mediates her understanding of concepts related to global warming. Covariational reasoning at the direction of change level (L2) appears to facilitate the understanding of the budget moving towards radiative equilibrium after a positive forcing by $CO_2$. This is a foundational understanding for introductory mathematical models for global warming since it highlights the impact of $CO_2$ pollution over the planet's flow of heat. Jodi's case also shows the importance of developing covariational reasoning at the amounts of change level (L3) by using the situation as object of reasoning. Without this connection, L3 covariational reasoning can be of little use to understand global warming. Moreover, L3 covariational reasoning based on a discrete conception of variation can led to misunderstanding regarding the energy budget. In the case of Jodi, her discrete L3 led her to conclude that the planet was cooling down after a forcing, which contradicts the link between $CO_2$ pollution and global warming. Additionally, Jodi did not make use of N(t) to construct the graph of T(t). This suggests that Jodi did not see N(t) as a measure of the rate of change of T(t). This may be explained by Jodi's inability to reason about co-variation at the rate of change levels (L4 or L5). Another explanation involves Jodi's conception of N(t). She did not see N(t) as a difference between downward radiation and upward radiation. Without such understanding, it is unlikely to see the relationship between N(t) and T(t). Also, her conception of N(t) led her to think that the planet's surface was cooling down. This contradicts the long-term impact of $CO_2$ emissions on the planet's average surface temperature.

# The Authority of Numbers: Fostering Opportunities for Rational Dependence in a Mathematics Classroom

Ander Erickson
University of Washington – Tacoma

*This cross-case analysis of quantitative literacy instruction at the undergraduate level compares three different settings where activities were introduced that required students to seek out and make use of information outside of the classroom. These activities provided students with opportunities to engage with quantitative claims made by experts and by comparing these cases I was able to identify several axes of variability that affect the extent to which the problems supported the practice of rational dependence, or the reasoned dependence on the knowledge of others. These variables include the extent to which students are held accountable for their choices of information sources, the way in which the teacher frames what it means to critically appraise a quantitative claim, and the role that mathematics plays in the activity.*
*Key Words*: Quantitative Literacy, Information Literacy, Statistics, Comparative Case Study

Rational dependence (Erickson, 2016) is the reasoned dependence on the expertise of others. If mathematics instruction is to help prepare students for the quantitative claims that they may expect to encounter in their everyday lives, then they need to be given the opportunity to develop rational dependence. In order to explore what happens when such opportunities are created, I collaborated with several teachers of quantitative literacy-focused undergraduate mathematics courses in order to introduce information-based problems (Walraven, Brand-Gruwel, & Boshuizen, 2008), or those problems that require students to seek out and evaluate information sources outside of the classroom. I developed case studies for each location which informed cross-case observations about how these teachers used information-based problems. The resulting multiple case analysis allowed me to answer questions about whether and how opportunities for rational dependence arose in the context of the activities.

My analysis of classroom work suggests that opportunities for rational dependence were associated with the way that teachers used information-based problems and, in particular, the structure of the academic tasks through which the problems were implemented. All of the teachers prioritized their students' development of a critical stance towards quantitative claims over direct assessment of the credibility of sources. I found that the classroom tasks that contributed to opportunities for rational dependence included (a) how students were held accountable for the sources that they found, (b) how the teachers operationalized their students' development of a critical stance towards quantitative claims, and (c) the role that mathematics played in the tasks.

## Review of the Literature

### Quantitative Literacy

Mathematics instruction has long had an instrumental role with respect to training in the STEM fields, but there has been a more recent push targeting the development of the general mathematical skills and attitudes that might best serve students in their daily lives. This aggregate of skills and dispositions is sometimes referred to as quantitative literacy (Steen, 2004), mathematical literacy, quantitative reasoning or statistical literacy (Cullinane & Treisman, 2010; Watson, 2013). Accordingly, the development of quantitative literacy has become an important goal of courses offered by many colleges for non-STEM majors who need to fulfill a mathematics requirement as part of their liberal arts education. Examples of quantitative literacy are usually directed at quantitative claims made by journalists, politicians, or advertisers rather than experts, but the question of how students should relate to experts does occasionally arise. For example, Gal (2002) in his analysis of statistical literacy, suggests that critical skills, i.e., knowing which questions to ask about sources of information and their biases, is a component of statistical literacy, and that this must also be accompanied by a disposition to maintain a critical stance towards statistical claims. However, one of the most thorough attempts to understand how students can come to interact productively with expert information can be found in the field of scientific literacy.

**Learning to Live with the Expertise of Others**

Norris (1995) breaks down what science education might look like if it served to prepare students to attain an intellectual independence tempered by their dependence on expert communities. He stressed three components of this program: a) learning science in the sense outlined by Moje's (2007) "usable disciplinary knowledge", b) learning about the history and philosophy of science, and c) "learning to live with science" (Norris, 1995, p.214).

This last component is elaborated by Norris, "the only access to scientific truth for most of us is through the efforts of scientific experts [...] therefore, students need to acquire the disposition to question, and to seek other opinions on scientific issues that matter in their lives and in their community" (Norris, 1995, p.215). But this questioning disposition should not, per Norris, be indiscriminate,

> A skeptical disposition is not sufficient if one does not know how to exercise wisely that skepticism. […] [Students] should be taught how to use criteria for judging experts: the role and weight of consensus; the role and weight of prestige in the scientific community; the role and weight of publication and successful competition for research grants; and so on. As part of learning to live with science, students need practice in judging the credibility of scientific experts. This practice should be based on real-world problems that currently affect their lives. (Norris, 1995, p. 216)

Gaon and Norris (2001) go on to argue that there are *content-transcendent* modes of inquiry into claims made by experts and that a non-expert can, and should, ask questions about scientific claims:

> Does this scientific belief embody or support any particular social hierarchies such as those based on race, on gender, or on class? If so, what normative assumptions have been made? Have these norms been thematised and justified scientifically, or are they simply assumed? Have alternate accounts of the same phenomenon been developed? By whom? What were the grounds for choosing one account over another? Are these grounds themselves free of normative assumptions; are they as certain as they appear? Who decided? (Gaon & Norris, 2001, p.200)

These questions apply equally well to quantitative claims and serve as a road map for thinking about what it looks like to live with expertise in any disciplinary area. This gives rise to a further question: How could activities be created that would provide students with the opportunity to develop these skills?

**Information-Based Problems**

The seeking out of information on the internet can become a dilemma for the instructor once they allow this activity to take place in their classroom. At this point, the question becomes not so much about classroom management (e.g., "What should the smartphone policy be?", "How do I keep students from surreptitiously texting?") but rather about managing the classroom's *didactical contract*. I borrow this last term from Guy Brousseau (1997) who refers to the division of labor and system of accountability that specifies how a classroom activity provides evidence that the envisioned learning has in fact occurred. In particular, this type of activity amounts to a modification of the traditional terms of the mathematical *tasks* (Herbst, 2006; Doyle & Carter, 1984), or the actions associated with a given problem along with an established set of resources. This may help explain why, even though the information-seeking behavior of academics differs across disciplines (Palmer & Cragin, 2008), there are few attempts to educate students in the discipline about how that discipline-specific information-seeking is carried out (Grafstein, 2002). This would not necessarily be a problem if students were able to learn how to seek out information through generic instruction that could then be used to support quantitative reasoning, but research has shown that content knowledge is deeply tied to successful information-seeking (Walraven et al., 2008).

## Theoretical Framework

**Rational Dependence as an Educational Goal**

Successful engagement with real-life quantitative claims is predicated on our *epistemic dependence* (Hardwig, 1985) on others, or the fact that much of what we know is dependent on our trust in the expertise of others. This observation must be tempered by the fact that an individual can rely on others in a more or less rational way (Siegel, 1988). What does all of this mean for mathematics instruction? Although the importance of information-based problems for disciplinary literacy is easy to justify as long as one accepts that information-seeking is an important part of practice in the disciplines, it requires a little more unpacking to explain why this type of instruction might have a place in mathematics instruction. One way to begin such an explanation is to imagine an applied mathematics problem -- say students are given an editorial in which the author argues that federal guidelines on fuel efficiency will end up costing the country more money than it will save (Diefenderfer, 2009). Students are asked to read the editorial and then provided with several guiding questions that encourage the students to analyze the numerical argument contained in the article while noting some of the additional information that might be required prior to coming to a final verdict on the validity of the editorial's argument. If a reader were to actually want to determine whether a quantitative claim was true or not, they would want to locate the relevant *epistemic community* (Haas, 1992), i.e. that community that possesses the expertise to tentatively rule on the truth of the claim. In other words, they would need to engage in the practice of rational dependence by finding experts on whom the students have good reason to rely. An *information-based problem* (Walraven et al.,

2008) provides such an opportunity by requiring students to seek out and evaluate sources outside the classroom. In order to come to a better understanding of an information-based problem, the student must "identify information needs, locate corresponding information sources, extract and organize relevant information from each source, and synthesize information" (Walraven et al., 2008, p.2) in a process called *information-problem solving*. My inquiry can be framed, then, as a question about how mathematics teachers and their students cope with the introduction of information-based problems, and whether and how these problems afford opportunities for rational dependence in the classroom.

Accordingly, this study seeks to answer the following research questions:

1. How can opportunities for the practice of rational dependence be introduced to a quantitative-literacy focused mathematics class?
2. What aspects of information-based problems in a quantitative-literacy focused mathematics classroom most influence students' opportunities to practice rational dependence?

## Research Methodology

I investigated the research questions outlined above through a multi-case analysis (Stake, 2013) of collaborations with three teachers of terminal undergraduate mathematics classes targeting non-STEM majors. We worked together to design activities in which information-based problems would be introduced to their students. Table 1 provides more information about the sites where this research took place. At Phi University students were assigned to argue one side in a classroom debate. To prepare, they were required to research their topic and provide some statistical evidence supporting their side of the issue. At Rho University, we developed a two-part activity where students were asked to look for articles in which a conjecture about causation was being studied (e.g., vaccines and autism). They were asked to locate the quantitative evidence used to claim that the two variables were or were not correlated, and then engaged in a small-group discussion with their peers about the topic. Their groups tried to come to a consensus on the issue at stake and then shared their verdict with the rest of the class. The students at Delta University also worked in small groups, but here they were asked to create a presentation in which they would analyze the way that statistics were used in a research article for the rest of the class. The focus of this analysis would be on the sampling methodology, but they were free to talk about other facets of the article if they chose to do so.

The *quintain* (Stake, 2013), or the phenomenon of interest for this cross-case analysis, is the introduction of information-based problems to an undergraduate mathematics course. The data for this study includes pre- and post-interviews with the instructors at each of the three sites, supplementary interviews with teaching assistants and students, field notes taken while observing instruction prior to the introduction of the information-based problems, video and audio-recordings of the in-class component of the activities, and copies of the work that the students submitted. These data sources informed the writing of individual case reports which were, in turn, used to develop the cross-case analysis. Following Stake (2013), I developed themes based on my research questions that I then used as an analytical lens for the development of case reports for each of the three sites. After writing up the case reports, I cross-referenced case-specific with the themes of the larger study. This allowed me to warrant theme-based assertions and used those to inform the final cross-case assertions (see Figure 1) about the introduction of information-based problems to undergraduate mathematics classrooms.

| University Name[a] | Course Name[a] | Students | Topics | Structure |
|---|---|---|---|---|
| Phi University (Research) | Topics in Mathematics | 22 entering Freshman, Liberal Arts Majors | Gun Control, Marijuana Legalization, Single-Sex Education, Death Penalty | Debate Format |
| Rho University (Regional) | Quantitative Reasoning | 14 Juniors and Seniors, many are prospective Nursing students | Autism and Vaccination, The Mozart Effect, Gun Control, Health Care Reform | Small-group Discussions |
| Delta University (Doctoral) | Mathematics in Today's World | 24 Juniors and Seniors, many are prospective Nursing and Education students | Autism and Vaccination, Gun Control, Murder Rate, Vehicular Accidents, Employee Prospects | Small-group Presentation |

**Table 1.** Description of research sites and student population

## Results

The three cases provided instructive examples of how and why the actions of a teacher can open up or limit opportunities for rational dependence. I have broken down these observed axes of change into three categories. First, the degree to which students are made accountable for their choice of sources to draw from; second, the way in which a critical stance to quantitative claims is framed by the instructor; third, the role of mathematics in the information-based problem.

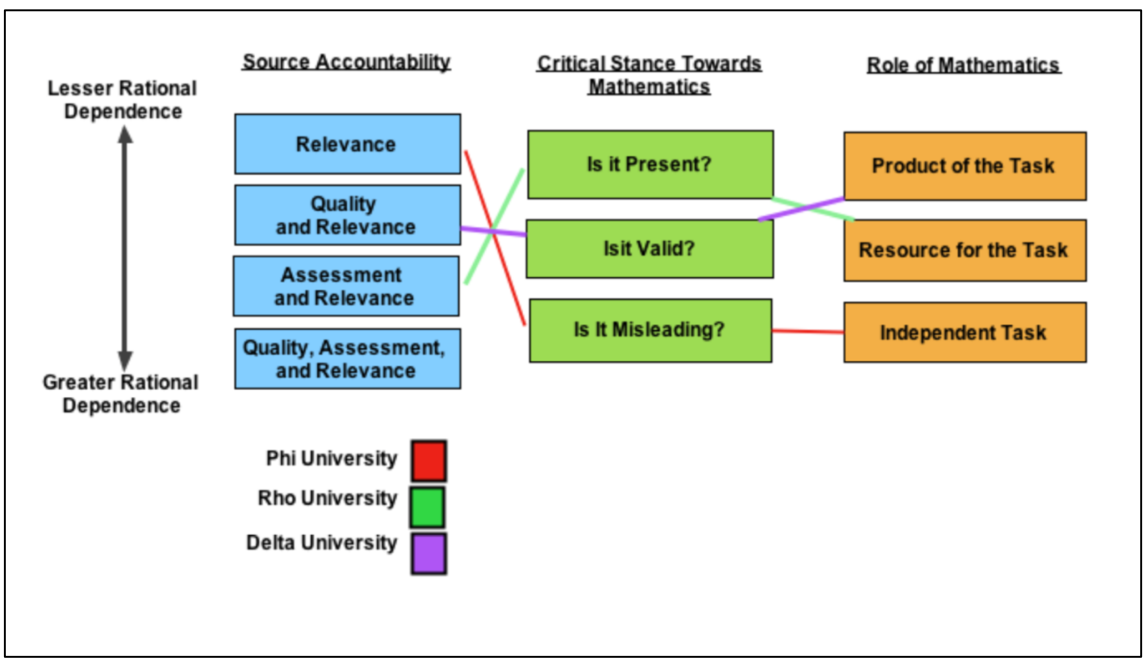

**Figure 1.** Opportunities for rational dependence in each of the three cases.

## Source Accountability

The information-based problems, as specified by these teachers, differed with respect to the way in which the students were held accountable for the sources that they found. This feature appears as the leftmost column in Figure 1 and contains four categories that I have ordered based on the degree to which the feature presents opportunities for rational dependence. The least conducive to rational dependence are those problems for which students are held accountable for finding sources that are *relevant* and nothing more. For example, students participating in the debates at Phi University did not need to say anything about the quality of their sources nor did they have to account for the process through which they decided on those sources. At Delta University, students were required to assess the quality of their sources through an analysis of the researchers' sampling methodology – this also provided students with an opportunity to bring to bear the statistics that they had been learning. The greatest opportunity for engaging in rational dependence with respect to sources of information, however, occurred at Rho University where students were accountable for the process that they used to find sources and were asked to compare sources to one another. Thus, students engaged in the type of work described by Gaon and Norris (2001) by comparing different accounts of the same phenomenon and the grounds by which one account might be prioritized over another. For example, students prioritized research published in scholarly journals by relevant experts in the field over reports by journalists who had a record of supporting one side of the debate over the other.

## Critical Stance Towards Mathematics

In the second column of Figure 1, I refer to the manner in which the teacher intends their students to take a critical stance towards mathematical claims. As these were mathematics classes, the students were expected to be critical of mathematical content specifically but, perhaps surprisingly, this expectation took a different form in each of the three cases: the students at Phi University were encouraged to watch for biased mathematical content, at Delta University they were asked to assess the validity of the mathematical argument supporting the claims, and at Rho University they were simply told to check for the presence of mathematical backing in the form of a correlation coefficient or a confidence interval. This last approach is positioned as least conducive to rational dependence in Figure 1 because the presence or absence of mathematical content does not say anything consequential about either the validity of the arguments being made by a source or whether a source's claims are supported by a broader epistemic community. Assessing the validity of the mathematical argument used by a source is more conducive to rational dependence because answering that question gives a better sense of whether a sources' claims are supported. However, that approach fails to account for the possibility that the author of an article might present a mathematically invalid argument due to their lack of mathematical knowledge even if the claim is held to be true by those with expertise in the area. Indeed, it is commonly held that popular science reporting falls prey to this exact problem (Bubela et al., 2009). Thus, the approach most consistent with the development of rational dependence is to determine whether a source has a bias and to stay conscious of how the relevant research is being framed by the source in question (Bubela et al., 2009).

### Role of Mathematics

Finally, in the third column of Figure 1, I address the role of mathematics in these information-based problems. Ideally, this role would be consistent with the manner in which rational dependence arises in out-of-school contexts where the goal is to educate oneself more broadly about a specific claim rather than a mathematical concept in isolation. Information-based problems where the mathematical task is independent are the most consistent with rational dependence since this approach best reflects the reality that mathematics is one tool among many for approaching such problems. This is how the debates at Phi University treated the use of statistical charts, it was a component of the debate, but not treated as the determining factor for deciding on the credibility of a source. It is less consistent with rational dependence to give the identification of mathematical content a central role in credibility assessment, as occurred at Rho University. For example, by directing students to focus on the presence or absence of a correlation coefficient, the teacher led students to use this one element of a source as a marker of credibility over and above other important elements such as its institutional affiliation or the presence of corroborating sources. The activity at Delta University positioned the role of mathematics in a way that was least consistent with the practice of rational dependence as the product of the task prioritizes mathematics as the sole determinant of credibility.

## Discussion and Conclusion

Although this cross-case analysis is only a first look at the introduction of information-based problems to quantitative literacy-focused instruction, the present findings provide some guidance for future iterations of these activities. First, they suggest the importance of holding students accountable for both how and why they choose sources to address the problems that they are assigned. This was deftly achieved at Rho University by the teacher when she facilitated small-group discussions in which students had to defend their choices to one another and come to a consensus about which sources were the most credible. Second, pushing students to reflect on the larger context in which their sources are providing information will provide them with an opportunity to identify the existence of competing explanations for the phenomenon under investigation as well as possible sources of bias. Finally, even though mathematical concepts must necessarily remain the focus of a mathematics class, it may be productive to provide students with a perspective on their problem-solving work that foregrounds the limited role of mathematics in establishing the credibility of sources. This does not have to mean that the mathematics itself is given short shrift, after all, the students need to be provided with the opportunity to develop the quantitative literacy skills that will help them engage in information problem-solving in their everyday lives – however, it does mean that students should be reminded that there are other facets to the information problem-solving process and that quantitative reasoning is only one, albeit important, element of their repertoire.

Sensemaking in Statewide College Mathematics Curriculum Reform

Matthew Wilson
Oklahoma State University

Michael Oehrtman
Oklahoma State University

*We draw on the theory of sensemaking and sensegiving to characterize the social cognitive aspects of transformative organizational change in the context of statewide college mathematics curriculum reform efforts with the goal to understand the barriers to implementing the forms. In order to further understand the change process and the challenges these changes present, we conducted interviews with institutional, state, and national leaders of these efforts.*

*Keywords:* Sensemaking, Corequisite Remediation, Math Pathways, Faculty Change

The public institutions of higher education in Oklahoma are currently in the process of designing and implementing corequisite remediation and mathematics pathways. The goal of these efforts is increased student success in introductory mathematics courses and, ultimately, increased persistence to certificate and degree completion. In contrast to the traditional remediation model which places undersparred students into non-credit barring courses, corequisite rededication places underprepared students directly into college-level courses with assistance. The goal of math pathways is to create alternatives to the college algebra/calculus sequence to better serve students in primarily non-STEM degree programs. The alternative pathways provide students with mathematics courses which are more applicable to these other majors, incorporating relevant skills and applications. Preliminary data show promising results from these reforms (Wilson & Oehrtman, 2017). In this paper, we aim to characterize the social cognitive aspects of the reform process drawing on constructs of sensemaking and sensegiving in order to characterize the barriers or challenges in implementing systemic reforms.

## Theoretical Perceptive

In this section, we give a brief overview of the theory of organizational change. Van de Ven and Poole (1995) define organizational change as, "an empirical observation of difference in form, quality, or state over time in an organizational entity" (p. 512). However, as Kezar (2001) notes, this characterization ignores the individual's perception, which can be just as important. Therefore, we use Kezar's definition that amends Van de Ven and Poole's definition to include, a perceived "difference in form, quality, or state over time in an organizational entity." We define *a change process* to be a series of change events. An individual attempting to invoke or direct a change process is called a *change agent*.

Organizations are continually changing. The question is, to what degree or to what scale is that change occurring. First-order change or organization development is continual change or change within normal operating practices. First-order change does not require a substantive shift in participants' beliefs. However, second-order change (transformational change or deep change) does require a substantive shift in beliefs or values of the members of the organization. Second-order change is a substantive divergence from previous operating practices. As such change requires a shift in beliefs, the process is often studied by using theories that emphasize cultural or social cognitive aspects. (Kezar, 2014).

One such theory is *sensemaking*, so-named by Weick in 1979, which has been employed by many theorists and researchers throughout a large body of interdisciplinary literature.

Sensemaking is how individuals continually create and understand their reality and role in the organization. Sensemaking is inherently both an individual and social process. Organizations are made up individuals who have to make sense of their reality which is, in-turn, shaped by their social context in the organization. Therefore, the organization changes as a response to the sensemaking activities of its members then members must then make sense of new realities. Through such a dialectic, Weick (1993) explained, “the basic idea of sensemaking is that reality is an ongoing accomplishment that emerges from efforts to create order and make retrospective sense of what occurs” (p. 635). The key to sensemaking is its retrospective nature (Weick, 1995). In a transformational change process, sensemaking is used to plan for the future by reflecting on “errors” of the past, “tight implications formed in hindsight, are wrong because the future is actually indeterminate, unpredictable” (Weick, 1995, p. 28). Weick goes on the say that, “the past has been reconstructed knowing the outcome.” That is, any errors of the past are only errors now that we know the outcome. For individuals involved in a change process, “sensemaking is about understanding a change and making it meaningful” (Kezar, 2013, p. 775). In summary, sensemaking is how individuals involved a change understand the change, in particular how they make sense of their role in the changing organization and how they understand and interpret past events.

Often, sensemaking is studied in conjunction with the idea of *sensegiving* from Gioia and Chittipeddi (1991). Sensegiving describes how the change is disseminated and framed to those involved or affected by the change. That is, sensegiving is done to help others engage in sensemaking. Kezar (2013, p. 763) defines sensegiving as “influencing the outcomes” of a change strategy. Gioia and Chittipeddi, (1991) devolved a four-stage process for change linking, sensemaking and sensegiving. The stages are envisioning (an aspect of sensemaking), signaling (sensegiving), re-envisioning (sensemaking), and energizing (sensegiving). In the envisioning phase, change agents develop a strategic vision for the change. Overlapping the envisioning phase, *signaling* involves communication about the change by its agents to those it affects. The individuals affected by the change process voice feedback stemming from either support or opposition in the re-envisioning phase, which may cause a modification of the change process. Finally, in the energizing stage of effective large-scale reform, a broad coalition is built as the changes begin to be implemented.

Gioia and Chittipeddi describe these phases in terms of cogitation and action. Sensemaking is a mental understanding that one must engage in while sensegiving is an action that one does to affect or influence the change.

In 2013, Kezar found that, when looking at a campus wide-effort to implement interdisciplinary learning, the change process did not follow a linear path. In particular, they found that change agents must transition back and forth between the sensemaking and sensegiving often when implementing the change process.

## Methods

As discussed in the previous section, the purpose of the study is to understand the change process as well as the challenges in implementing corequisite remediation and mathematics pathways. In order to answer this question we conducted semi-structured interviews with institutional, state, and national leaders involved in the Oklahoma effort. The purpose of conducting the interviews was to understand the affordances and barriers in implementing the reforms in Oklahoma, including obstacles faced by faculty, mathematics departments, and institutions. The aim was not only to situate the reforms in a national context, but to understand how the efforts of different states across the county can inform the efforts here in Oklahoma.

The participants of the study were individuals involved in the reforms in Oklahoma and individuals involved in the national reforms who were engaged in supporting the Oklahoma reform efforts. Interviewees consisted of co-chairs from state task-forces on corequisite remediation and math pathways, instructors involved in implementing pilot courses at OSU, and administrators/faculty at institutions across the state. The interviews were conducted during the spring of 2017 which included a total of 10 participants. The interviews were conducted in person or over the phone and were audio recorded. Each of these participants has a unique perspective from their role in the change efforts.

The interviews were transcribed and coded using open coding. The aim was to understand the barriers to implementation and analyze the change process. Therefore, in coding we looked for challenges that change agents faced in the process of implementing the reforms and how the participants engaged in sensemaking through the barriers. That is, we looked for instances where change agents would be engaged in sensemaking, in particular, where one would try to make retrospective sense of past events or engage in envisioning changes. Narratives describing the challenges for each corequisite remediation and math pathways are given in the results sections as well as a characterization of the change process through the lens of sensemaking.

## Findings

Over the course of conducting the interviews, several themes emerged. First, we discuss the change process using the sensemaking perspective and then discuss the challenges unique to each of these change efforts.

### Change Process

The change process began in 2011 when the state signed on to CCA's agenda and specified the following three goals though the state regent's office: (1) improve mathematics preparation of students entering college, (2) reform mathematics remediation to be more effective and (3) strengthen mathematics preparation for all majors.

In order to address the second goal, in April of 2012, the Oklahoma State Regents held the first of several statewide meetings, *The Remedial Reform Summit.* This summit, facilitated by presentations from individuals outside the state, included discussions about the current remedial landscape. This summit led to the regents holding the *Mathematics Faculty Conference* in September of 2012 with 150 mathematics faculty and administrators to identify "a systemwide strategic approach of encouraging and implementing innovation to improve student success" (Oklahoma State Regents for Higher Education, 2015, p. 5). One the outcomes was the creation of the working group called the *Math Success Group.* The Math Success Group held a planning meeting in September of 2013, which lead to strategies to address three goals. One of the strategies to address the second goal was to offer corequisite courses.

The *Math Pathways Taskforce,* formed in 2014 following Oklahoma joining the Charles A. Dana Center's New Math Pathway's Project, consists of mathematics faculty from each public institution. The taskforce published recommendations in February of 2017. In March 2016, CCA and OSRHE hosted the Corequisite at Scale Conference. In April of 2017, the Dana Center and the OSRHE hosted the math pathways meeting.

These meetings allowed for collaboration and for attendees to engage in sensemaking as a social activity. In particular, attendees we able to engage with the idea of corequisite remediation reflecting on the past remediation model.

The taskforce and workshop attendees are able to gather information and envision the changes while engaging with other attendees. As one of the faculty members and co-chair noted:

> I think one of the challenges is to make every feel that they have a voice at the table that they are involved. I think the workshops are tremendous in that…. everybody expresses what their opinion, their idea is of what we're doing, and then it's discussed and then things are sorted. And tables get together and pick these particular topics. And then tables discuss them in small groups all the topics get discussed. Then the tables report back and that's refined over a period of time. And so you get a lot of buy-in, because everybody's had a voice and a chance to say what they think is important what the challenges are and how they think it should be addressed and sit there and discuss with other people.

Another faculty member had similar sentiment:

> We've gone through such a slow and deliberate process where we've engaged everybody in the conversation and it's clearly not been a conversation 'you do this and that' right it's been even from the beginning let's clearly identify what problems we're trying to solve right and what we think are promising solutions and explore those...

Moreover, the process and open-ended nature of the workshops afforded attendees the opportunity to engage in sensemaking and construct their own sense for the changes. In particular, the attendees can understand the change and envision the change on their campus and what the challenges will be for their particular campus. As each of these campuses has a unique mission and goals, its challenges will be unique as well. Statewide meetings can facilitate understanding the challenges entailed in these changes, which was highlighted by one faculty member:

> And so there's a little bit of kinda mismatch of perspective right when you think of the goals of each institution what they're trying to implement. That's required some navigating and frankly just even understanding. You know we don't even know there are issues like that until we all sit down at the table together and say 'why are you trying to do this?', well because our students have these needs and they don't already have a stat course right. Oh that's not even part of our perspective because we're not dealing with associates degrees.

After the workshop, the attendees were able to return to their campuses to engage in sensegiving with others, helping others understand what the change will entail on their individual campuses and creating buy-in. In the language of Gioia and Chittipeddi (1991), these meetings constituted an envisioning phase of the reform, laying the ground work for what the change will entail across the state. In a signaling phase, the taskforce presented recommendations and engage others on at their institutions in the change process. On their respective campuses, faculty and administrators can engage in the re-envisioning phase by framing the reforms in the context of their campus. The institutions then began to implement these changes in the energizing phase. The process here is iterative as the implementation has involved pilot programs.

## Challenges in Corequisite Remediation

In the efforts to implement corequisite remediation, many of the challenges are related to policy and implementation. One of challenges articulated by the participants of this study was assessment and placement of entering students. The goal is to place students into mathematics courses in which they will succeed without unnecessarily extending their sequence of required courses. In order to place students, an assessment mechanism is needed, however, some are costly. As one community faculty member noted, "I know that [one of the research institutions] uses ALEKS but that's little cost prohibitive for us." One administrator noted,

> The fact that we have the placement test with the online learning modules that's something that we are big enough that we have an economy of scale we can pay for by imposing fees

> and we have an apparatus to deal with it with the testing center… Having that large apparatus and this large infrastructure makes those sorts of things easier in some respect.

These challenges highlight the different experiences between two-year and four-year institutions. Additionally, there are logistical challenges of placing students in corequisite sections. These logistical challenges are highly localized. For example, the implementation at the research institution was so that the course did not appear any different on the transcript between corequisite and non-corequisite students. As the administrator responsible for implementing the corequisite course at the institution noted:

> Our big challenge right now [the enrollment management system] can't really test for this population of students. So we have the corequisite sections set up as department permission only.

Because of this, the department had to manually add each of the students in the corequisite courses. The administrator continued,

> That's a labor intensive sort of thing, I haven't figured out a better way to do it. It's worth it to me to use that labor to help the students.

While the model had its challenges, the university did not want to offer 0-credit hour courses nor did it want to give students five credits for the course. Using a 0-credit hour course in some form to deliver the supplemental instruction also comes with its own challenges. Depending on whether the instructor is the same for the regular course as for the supplemental course can lead to challenges either way. If the instructor is the same, scheduling can be difficult. However, the benefit can be that the instructor is familiar with where the students are at and what they know. These challenges in scheduling lead one community college to attempt to intermix the students. That is allowing students regardless of preparation to enroll in any college algebra section and using 0-credit hour supplement course which are not tied to any particular section. However, this approach introduces its own challenges with communication and as faculty member at the college noted "making sure students get enrolled in both," which is particularly challenging as the course is not linked to a supplement course. Moreover, not all the students in the college algebra sections need to enroll in a supplemental section as some are college ready.

**Challenges in Math Pathways**

The most prevalent challenge to emerge concerning math pathways was on course transferability, particularly from two-year to four-year institutions. The issue is ensuring courses with the same or equivalent content transfer between institutions, so students who transfer are not taking duplicate courses. In Oklahoma, the *Course Equivalency Project* or CEP[1] is a matrix, which codifies course transfer between public Oklahoma Institutions. That is, the matrix guaranties that a course *will* transfer and *how* the course transfers. Currently, College Algebra transfers between every public institution as it is listed on the CEP, and the course can be used to satisfy the degree requirements. However, course transfer is not guaranteed for alternative pathways. The focus of the change agents and change leaders to address this challenge is to add the new pathways to the CEP. By adding these alternative pathways to the CEP, students taking for example the course for the modeling pathway at an Oklahoma institution will transfer to any other institution as the equivalent modeling course.

---

[1] The CEP matrix can be found http:/www.okhighered.org/transfer-students/course-transfer.shtml

The issue of course transferability is particularly relevant to the two-year colleges where students intend to transfer to a four-year university. Faculty at a two-year college explained they will not offer a course until they can know it transfers, that is until it appears in the CEP matrix,

> We've also got a new modeling course, but I haven't put it in the schedule yet because I'm not sure it's going to transfer. Once we get that pathway developed and in the matrix, I'll put it in the schedule.

Also, important for course transferability is ensuring the course satisfies the desired degree requirements at the transfer institution, otherwise a student would need to take another mathematics course. This issue came up in context of the statistics pathway:

> …when talking about statistics pathways right, so our two-year schools their associates in something like psychology currently has no statistics in it, so adding statistics as part of the pathway kinda makes sense for them, cause they are giving them some content and experience that's useful. Now at four-year school where the bachelors program in psychology students are taking already have lots of statistics built in adding another statistics course that repeats some of the most of the content maybe at a lower level that's already in their program. It doesn't really help right. You're trying to put a course in there they've already got.

Solving the transfer problem and offering courses is only the first challenge. One also has to get students enrolled in these courses. This change has multiple parts, one needs to get the degree programs to allow alternative pathways and have advisors place the students into the courses:

> These are real challenges. The client disciplines getting them on board and doing it. The math departments may be on board, but you've got to get the client disciplines on board. Then you've got to get the advisors on board. The advisors are going to be the one that when you come in say what you want to be, they're going to tell you which pathway to go to. Well a lot of them are scared. Cause they've always told people you better take college algebra, it transfers anywhere. If you take modeling, you may not be able to transfer that and get your requirement, so you'll have to take college algebra when you get there, and so that's a real problem.

Mathematics departments will need to engage other departments and advisors in sensegiving. Specifically, they will have to help client departments and the advisors make sense of the College Algebra alternative and what these courses would mean for their students. Advisors need to understand the goals of each student and which course will best help the students achieve those goals. This challenge is compounded by the fact that many students enter college without a declared major. Placing these students into the correct course can be particularly challenging. However, the pathways are intended for broad groups of majors, hereby enabling students to select a field instead of a more specific major when entering.

## Conclusion

The change process to design and implement statewide reform of corequisite remediation and new mathematics pathways is multileveled and highly collaborative, involving individuals from the regent's office to campus administrators to advisors to mathematics faculty, with many of these individuals involved in leading and shaping the change efforts. The numerous participant meetings, workshops, and taskforces helped to facilitate and guide the change process. The statewide meetings helped attendees to engage in sensemaking and sensegiving activities which enabled broader buy-in. Additionally, the statewide meetings helped others make sense of the implementation process on their campus, but also allowed individuals to see the changes faced by other institutions.

In this paper, we have identified a few important challenges; however, there are many more challenges. Some of these may be implementation or institution specific. Additionally, there will undoubtedly be challenges in the classroom.

Adapting an Exam Classification Framework Beyond Calculus

Brian P Katz
Augustana College (IL)

Sandra Laursen
University of Colorado Boulder

*This paper reports a methods-building project that seeks to make inferences about mathematics instructors' teaching practices from their exams. We adapt and revise a framework by Tallman et al. (2016) and expand its applicability across the undergraduate curriculum, beginning with a sample of seven exams from early-career mathematics instructors. We describe the rationale for the adaptation process and patterns of differences between exam sets. Future work includes coordinating this analysis with results from other data sets from the same instructors.*

*Keywords:* Exams, Teaching Practice, Methods-building

This paper is part of a larger research project that seeks to detect changes in the teaching of individual instructors. To accomplish that, we are working to develop and coordinate methods that capture aspects of instructors' teaching from diverse data sets including syllabi, classroom video, instructor and student surveys, and classroom artifacts such as assessments. We expect that these data sources capture different aspects of instructors' teaching, and they vary in how invasive or expensive they are to collect and analyze. Rather than hoping to argue that one of these data sources and methods is best, we seek to understand the affordances of each method and the kinds of questions that are appropriate for each for the purposes of detecting change through professional development. Additionally, we hope to help clarify the desired outcomes of professional development, the change trajectories of participants, and the kinds of evidence that demonstrate that change is occurring. The results of this project could be used to help assess and improve professional development for mathematics instructors, which may in turn support the shift towards active and inquiry-based pedagogies advocated by professional organizations for collegiate mathematics instructors (CBMS, 2016).

This paper focuses on course exams to ask the following question: What can an instructor's exams tell us about that person's teaching? Exams are generally high-stakes assessments, so presumably they represent the values, beliefs, practices, and theory-in-use (Argyris, 1976) of the instructor who authored them (Black & Wiliam, 1998). However, timed exams also put constraints on the kinds of activities that are possible for students, so we do not expect exams to capture all of an instructor's perspective in general. Exams are easy to collect; they are also authentic artifacts in the sense that they are created as part of the course, for the students. Thus, we articulate the detailed research question:

- Can we build or adapt a coding scheme that detects patterns and differences among instructors' exams in order to support inferences about their teaching?

This phase of the project is methods-building, so this paper emphasizes the development of a scheme for coding exam items from undergraduate mathematics courses across the curriculum. We include some results from coding of a small study sample as evidence that the resulting scheme captures patterns and differences among instructors' exams that in turn may offer evidence about their instructional choices.

Later stages of this program could develop a theoretical perspective on the aspects of teaching and their hypothesized relationship to professional development, but we are not yet at the stage where we can articulate such a framework. Instead, we seek to develop methods that focus our attention on aspects of instructors' teaching, seek patterns and connections within or across these data and methods, and use both our theoretical sensitivity as researchers and our experience as teachers and professional developers to identify potentially meaningful observations.

## Literature Review

We are building a scheme for coding exams to learn about instructors' perspectives on teaching, so we focus on the requirements that they make of students in exam items. Subsequent to this paper, we will coordinate this scheme with analyses of other aspects of these instructors' practice, so our scheme must be independent of specific knowledge of other elements of the course or the students' backgrounds, though it can depend on a coder's more generic knowledge of undergraduate mathematics.

We draw on work of Tallman et al. (2016) to summarize some prior research that has examined individual mathematical tasks. Li (2000) built a three-dimensional coding scheme to assess whether the item required one or more mathematical procedures, whether the item was purely abstract or set in an illustrative context, and what format and cognitive demand were required for a response. It is difficult to determine the grain size of a single procedure without information about the specific course context, but the other dimensions of this scheme align with our goals. Lithner (2004) focused on the potential student strategies for seeking a solution to an exam problem; our project focuses on what is expected of all students in common rather than on potential differences. Smith et al. (1996) and Anderson and Krathwohl (2001) produced coding frameworks that modify and update Bloom's taxonomy. Bloom's taxonomy has been critiqued because the actual cognitive demand of any task depends on the individual student's prior experience, but we accept that an instructor can have a well-defined intended cognitive demand for a task, and that a coder with mathematical expertise could assess this intent from the exam. Mesa et al. (2012) used Charalambous et al. (2010) to incorporate information about representations and metacognition in their coding framework. These dimensions align with our goals, but we focus on how they are required by the instructor rather than on possible student understandings and approaches they support.

As part of a project to determine characteristics of successful programs in post-secondary calculus, Tallman et al. (2016) developed a scheme for coding individual items on Calculus I final exams, called the Exam Characterization Framework (ECF). The ECF has three dimensions: *item orientation*, which captures the cognitive demand required to respond successfully to the item; *item representation*, which captures representations and other objects in both the task and required response to the item; and *item format*, which captures the structure and scope of the expected response to the task. Consistent with their critique of prior work, we observe that the ECF aligns with our own approach except for its exclusive focus on calculus. They applied the ECF to a large corpus of exams from 2010/11 to develop a summary of the expectations of calculus courses, and they contrasted these exams with a sample from 1986/87 to describe the impact of 25 years of reform efforts. Based on this work, we determined to start our scheme-building process by trying to adapt or generalize the ECF to a broader context.

## Methods

Our data set is the exams (or mastery quizzes) from seven instructors who had completed a professional development program for early-career mathematics instructors. We expect this population to exhibit a range of teaching behaviors, styles, and skill levels. This sample is small because we collected multiple other kinds of data, including classroom video, from the same instructors (not discussed here). These seven instructors are teaching abstract algebra, discrete mathematics or introduction to proofs, content courses for future elementary teachers, introductory statistics, or calculus II/III. The first author, who is the main coder, has the credentials to teach all of these courses and has experience teaching courses similar to 6 of them. The data set includes 208 items from 13 distinct assessments from these seven courses.

The first author familiarized himself thoroughly with the ECF as described in Tallman et al. (2016) and then attempted to use his understanding of this framework to code the seven sets of exams, along the way adapting and revising the ECF into a new but related scheme. The goal was to develop a coding scheme that was applicable across undergraduate mathematics courses, that captured all aspects of exam items that seemed to speak to larger patterns in the instructor's teaching, and that was articulated in an internally coherent way that supported reliable coding and distinction between codes. As he coded, the first author noted items for which his current understanding of the framework was not sufficient to assign definitive codes; he also noted aspects of items that were not captured by the codes. He later repeated this process and then compared the codes and comments as an indicator of intra-coder reliability. He then revised his interpretation of existing codes and defined new codes based on repeated comments; these revisions required overt articulations or re-articulations of the hierarchical structure of the codes in each dimension. Finally, he repeated this process of coding and revision until the framework and its interpretation stabilized.

For two of these cycles and for the stable framework, the first author presented examples of coded items, rationales for changing the framework, and descriptions of the hierarchical structure of each dimension of the scheme to the second author as sense-making checks; these checks were an initial effort to establish face validity in our study context. These discussions emphasized consistency in interpreting individual code definitions and coherence and discrimination across the framework components.

## The Item Characterization Framework

The resulting framework, which we call the Item Characterization Framework (ICF), contains three broad dimensions: item orientation, item format, and item components. These dimensions are analogous to those in the ECF, but include new categories and codes (Table 1).

*Table 1: Dimensions, Categories, and Codes in the Item Characterization Framework*

| **Item Orientation** | | | **Item Format** | | | | **Item Component** |
|---|---|---|---|---|---|---|---|
| Cognitive Demand | Familiarity | Certainty | Breadth | Format | Formality | Other Support | Task/Response |
| Remember | Recreate | Low | Single | Multiple choice/TF | No support | Neither | Applied/Modeling context |
| Recall and apply Procedure | Adapt | Medium | Forked | Fill in the blank | Informal support | Interpretation/ Context | Symbolic representation |
| Recall and reproduce argument | New | High | Delineated | Short answer | Formal support | Control/ Evaluation | Verbal representation |
| Understand | | | Open | Long answer | Unclear | Both | Graphical representation |
| Apply understanding | | | | | | | Tabular representation |
| Analyze | | | | | | | Statement (Thm/Dfn) |
| Evaluate | | | | | | | Claim (Conj/Arg) |
| Create | | | | | | | (Counter-) Example |

### Item Orientation

This dimension captures the assumed cognitive demand of producing a successful response to the item. The category *Cognitive Demand* uses an expanded version of Bloom's Taxonomy. *Recall and reproduce argument* is the only novel code here; this code is analogous to *Recall and apply procedure* but applicable to the context of proof construction.

The cognitive demand of a task depends heavily on the student's past experience with the task (Anderson & Krathwohl, 2001). Both ECF and ICF assume that the coder holds an understanding of the generic undergraduate curriculum and student; in ICF, these assumptions are made explicit by coding how novel the coder believes the task to be for the intended student in *Familiarity* and their confidence in this assessment (and thus of *Cognitive Demand*), in *Certainty*.

### Item Format

This dimension captures the structure of a required response. *Breadth of Responses* captures whether there is a single or multiple acceptable form(s) for a successful response, as well as whether that form is overt in the task statement for the student. *Format of Responses* captures the extent to which the structure of a successful response is provided for the student. *Formality of Response* captures the explicit requirements for justification and support for a successful response. *Other Support* captures the extent to which the item requires the student to corroborate conclusions with secondary evidence or metacognition (e.g., checking work).

The ECF also has a dimension called *Item Format* that is significantly revised in the ICF. The ECF *Item Format* codes blend ideas of breadth, format, and support; additionally the ECF *Item Representation* code *Explanation* contained ideas that blended formality of support and other support with item components. Splitting and rearranging these ideas in this fashion represents the largest revision from ECF to ICF. The shift is from questions about the overt structure of the task and response to questions about how much of the structure of the task and response is made explicit or unknown for a student.

### Item Components

This dimension captures the representations, objects, and statements in the item. These codes apply separately to both the task statement and the required response. For example, *Statement* is applied to tasks that contain a statement, such as a theorem or definition, whose truth-value is (framed as) known, while the same code applied to a response means that the student is required to produce such a statement. The *Claim* code is applied to tasks containing statements with unknown truth-value and to responses that require students to decide on the truth-value of a statement or to generate a statement with unknown status, such as a conjecture.

## Data and Results

Tables 2 and 3 summarize the frequencies and ranges seen for the exams in this data set. Averages are computed from the percentages of each exam set, rather than from the total collection of items, to give the same weight to each participant.

### Comparing Courses

**Item Orientation and Item Format.** To compare exams, we label each as average (within 10% of the group average), or otherwise high/low frequency for each code. For example, P1 and P3 have low frequencies of items with single answers; P1 has correspondingly high frequency on questions with forked responses, while P3 is high on delineated and open items. Similarly, P1 and P3 are both low in items asking students to remember declarative facts, but P1 is high in terms of asking students to reproduce arguments, and P3 is high in tasks that ask students to apply understanding or analyze.

*Table 2: Observed frequencies and ranges for Item Orientation and Item Format codes*

| Item Orientation | | | Item Format | | |
|---|---|---|---|---|---|
| Code | Average | Min-Max | Code | Average | Min-Max |
| Remember | 14% | 0% - 36% | Single | 64% | 16% - 100% |
| Recall and apply proc | 30% | 0% - 66% | Forked | 22% | 0% - 79% |
| Recall and reproduce argument | 12% | 0% - 47% | Delineated | 7% | 0% - 36% |
| Understand | 0% | 0% | Open | 7% | 0% - 18% |
| Apply understanding | 38% | 19% - 69% | Multiple choice/ TF | 16% | 0% - 38% |
| Analyze | 2% | 0% - 8% | Fill in the blank | 11% | 0% - 39% |
| Evaluate | 5% | 0% - 20% | Short answer | 44% | 11% - 62% |
| Create | 0% | 0% | Long answer | 28% | 2% - 74% |
| Recreate | 37% | 7% - 79% | No support | 40% | 0% - 93% |
| Adapt | 60% | 21% - 93% | Informal support | 33% | 3% - 57% |
| New | 3% | 0% - 19% | Formal support | 27% | 0% - 74% |
| Low certainty | 3% | 0% - 14% | Unclear | 0% | 0% - 3% |
| Medium certainty | 24% | 2% - 46% | Neither | 87% | 62% - 100% |
| High certainty | 73% | 54% - 98% | Interpretation/ Context | 1% | 0% - 5% |
| | | | Control/Evaluation | 9% | 0% - 38% |
| | | | Both | 2% | 0% - 14% |

*Table 3: Observed frequencies and ranges for Item Component codes*

| Item Components | Task | | Response | |
|---|---|---|---|---|
| Code | Average | Min-Max | Average | Min-Max |
| Applied | 13% | 0% - 46% | 8% | 0% - 32% |
| Symbolic | 71% | 12% - 100% | 64% | 16% - 100% |
| Verbal | 15% | 0% - 64% | 12% | 0% - 56% |
| Graphical | 15% | 0% - 40% | 12% | 0% - 56% |
| Tabular | 9% | 0% - 31% | 6% | 0% - 15% |
| Statement | 14% | 0% - 38% | 9% | 0% - 46% |
| Claim | 33% | 4% - 79% | 33% | 0% - 79% |
| Example | 8% | 0% - 31% | 16% | 0% - 44% |

Of potential interest for detecting instructors' authentic instruction practices (Gulikers et al. 2004) through exams are the codes that capture uncertainty and open-ended tasks. In Table 4, we summarize the data by participant for four such codes or combinations: analyze, evaluate, and create (A+E+C); new; forked, delineated, and open tasks (F+D+O); and claim.

*Table 4: Observed frequencies for combined uncertainty/open-ended codes by course*

| | P1 | P2 | P3 | P4 | P5 | P6 | P7 |
|---|---|---|---|---|---|---|---|
| A+E+C | 5% | 8% | **28%** | 0% | 7% | 0% | 0% |
| New | 0% | **19%** | 0% | 0% | 0% | 0% | 0% |
| F+D+O | **84%** | 0% | **80%** | 31% | 29% | 13% | 12% |
| Claim | **79%** | **54%** | **48%** | 38% | 4% | 7% | 36% |

**Item Component.** We separate the task and response component codes. Table 5 shows that P3 is high frequency in five *Item Component* subcodes, which is more than the other exam sets, and is also the only course to be high frequency for more student response subcodes than task codes.

The ICF appears to capture the distinctive demands of teaching subfields of mathematics. P5 is the statistics course, and it has the highest frequency of applied components. P1, P2, and P4 are proof-based courses that have symbolic representations in every task and response; P2 and P4 are introductions to proof, with high frequencies of theorem and definition statements in tasks. P3 and P6 are courses for pre-service elementary teachers with lower than average use of symbolic representations and higher than average use of graphical and geometric representations. The high frequency of *Recall and apply procedure* in P5 and P7 may encode the fact that they are lower-division, computational courses.

*Table 5: Item Component code frequencies (light/medium/dark represents low/average/high frequency)*

| **Task** | P1 | P2 | P3 | P4 | P5 | P6 | P7 |
|---|---|---|---|---|---|---|---|
| Applied | 0% | 0% | 20% | 0% | 46% | 23% | 0% |
| Symbolic | 100% | 100% | 12% | 100% | 75% | 23% | 86% |
| Verbal | 5% | 0% | 64% | 0% | 0% | 20% | 12% |
| Graphical | 0% | 0% | 40% | 0% | 14% | 36% | 12% |
| Tabular | 0% | 3% | 0% | 31% | 25% | 7% | 0% |
| Thm/Dfn | 5% | 38% | 12% | 38% | 0% | 0% | 2% |
| Claim | 79% | 43% | 40% | 23% | 4% | 7% | 36% |
| Example | 0% | 8% | 20% | 31% | 0% | 0% | 0% |
| **Response** | | | | | | | |
| Applied | 0% | 0% | 20% | 0% | 32% | 2% | 0% |
| Symbolic | 100% | 100% | 16% | 100% | 43% | 36% | 52% |
| Verbal | 0% | 5% | 56% | 0% | 21% | 0% | 2% |
| Graphical | 0% | 3% | 56% | 0% | 0% | 18% | 5% |
| Tabular | 11% | 3% | 4% | 15% | 0% | 7% | 0% |
| Thm/Dfn | 0% | 46% | 0% | 0% | 18% | 0% | 0% |
| Claim | 79% | 54% | 48% | 38% | 4% | 0% | 7% |
| Example | 26% | 0% | 44% | 23% | 7% | 11% | 2% |

## Discussion

Our evidence tentatively supports the claim that the ICF also detects differences among teaching practices in similar courses. For example, P3 and P6 are both courses for future elementary teachers, but P3's exams include more higher-order and open-ended summary codes in Table 4, and more item components, especially those required in the response, while P6 is average or below in each of these indicators. We suggest that P3 is asking more, or perhaps more authentic mathematics, of students than P6, which could indicate that its instructor holds a more-developed teaching perspective. There are similar, if weaker, patterns of difference between P2 and P4 (introduction to proofs, discrete) and P5 and P7 (lower-division, computational, applied).

These analyses also highlight the ways P3, and to a lesser extent P1 and P2, are asking students to do mathematics that is potentially more authentic (Gulikers et al., 2004) on exams than P4, P5, P6, and P7. P1 accomplishes this by asking students to prove or disprove statements, P2 by asking students to work with new definitions, and P3 by asking students to evaluate arguments and to coordinate multiple goals simultaneously. The evidence and analysis above is consistent with the assertion that the ICF captures dimensions of teaching that are of interest to professional developers of mathematics instructors.

We would predict that items that use different representations in their task and response would be more complex and demanding for students. Tallman et al. (2016) use statistical methods to determine if task components correlate with response components or other codes, but this kind of analysis is not possible on our small sample. In a larger sample, this might highlight another aspect of more-developed teaching practice.

The next phase of the project will involve coordinating the analyses of these seven participants' teaching using other data sets, including their syllabi, video recordings of their classrooms, and surveys of both the participants and their students, for which method development and coding have proceeded independently. Initial conversation indicates that these different data sets generally highlight a similar subset of courses as exhibiting valued teaching aspects, but these data will also highlight different aspects of their teaching, such as espoused theory (Argyris, 1976) from instructor surveys to contrast with theory-in-use from exams.

We have not yet tried to code and test for inter-rater reliability. Thus far, reliability rests on three points of content validity. The first author re-coded the data repeatedly until the framework and codes stabilized, and justified codes and changes to the framework to the other researchers. Restructuring the item format dimension around epistemological questions in particular helped the team agree on their understanding of codes. Finally, the *Certainty* codes serve as a measure of confidence in the coding. The majority of items were coded as medium (24%) or high (73%) certainty. If higher certainty is desired, items coded as medium certainty could be resolved either by scanning the course textbook to see if the question was familiar or asking the instructor to complete a simple survey declaring the familiarity of each item on their exams. These approaches are both more invasive than simply collecting exams, but could be ways to gather this information easily in future rounds of data collection. Next steps for this project must include reliability testing across multiple raters.

Thus far, claims about the utility of the ICF rest on the analysis of a small sample, which is intertwined with the researchers' experience with professional development of mathematics instructors, including advocacy for active and inquiry-based pedagogies. The local goal is to develop a method for coding exams so that we can understand whether and how analyzing exams may be helpful to characterizing teaching. If this method proves useful, the larger goal is to detect change in the instructors who participate in these kinds of professional development. The target teaching outcomes for this kind of professional development are often broad; developing a measure that is focused on assessments and that can be applied widely across course topics may contribute to detecting change in dimensions not currently studied in other ways. We do not claim that an ideal exam is entirely higher-order cognitive tasks, but we do believe that high quality teaching would include requiring students to engage *some* higher-order tasks on exams and that ask students to work in uncertainty. We do not think that an ideal exam completely avoids symbolic representations, but we have valued those exams that avoid using only symbolic representations and that ask students to reason with multiple representations. We also need to connect the ICF to existing research to solidify these utility claims.

Future research could explore these questions, some of which are analogous to those explored by Tallman et al. (2016). Are exams for courses other than calculus changing across time in the discipline? What correlations exist among the codes in the ICF (in a sample large enough for statistical analyses), and how do these correlations depend on course level/domain? To what extent are mathematics students asked to use and translate between multiple representations in their (high stakes, timed) assessments? With additional instructor data, how do instructors' perspectives about their exams related to researcher analyses of the items, and what are the relationships between instructors' stated values and their assessment practices? Using a coordinated and longitudinal data set from professional development, do changes in exams lead or trail other teaching changes in response to professional development?

# When "Negation" Impedes Argumentation: The Case of Dawn

Morgan Sellers
Arizona State University

*Abstract: This study investigates one student's meanings for negations of various mathematical statements. The student, from a Transition-to-Proof course, participated in two clinical interviews in which she was asked to negate statements with one quantifier or logical connective. Then, the student was asked to negate statements with a combination of quantifiers and logical connectives. Lastly, the student was presented with several complex mathematical statements from Calculus and was asked to determine if these statements were true or false on a case-by-case basis using a series of graphs. The results reveal that the student used the same rule for negation in both simple and complex mathematical statements when she was asked to negate each statement. However, when the student was asked to determine if statements were true or false, she relied on her meaning for the mathematical statement and formed a mathematically convincing argument.*

*Key words:* Negation, Argumentation, Complex Mathematical Statements, Calculus, Transition-to-Proof

Many studies have noted that students often interpret logical connectives (such as *and* and *or*) and quantifiers (such as *for all* and *there exists*) in mathematical statements in ways contrary to mathematical convention (Case, 2015; Dawkins & Cook, 2017; Dawkins & Roh, 2016; Dubinsky & Yiparki, 2000; Epp,1999, 2003; Selden & Selden, 1995; Shipman, 2013, Tall, 1990). Recently, researchers have also called for attention to the logical structures found within Calculus theorems and definitions (Case, 2015; Sellers, Roh, & David, 2017) because students must reason with these logical components in order to verify or refute mathematical claims. However, Calculus textbooks do not discuss the distinctions among different connectives nor do they have a focus on the meaning of quantifiers or logical structure in algebraic expressions, formulas, and equations, even though these components are used in definitions and problem sets (Bittinger, 1996; Larson, 1998; Stewart, 2003).

Undergraduate students frequently evaluate the validity of mathematical conjectures that are written as complex mathematical statements. By *complex mathematical statements*, I mean statements that have two or more quantifiers and/or logical connectives. Other work has investigated students' understanding of complex mathematical statements (Zandieh, Roh, & Knapp, 2014; Sellers, Roh, & David, 2017). However, these studies focus on students' understandings of statements as written, and do not address students' meanings for the negation of complex mathematical statements. Several studies have investigated student meanings for negation (Barnard, 1995; Dubinsky, 1988; Lin et al., 2003), but these studies do not explicitly address complex mathematical statements from Calculus. In order for students to properly justify why Calculus statements are true or false, and for students to develop logical proofs, they must understand a statement in both its written form and its opposite (Barnard, 1995; Epp 2003). For example, students at the Calculus level are asked to determine if sequences are convergent *or* divergent, if functions or sequences are bounded *or* unbounded. Thus, we also must explore student meanings for negation in the Calculus context—both the negation of an entire statement, and the negation of its logical components. In this paper, I will investigate one student's meanings for the negation of various types of mathematical statements as well as how these negation meanings affected her justifications for several Calculus statements. Thus, I seek to investigate the following research questions for this student:

1. *As mathematical statements become increasingly complex, will a student keep the same negation meanings? If some or all of her negation meanings change, which meanings change and how do they change?*
2. *How do the student's meanings for negation affect her evaluations of complex mathematical statements from Calculus and her justification for these truth-values?*

## Literature Review & Theoretical Perspective

Both colloquialisms for quantifiers and logical connectives as well as mathematical content may affect students' logic in mathematics courses. If I claim, "Every book on the shelf is French," the statement may be viewed as false if there are no books on the shelf. However, in mathematics, this statement would be vacuously true if there were no books on the shelf (Epp, 2003). If I claim "I'll get Chinese or Italian for dinner" one would assume that I was going to *either* get Chinese or Italian, but not both. We often use an *exclusive or* in our use of the English language, but in mathematics, we would consider that this statement would be true if both propositions were true (Dawkins & Cook, 2017; Epp, 2003). Students may also change their use of mathematical logic depending on the content of a mathematical statement (& Cook, 2017; Durand-Gurrier, 2003). Dawkins & Cook (2017) presented students with the statements "Given an integer number *x*, *x* is even or odd" and "The integer 15 is even or odd." Some students claimed that the first statement is true, but the second statement is false because they already knew that 15 is an odd integer.

Even if students correctly interpret a mathematical statement, their negation of parts or all of a mathematical statement may follow different conventions. If a statement contains more than one quantifier, students often negate only one of these quantifiers (Barnard, 1995; Dubinsky, 1988). Students may also leave disjunctions or conjunctions alone in a negation (Epp 2003; Macbeth et al., 2013). For example, some students negated statements of the form $P \wedge Q$ as $\sim P \wedge \sim Q$. In general, for all negations, Dubinsky (1988) claims that students often use *negation by rules*. The rules they use may or may not be correct rules of negation.

There may be other student meanings for negation that have yet to be discovered. My goal in this study is to describe my best perception of one student's own meanings for negations of complex mathematical statements at different moments. I use the phrase "student meaning" throughout this paper the same way in which Piaget views that each individual constructs his own meanings by assimilation and accommodation to schemes (Thompson, 2013). A *scheme* is a mental structure that "organize[s] actions, operations, images, or other schemes" (Thompson et al., 2014, p. 11). I cannot see a student's schemes, but can only do my best to create a model of students' negation schemes by attending to their words and actions throughout the clinical interview process. Schemes are tools for reasoning that have been built in the mind of the student over time. If a student repeats the same type of reasoning repeatedly, they begin to construct their *negation scheme* until the scheme is internally consistent. If students face inconsistencies, then they may adapt, or accommodate their schemes.

Some student meanings may be stable, but other meanings may be "meaning(s) in the moment" (Thompson et al., 2014). Thompson et al. (ibid) describe a meaning in the moment as "the space of implications existing at the moment of understanding" (p. 13), so students could be assimilating information in the moment by making accommodations to their current schemes. A student's thoughts may begin to emerge or different meanings may be elicited in different moments. Thus, I consider several different moments of interaction for each student because different moments of interaction may result in different types of student negation.

## Methods

This study is part of a larger study that will seek to answer these research questions with undergraduate students from various mathematical levels. For this particular study, I conducted clinical interviews (Clement, 2000) with one student, Dawn, who is currently enrolled in a Transition-to-Proof (T2P) course. Dawn completed two clinical interviews that were each two hours long. Both interviews were video-recorded. One camera was used to zoom in on her work, while the second camera was zoomed out to capture her gestures. Different levels of tasks were chosen to determine if Dawn's negations stayed the same or changed across different levels of complexity. Clinical interview questions were used that would help me to determine why Dawn's negations stayed the same or changed across different tasks.

**Interview tasks.** I first presented Dawn with thirteen statements with one quantifier or logical connective to address my first research question. Two of these statements are shown in Figure 1 (left).

| **Statements with One Logical Component** | **Statement with Two Logical Components** |
|---|---|
| 1. Every integer is a real number.<br>2. 12 is even and 12 is prime. | There exists a real number $b$ such that $b$ is odd and negative. |

*Figure 1*. Selected items with either one logical component or two logical components.

Dawn was asked to evaluate (i.e. provide a truth-value) and negate each statement, as well as evaluate her negations. After she completed these tasks, I presented her with a list of "other students' negations." I created these hypothetical negations based on variations of changing different parts of each statement. These hypothetical negations allowed me to test a wider range of possible negations that Dawn might accept as valid negations.

I also conducted a follow-up interview with Dawn to compare her negations of one logical component with her negations of complex mathematical statements in an attempt to begin to answer the second research question. I first presented Dawn with two statements, like the one shown in Figure 1 (right), which involves two logical components (an existential quantifier and either a conjunction or disjunction). I asked Dawn to evaluate and negate these statements in the same manner as she did in the first interview.

I later compared Dawn's negation of the more complex statements with her negations for the statements with one logical component to try to answer my first research question. I presented Dawn with three complex mathematical statements from Calculus, one of which is shown in Figure 2, in order to address my second research question.

There exists a $c$ in [-1, 8.5], such that for all $x$ in [-1, 8.5], $f(c) \geq f(x)$ and there exists a $d$ in [-1, 8.5], such that for all $z$ in [-1, 8.5], $f(d) \leq f(z)$.

*Figure 2.* Complex statement from Calculus.

I asked Dawn to evaluate if the statement in Figure 2 was true or false for seven different graphs. The statement given in Figure 2 is based on the conclusion of the Extreme Value Theorem (EVT) and the intervals shown in the graphs. Some of these graphs had only one of either an absolute maximum or absolute minimum, some graphs had neither an absolute maximum nor an absolute minimum, and some graphs had both an absolute maximum and an absolute minimum.

These graphs were selected in hopes that Dawn's data would include some moments where I could explore Dawn's negations in the context of her justifications for statements that were false (in her opinion). The Extreme Value Theorem (EVT) only holds for continuous functions. Since I omitted the hypothesis of the EVT, there are cases where this statement I present is false. I was then able to compare the negations that were part of her justifications with her previous negations with other statements.

**Data analysis.** My analysis was conducted in the spirit of grounded theory (Strauss & Corbin, 1998) using videos of the student interviews as well as the students' written work. Hence, the consistencies and inconsistencies in Dawn's negation meanings emerged from the data. I identified moments where distinctions could be made about Dawn's negation meanings. ew moment began when Dawn was presented with a new question or task, she changed her evaluation or interpretation of a given statement, or if she changed her argument or negation of a statement in any way. After identifying these moments of interest, I compared Dawn's one-component negations with the two-component negations. Finally, I compared her negations in the context of her justification for the Calculus statement with all previous negations.

## Results

A consistent pattern emerged from Dawn's negations when I directly asked her to provide negations. However, when I presented graphs and asked Dawn to evaluate the validity of the mathematical statements for each graph, Dawn's negations in her argumentation did not always match her previous patterns of negation. A difference in interview questions appeared to influence Dawn's patterns for the negation of logical connectives and quantifiers.

### Consistencies Across Negations

Dawn stated that in order to determine a valid negation, she could negate one part of the original statement, but not both parts of the original statement. I asked Dawn to explain why she believed she should only change one side of a statement for its negation. She stated, "In general, it's just some kind of rule that I follow, like you only negate one side." She also stated that negations for the same statement could have a variety of different truth-values (i.e. for the same statement, one negation that she deemed valid could be true while another negation that she deemed valid could be false). Since Dawn relied on a negation by rule and accepted negations with various truth-values, the evidence suggests that her overall meaning for the word "negation" was related to a constructed procedure rather than a statement that could prove or disprove the original statement.

I first noticed Dawn's use of this procedure for statements of the form $\exists x, P(x)$. For statements with an existential quantifier of the form "There exists an $x$ such that $P(x)$," she referred to "There exists $x$" as one part and "such that $P(x)$" as another part of the statement, and claimed that she "could only negate one part of the statement." Dawn would not accept negations of the form $\forall x, \sim P(x)$. She said that changing the "there exists" to "for all" would be "changing too much." Dawn usually preferred to start with the negation of the form "There does not exist an $x$ such that $P(x)$," which is a valid negation. However, she also stated that statements of the form "There exists an $x$ such that *not* $P(x)$" were valid negations. For example, for the statement, "There exists a whole number that is negative," Dawn wrote both "There does not exist a whole number that is negative" and "There exists a whole number that is not negative" as negations.

Dawn's algorithm for negating one part of a statement was also consistent with her negation of statements with a conjunction or disjunction because she still claimed that she could negate one part of a statement, but not both parts of the statement. For the statement, "12 is even and 12 is prime," Dawn wrote the negations, "12 is odd and 12 is prime" and "12 is even and 12 is not prime." For both of these negations, Dawn retained the logical connective and changed one part of the original statement in each negation. (Dawn usually kept the disjunction or conjunction from the original statement in her negations, but she sometimes accepted hypothetical negations that altered the logical connective if she felt as though a negation had the same meaning as the original statement.)

**A combination of negation meanings.** The statement "There exists a real number *b* such that *b* is odd and negative," has two logical components. Dawn interpreted the negation of both the quantifier and the conjunction in this statement in a similar manner as her earlier negations, as seen in her two negations: "There does not exist a real number *b* such that *b* is odd and negative" and "There exists a real number *b* such that *b* is even and negative." These negations are similar to the negations she preferred for "there exists" statements in the first interview, as they are also of the form "There does not exist an $x$ such that $P(x)$," and "There exists an $x$ such that *not* $P(x)$" (even though her negation of $P(x)$ is incorrect). Yet again, she did not consider the use of a universal quantifier in her negations and only changed one part of the statement. Dawn also negated the proposition within the statement that contained a conjunction in the same manner that she did with the first set of statements. The phrase "*b* is odd and negative" has its own parts that Dawn also considered. She negated "*b* is odd and negative" as "*b* is even and negative." She verbalized that she could have also used "b is odd and positive" for this part of her second negation. I asked her to consider explaining to a friend why her negation for the first complex statement was valid, to which she replied, "I would tell them that [my negation is correct] because I changed the second half of the statement." This reply indicates that Dawn is assessing the validity of her negation on her rule for negating one part of the statement, rather than comparing the *meaning* of the negation with the original statement.

**Negation in Argumentation: When Negation Isn't Viewed as Negation**

In the previous examples, I detailed Dawn's treatment of negation when I asked her to provide a negation. In the last set of tasks, I did not ask her to negate, but rather asked her only to determine if the statements were true or false on a case-by-case basis and to justify her claims. For the statement shown in Figure 2, Dawn interpreted the original statement as intended. Dawn explained why the statement shown below is true for the given graph:

| Statement & Graph Presented | Transcript |
|---|---|
| There exists a $c$ in [-1, 8.5], such that for all $x$ in [-1, 8.5], $f(c) \geq f(x)$ and there exists a $d$ in [-1, 8.5], such that for all $z$ in [-1, 8.5], $f(d) \leq f(z)$ .<br> | D: There is a maximum $y$-value at 3 [x=3] and a minimum $y$-value here (points to (8.5, $f$(8.5)) . So no matter what $x$ is, this [$f$(8.5)] is going to be the least $y$-value.<br>I: So what part of the statement tells you [that] you need to focus on the least $y$-value and the largest $y$-value?<br>D: Because we want to pick values for $c$ and $d$ strategically so that they are going to be the maximum and minimum $y$-value.<br>I: What part tells us we're going to pick the max and min?<br>D: Here, for all $x$, you want it to, no matter what the value of $x$, the value of $f(x)$ is going to change. And you want this statement here, this inequality, to hold true, and there's only one instance where that can be true—at the max or min. |

Dawn appeared to have a conventional interpretation for this statement. She expressed that she needed to choose *the* maximum or minimum that works *for all x*. Dawn's meaning for this statement and its negation was also revealed in her explanation of when the statement is not true. In the following example, Dawn claimed that the same statement is false for this case.

| **Statement & Graph Presented** | **Transcript** |
|---|---|
| There exists a *c* in [-1, 8.5], such that for all *x* in [-1, 8.5], $f(c) \geq f(x)$ and there exists a *d* in [-1, 8.5], such that for all *z* in [-1, 8.5], $f(d) \leq f(z)$ .<br> | D: The minimum *y*-value is $^{-}\infty$ , so you couldn't pick a value for… *d*, that would always make this inequality true (points to $f(d) \leq f(z)$ ).<br>I: Let's say your friend said, "For all the values that I look at, for all the *y*-values that I look at, if I chose *any* value for *d*, then I can always find a smaller value..." Would you agree with your friend's argument?<br>D: Yeah, I would agree with his argument.<br>I: Would you say that his argument is the same as your argument?<br>D: Yeah, because I said there isn't a value for *d*, where there's the smallest *y*-value. I think that's kind of the same thing. It isn't the smallest because you could always find one smaller. |

Dawn said that she *could not pick* a value for *d* such that this value of *d* would *always* satisfy the inequality. This response is similar to the negation "there *does not exist a d* such that $f(d) \leq f(z)$ ." Dawn's response was consistent with her prior approach to negate one part of a statement in her negation. Also recall that Dawn stated in the first interview that changing the second part of a statement and adding a universal quantifier would "change too much." Thus, I responded by asking Dawn to consider an alternative negation that used a universal quantifier and changed more than one part of the statement.

In the context of this statement where Dawn was asked about her argument rather than for a negation specifically, she accepted a negation that involved changing more than one part of a statement and she did not mention having an issue with the universal quantifier changing too much of the statement. Her original denial aligns with the argument, "there *does not exist* an *x* with a corresponding minimum *y*-value," but she also recognized that my proposed argument, "for *any x*-value, a smaller *y*-value than *f*(*x*) can be found," was equivalent to her original denial. Thus, she accepted the argument that aligned with the negation "for *any* value of *d,* there exists a *z* such that $f(z) \leq f(d)$ " by stating that this argument was "kind of the same thing" as her argument. She even explained why the logic for the two negations is equivalent: the *y*-value "isn't the smallest because you could always find [a *y*-value] smaller." Even though she had previously rejected alternate negations in the first interview that involved a universal quantifier, in the context of justification for this Calculus statement, she recognized that an alternate negation with a universal quantifier was valid.

In instances when my question or request omitting the word "negation," Dawn considered the *meaning* of the statement rather than her memorized rule to negate one part of the statement. Her interpretation of a statement and her negation for that statement varied based on the context of each mathematical statement. These moments in the second interview were characterized by the question, "Is this statement true or false for this graph?" rather than the command "Negate this statement." The word "negation" appeared to alert Dawn to negate only one part of the statement. However, when asked to think about the validity of a statement in a particular context, Dawn's approach was to use her reasoning to apply logical argument.

## Conclusion & Discussion

When responding to negation tasks in the first interview, Dawn negated one part of a given statement, but not both parts of a given statement. This finding is similar to Dubinsky's (1988) finding that students tend to use rules (which may or may not be correct) to negate a statement. Dawn's meaning for the command to "negate" was to change any one part of the given statement, no matter what type of statement that was given. Her procedural approach for negating a statement could help explain why students only negate one of two quantifiers when statements contain multiple quantifiers (Barnard, 1995; Dubinsky, 1988) and why they often retain disjunctions and conjunctions in their negations (Epp, 2003; Macbeth et al., 2013). In Dawn's words, changing two quantifiers or changing a logical connective might be "changing too much" in the student's view. Dawn's negations are also consistent with other literature that has claimed that students' logic can change across different tasks (Dawkins & Cook, 2017; Durand-Gurrier, 2003). Evidence from this study indicates that we may have undergraduate students in our classes who only *negate by rules in certain mathematical contexts*. The negation scheme evoked with tasks that used the word "negation" did not appear to be elicited with tasks that did not use the word "negation."

For many students, the word "negation" may be associated with a *procedure* rather than using logical arguments based upon their own *reasoning*. Dawn applied the same negation meaning even as statements became increasingly complex as long as I asked her to negate. However, the command to determine if a statement was true or false actually led her to negate according to mathematical convention. Students who apply a memorized rule to negate a mathematical statement may have the ability to negate appropriately if the word "negation" does not hinder their argumentation. Students may benefit from tasks that use the command, "Explain why the following statement is true or false" and from negating quantifiers and logical connectives in different mathematical contexts. Then, the students may be asked questions that may help them construct their own rules for negation that are consistent with their argumentation. The word "negation" may be more appropriate to use *after* students have already used negation and constructed their own rules for negation based on their own reasoning about multiple mathematical statements.

*In covariational reasoning, when a student conceives of a situation as composed of measurable attributes that vary in tandem, discussing the relationship between quantities represented in a formula requires an interplay between a students' image of the situation and their conception of a formula. In this study, I categorize four pre-service teachers' images of both the situation and the formula as they describe the relationship between a given triangle's height and area. The results indicate how students' images of the situation and conceptions of a formula influence reasoning about the relationship between two quantities, specifically the role of numerical values and the development of a sophisticated dynamic image of the situation from which the student is able to draw conclusions.*

*Keywords:* Covariational Reasoning, Cognition, Geometry, Pre-Service Secondary Teachers

## Introduction

Researchers have identified the importance of covariational reasoning – conceiving of a situation as composed of measurable attributes that vary in tandem – in numerous K-12 topics including ideas surrounding rates of change (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Confrey & Smith, 1995; Ellis, 2007; Johnson, 2015; Moore, 2014; Thompson, 1994). In undergraduate mathematics courses, students often invoke ideas of rate of change when reasoning about formulas (e.g., using formulas for basic shapes to find the area under a curve, deriving formulas for areas and volumes using derivatives and antiderivatives). However, following the Common Core Standards Initiative (2010), students' middle and high school experiences with formulas mostly involve informal proofs using manipulations of static objects (e.g., using Cavalieri's Principle); these types of experiences do not give students the opportunity to explore how covariational reasoning can be invoked when reasoning about geometric objects. In other words, this treatment of formulas does not consider the variables involved in the formula as *varying* as described by Thompson and Carlson (2017). With these ideas in mind, I explore how four pre-service secondary teachers (heretofore referred to as students) who have successfully completed an undergraduate calculus sequence reason about the area of a geometric shape, a triangle, and its height. Thus, the research question for this report is the following: (How) do students explore the covariational relationship of the height and area of a well-known shape, an isosceles triangle, using a formula?

## Background and Theoretical Perspective

In this study, I attend to students' images of a situation and students' conceptions of formulas when describing the relationships between quantities—measurable attributes of objects (Thompson, 1994). Throughout the study, I assumed the idiosyncrasy of individual's conceptions of quantities and images of a situation because I approach quantities as actively constructed by an individual (Steffe, 1991; von Glasersfeld, 1995). Moreover, I assumed when an individual constructed a relationship between quantities, the individual relied on their understanding of the quantity and their image of the relevant situation, which may have evolved over the course of the interview. Because of these two assumptions, I did not assume that students conceive the situations I provided to them in the same way I did; that is, they conceptualized the task using different quantitative structures. I noticed some of these differences, for example, when one student discussed changing the height of the triangle by drawing new triangles beside one another while other students described a smooth image of one triangle whose height was varying.

Moore & Carlson (2012) and Thompson & Carlson (2017) indicated how students' images of a situation impacted their reasoning, and other researchers have observed students reasoning quantitatively about real-world situations leading to their successful construction of equations (e.g., Ellis, 2007; Izsák, 2000; Moore & Carlson, 2012). Ellis (2007) differentiated this type of interplay between a student's image of a situation and their understanding of an equation in terms of covariational reasoning based on a student's attention to quantities. She, and other researchers who have prompted students to construct formulas via covariational reasoning using *area* situations, (Matthews & Ellis, In Press; Panorkou, 2016; Stevens et al., 2015) relied on the covariational reasoning defined by Carlson et al. (2002). In this view of covariation, giving the students a situation with which to operate is crucial. One popular context is that of a growing rectangle, which Thompson (1999) proposed and researchers have implemented with elementary and middle school students (Matthews & Ellis, In Press; Panorkou, 2016).

Alternatively, in the covariational reasoning described by Confrey and Smith (1994), students identify patterns in tables and use those numerical patterns to construct an equation. In this case, students are likely reasoning about values abstracted from operations of measurement rather than quantity's measurements (Thompson & Carlson, 2017). I use these two ways of covariational reasoning to differentiate students' reasoning with formula values versus those students who reason using their image of the situation.

I also situate my discussion around the results of two studies from researchers who have used growing area contexts. Matthews and Ellis (In Press) used a growing triangle context in their work. In their situation, the triangle's base remained on the left side of a square and the third vertex of the triangle began at the bottom left corner and traveled counterclockwise around the square. Although the two middle schoolers in their teaching experiment eventually successfully produced a normative graph of the distance the moving vertex traveled and the area of the triangle, never explicitly referencing a formula, the authors offer a caveat that the students may have reached their conclusion of a constant rate of change based on perceptual features, such as the constant speed of the traveling vertex. The authors also mentioned the difficulty of measuring area in their context. I extend this study by offering a point of comparison by working with students who have had vast experience with symbolization, area, and rates of change.

Stevens et al. (2015) also used an area context in a study with pre-service teachers; the pre-service teachers watch a dynamic image of a growing cone whose slant stayed at a constant angle and whose height grew and then shrank at a constant speed. The pre-service teachers described the relationship between the surface area and height of the cone. Half of the ten students in the study attempted to create and use a formula to determine the relationship between the quantities, and only two students constructed a graph using images of covariation rooted in the situation. None of these students produced a normative formula for the surface area of a cone. These results highlight the difficulty students seem to have relating a covariational relationship between two quantities they have constructed using their image of a situation with a formula that represents that relationship. It is important to note that in this task, both the 3-D nature of the cone and the formula for the surface area of the cone may have contributed to the students' difficulties with the task. This study extends this work by examining the relationship between the two when the student is given a simpler 2-D image and can produce a correct formula.

## Methods

In an effort to focus this study on exploring ideas of how students connect ideas of rates of change and geometric objects, I chose a population of students who have had vast experiences with both. The four participants of the study were either in their first or second semester of secondary mathematics teacher program at a large public university in the southeastern U.S. Each student had completed a Calculus sequence and at least two other upper level mathematics courses (e.g., linear algebra, differential equations) with at least a C in the course. The students had all been enrolled in a spring semester content course exploring secondary mathematics topics through a quantitative and covariational reasoning lens using the *Pathways Curriculum* (Carlson, O'Bryan, Oehrtman, Moore, & Tallman, 2015). I interviewed all four students who expressed interest in the study after contacting the entire class about the study. This particular study focuses on the second task of a semi-structured clinical interview style (Clement, 2000) pre-interview in a series of 3-5 interviews; the interview was exploratory in nature. These pre-interviews lasted about two hours each, and for two of the interviews, there was an observer present. I encouraged the students to think aloud (Goldin, 2000) and attempted to ask only questions that would enable me to construct viable models of the *students' mathematics* (Steffe & Thompson, 2000).

Each interview was videotaped and these videos were digitized for analysis. Using an open (generative) and axial (convergent) approach (Strauss & Corbin, 1998), I offer distinguishing features of students' approaches to the *Growing Triangle* task based on my models of their images of the situation, their conception of their formula, and the role of the two in their description of a relationship between quantities. Students interpreted the relationship between the quantities differently; three of the four wanted to draw a conclusion about the directional change between quantities, and only one of the four attempted to consider amounts of change in one quantity with respect to the other. The results highlight further distinctions.

## Task Design- *Growing Triangle*

In *Growing Triangle*, the student views a sketch on *Geometer's Sketchpad* of a static isosceles triangle. Students can drag a vertex of the triangle to increase or decrease its height and base while maintaining an isosceles triangular shape (i.e., $\overline{AB}$ stays constant but point $C$ can be dragged along the perpendicular bisector of $\overline{AB}$) (Figure 1). Only Charlotte dragged $C$. I asked each student to "describe the relationship between the *height of the triangle* and the *area of the triangle*." All students considered the height to be the perpendicular distance from point $C$ to $\overline{AB}$.

I purposefully designed the task to be a static image to see if asking about the relationship between two quantities would invoke a sense of change independent of watching a dynamic image. Also, not providing a dynamic image enabled me to avoid students concluding a constant rate of change based on a perceptual feature of the constant movement of a dynamic vertex. I also chose not to identify a specific height on the triangle for two reasons. First, I did not want to restrict their thinking if a student were to imagine rotating the figure at any point and wanted to consider a different height (Charlotte did, but quickly abandoned the idea). Second, by not identifying two particular quantities in the situation, I gained insight into what about the given situation they thought would stay constant and what would change in order to make a conclusion about the two given quantities. For instance, two students (Kimberley and Charlotte) considered different bases and categorizations of triangles (e.g., changing base with constant height, equilateral triangle shape maintained). For those students, I let them make a conclusion before directing them to consider specifically the case when $\overline{AB}$ stays constant and point $C$ changes.

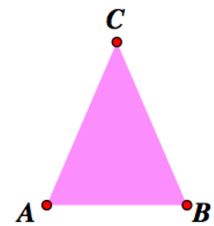

*Figure 1. Original position of triangle ABC.*

## Results

I describe how each student's image of the situation and use of the formula played a role in how they described the relationship between the height and area of the triangle.

### The Case of Jordan

Jordan was quick to discuss both a formula for the area of a triangle and to relate her conclusion to her image of the situation. When given the prompt, she said, "My first thought is the formula for the area of a triangle is one-half the base times the height, so if everything else is staying constant, except for height, which is increasing, then I would think the area would increase." Although her language may have seemed to indicate that she was reasoning about the formula, she says that she is imagining "*C* just like being pushed up," indicating that she was imagining the triangle varying as she was reasoning. Jordan's follow-up statement is further evidence she was reasoning by imagining at least one other image of a triangle:

> *Jordan*: So I'm thinking if it goes the other way. So, if you take C and you drop it [*motions finger downwards*], then it would decrease. Then there's just not as, like the base is staying the same, so [*makes pinching motion with fingers*]… if you have a squat triangle [*reaches to sketch and makes pinching motion smaller than the given height of the triangle*], like if I took *C* and dropped it, you can draw inside of this one [*motions where the two legs of the shorter triangle would be given the height of the squat triangle*] and see that it's taking up less space as this one [*makes circling motion around original triangle*].

After making this statement, Jordan justified her conclusion about her gross comparisons of the areas of the triangles by noticing that as *C* "goes up", the angles from the base and the legs increase, and said that the smaller triangle would fit inside the bigger triangles. After making this statement, she drew Figure 2 to illustrate her thinking. From this drawing, she concluded, "As *h* increases, *A* increases, and as *h* decreases, *A* decreases (see Figure 2)," once again supporting the idea that she imagined a dynamic image of a triangle. Moreover, her dynamic image of the triangle had quantitative entailments and invariant properties upon which she could operate in order to make a conclusion about the relationship between the two given quantities.

When asked if she could make any other conclusions about the relationship between the quantities, she stated, "I don't know by how much the area is changing when the height is changing." She added that she was not sure whether "it [would] be a constant change…I just can't picture like the height changing consistently, how that would change the area." This statement indicates that although her image of the situation had quantitative entailments and invariant properties sophisticated enough to imagine directional change of the area of the triangle with respect to height, it did not entail images of amounts of change in the quantities' magnitudes she could quantitatively compare to one another. I also note that Jordan did not return to her formula to attempt to make conclusions about how much the area is changing. In conclusion, Jordan relied only on her image of a dynamic situation to make conclusions about the relationship between quantities; she expressed knowledge of a formula for the area of a triangle, but she did not assimilate reasoning with the formula as a way to make conclusions about the rate of change between the height and area of the triangle.

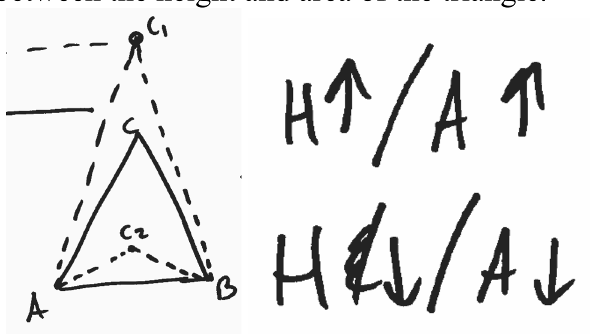

*Figure 2. Jordan's illustration of the triangles resulting after moving point C up and down and her conclusions about the relationship between the height and area of the triangle.*

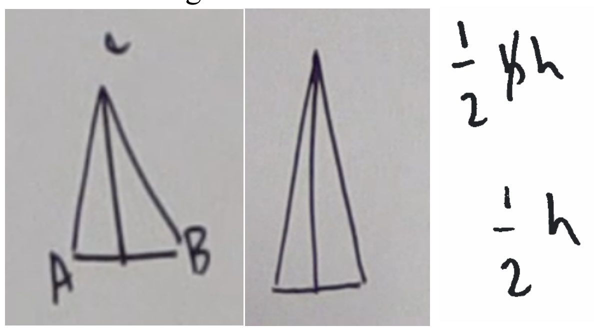
**The Case of Kimberley**

Kimberley drew and considered a different instance of the triangle's growth when asked to consider the case when $\overline{AB}$ stays the same and *C* changes, but she was unsure how to make gross comparisons of the areas of the resulting triangles she drew. She drew a triangle (Figure 3b), noted that, in this case, the height has increased and said, "I'm not sure that the area has increased" when comparing it to the image on the screen (Figure 1a) "'cause we're getting [*makes narrowing motion with hands by bringing palms of hands closer to one another*], well [*pause*]". This statement indicated she was attempting to make a gross comparison of the area of the original triangle and the triangle with an increased height, but her image of the two triangles' areas, like Jordan's, did not afford her a way to make a conclusive comparison.

After this statement, she paused before saying, "Then the area of a triangle is one half base times the height [*writing* "½*bh" on her paper*]. So we keep-kept that part the same *[highlighting* $\overline{AB}$ *in her drawing of the original triangle* (Figure 3a)], that part [*highlighting bottom of triangle in Figure 3b*], but then the height increased [*motioning upwards from base of triangle*]." After making these comparisons between the bases and heights of the two triangles, she immediately concluded, "So then the area did increase." She justified her conclusion by saying, "So we know base is the same [*crosses out "b" in* "½*bh"* (Figure 3c)], so we can just look at what my height [*writes* "½*h"* (Figure 3c)], one half the height is, so if we know that the height is this here [*traces along height in original triangle* (Figure 3a)], but we know it got bigger here [*traces along height in Figure 3b triangle*], then that would have to be bigger [*pointing to* ½*h*] in this scenario." When asked to clarify how that discussion related to area, she said, "The area would be bigger because the height would be bigger." This discussion indicated a shift in how Kimberley was analyzing the situation. When her image of the situation did not afford her to make a conclusion about the relationship between the given quantities, she recalled and relied on a known formula for a triangle's area. Specifically, she compared her two cases and noticed that only *h* would have a different value in her formula. She did not use specific values, but rather unknown values such that one was greater than the other. By also noting the letter *b* in her formula was inconsequential to the resulting values for comparison because the base of the triangle stayed constant, she realized that by making a gross comparison of the values of ½*h*, she could also make gross comparisons of the area. Thus, she concluded that an increased height implied an increased area. In summary, Kimberley's conclusions about the areas of the two triangles resulted from a comparison of unknown values in a formula after a comparison of her image of the areas of the triangles was insufficient for her to make a definitive conclusion. She connected her conclusions back to the situation, but unlike Jordan, Kimberley's justifications relied on her conclusions from reasoning with the formula.



*(a)* *(b)* *(c)*

*Figure 3. (a) Kimberley's representation of the original triangle given in the sketch with height labeled, (b) drawing in the case when C is "higher" than the initial point, and (c) reasoning with the formula for a triangle's area.*

**The Case of Charlotte**

Unlike Kimberley, Charlotte immediately considered using a formula for the area of a triangle; when Charlotte is first presented with the task, she asked if it can be "something I've already been taught about triangles and areas and heights." Also unlike Kimberley, Charlotte was unsure about her recollected formula, stating that area equals "base times height" but that the formula may only be true for right triangles. Being unsure of her formula, she turned to reasoning with the static image of the triangle because, as she later reflected, "I tried to throw it [her formula] away, because I thought it only applied to right triangles for a moment" and that she did not know a formula for the triangle in front of her. She claimed that an increase in height implied an increase in area, noting that she was "picturing [her]self dragging this *C*". Thus, like Jordan, Charlotte had a mental image of a dynamic triangle in mind to try to make a conclusion about the relationship between the given quantities. However, her dynamic image was not as sophisticated as Jordan's image because Charlotte was unable to justify her claim as Jordan did. For instance, Charlotte dragged point *C* up in the sketch to illustrate to me how she was thinking of the situation, and remarked that "it made a bigger pink space" but later returned to the situation to drag *C* again and said, "If I increase and decrease that [height], wait, am I changing the area? Yea, definitely. At some points, it's easier to tell than others, but I feel like I'm changing the area." Like Kimberley, Charlotte had difficulty comparing areas with different heights, relying on what she *felt* was happening, rather than being able to draw conclusions using her image of the situation. Charlotte gave some insight into her image of the situation when we returned to this task later on in the interview when I asked her to draw how she was imagining "moving C up." She drew in Figure 4a and says, "I don't know. I can't draw that. Can I see it [the animation] again?". Upon doing so, she drew Figure 4b. From those drawings, we see an idea of narrowing sides (perhaps similar Kimberley's image) (Figure 4a) and a notion of stacking (Figure 4b), neither of which support an image of an isosceles triangle with increasing height that would enable her to identify amounts of change in area for equal changes in height.

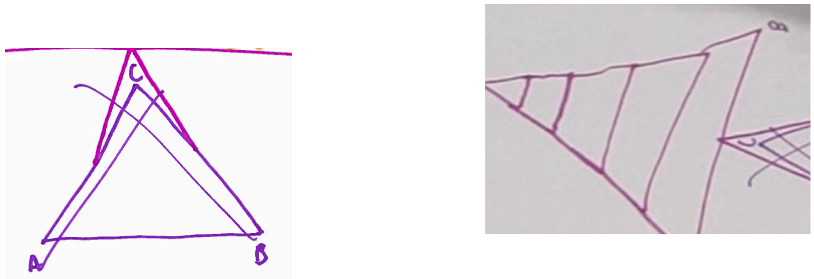


*Figure 4. Charlotte's first (left) and second (right) attempt to draw her image of the dynamic triangle.*

**The Case of Alexandria**

Like Charlotte and Jordan, Alexandria immediately referenced a formula and writes " ½*bh*=*A*". She represented the triangle on the sketch in a way similar to Kimberley's triangle (*Figure 3a*), pointing out the base ($\overline{AB}$), the height (*vertical line*), and the area (*region inside triangle*). However, unlike the other students, she did not consider changing the size or shape of the triangle. To her, the formula itself *was* the relationship between the triangle's height and area. Each variable in the formula represented an unknown value she could identify in the situation. Thus, she had no intellectual need to consider different values for height or area to plug into her formula to make a conclusion about covariational relationships. Her image of the situation remained static through the discussion.

## Discussion

From these results, I argue that a student who assimilates a formula to a given situation will not necessarily assimilate a task asking to describe the directional covariational relationship between quantities by using numerical values. None of the students in this study did. Moreover, if a student attempts to reason about the relationship between two quantities by focusing on the situation instead, their image of the situation plays a crucial role in their ability to justify their conclusions about the relationships between quantities. For instance, only Jordan's image of the situation had quantitative entailments and invariant properties that enabled her to justify the directional relationship between the quantities by seeing that one instance of a triangle fit completely inside another. Conversely, Kimberley and Charlotte were only able to provide intuitions about changes in area based on their image of the situation. Kimberley was able to justify her claim by reasoning with her formula. She did not use specific values and so we cannot say she reasoned numerically as described by Confrey and Smith (1994), but she did illustrate a separation from reasoning about quantities' measurements in the situation in order to make gross comparisons between two hypothetical unknown values that had a specific relationship to one another. Afterwards, she reconnected her conclusion to the situation. Lastly, only Jordan made an attempt to reason using amounts of change, but her image of the situation was insufficient for her to make a definitive conclusion. These results call for a way to support and scaffold students' images of change quantitatively that they might be able to make conclusions about rates of change using amounts of change.

The Emergence of a Prototype of a Contextualized Algorithm in a Graph Theory Task

John Griffith Moala

Igor' Kontorovich
The University of Auckland

*Research has described the necessity and dangers of prototypes in mathematical learning, without offering explanations for what makes prototypes appropriate or inappropriate, or indeed how prototypes emerge in the first place. We explore one part of the emergence of a prototype: how a feature of a concept's example becomes predominant in subsequent generated examples. We describe how three students developed what they regarded as four examples and one non-example of an algorithm suitable for a client with a contextualized graph theory problem. The students engaged in a 'patching process' that preserved an inappropriate feature of the initial example in the other examples that were generated. We argue that the development of appropriate prototypes may depend on the types of processes (like the 'patching process') that students use to abstract and preserve features of the concept examples.*

*Keywords:* Concept, Prototype, Algorithm, Graph Theory.

## Introduction

Prototypes—those examples of a concept that are said to be *popular* or *typical*— play a significant role in mathematics learning (Hershkowitz, 1989; Tall & Bakar, 1992). On the one hand, prototypes make formal and abstract concepts more accessible (Tall & Bakar, 1992). On the other hand, prototypes can become obstacles when their properties that are unnecessary from the perspective of the formal concept, are perceived as something that any concept example must have (Hershkowitz, 1989). For instance, studies show that students are more likely to classify objects as examples of a concept when they "seem closer" (e.g., visually) to the prototype(s) (e.g., Presmeg, 1992). Accordingly, Tall and Bakar (1992) suggest that educators should help students to develop prototypes that are "as appropriate as possible" (p. 13), thereby implying that some prototypes are more appropriate than others. We propose that the appropriateness of a prototype is not its innate quality, but something that depends on the situation in which it emerges and is used. The study reported in this short paper comes to contribute to classic research that identifies prototypes that students have already developed (e.g., Hershkowitz, 1989; Rosch, 1979; Tall & Bakar, 1992), by exploring how prototypes emerge in the first place.

## Theoretical Underpinnings

### How have prototypes been conceptualized in the literature?

Rosch (1973) introduced the term *prototypes* to refer to examples of a category that were more 'central' or 'popular' (among a group of people) than others. The notions of centrality and popularity arose from the observation that humans perceive examples of a category as not having equal status—an example's 'closeness' to the prototype(s) influences its status (Rosch & Mervis, 1975). Hershkowitz (1989), conducting research in learning geometry, made a similar claim to Rosch's: "All the concept examples are mathematically equivalent [...] they satisfy the concept definition, but they are different from one another visually and psychologically. There are super examples which tend to be much more popular than all others" (p. 63). Tall and Bakar (1992) also observed that students, when asked if an object is a function, tended to answer "yes" if the object resonated with their prototypes, and “no” otherwise. We observe three different usages of the term *prototype* in this classic research of Rosch (1973), Hershkowitz (1989) and Tall and Bakar (1992). First, a prototype may refer to a concrete example of a concept, for example, a robin seen flying outside is a prototype of a bird. Second, the “category of a robin”, that is, a set containing the defining features of a robin, is a prototype of a bird. Third, a prototype of a bird is a set of features that are predominant among all birds.

We use the third sense of the term prototype in our research by looking at how features of one example of a concept come to appear in other examples students generate. Specifically, the definition of *prototype* that we follow in this paper is: an abstract representation (as opposed to a concrete example) that possesses the most predominant features of examples of a concept (note our definition aligns with the way it is used in Dean, 2003; Rosch & Mervis, 1975). By this definition, the emergence of a prototype is equivalent to the emergence of predominant features among examples of a concept.

Consequently, our research question is: what processes are involved when a particular feature of an example appears in other examples of a target concept? We explore this question by analyzing the work of three students who worked together on a contextualized graph theory task, in which they were asked to develop an algorithm to satisfy a client’s needs. After establishing their first example of the target concept, the group used a ‘patching process’ to generate their other examples. This particular patching process preserved a feature of the initial example in all the other examples that the group generated. We propose that this patching process is one instance of the processes that students might be engaged in when they abstract and preserve the features of the concept examples that become predominant.

**What do we know about how prototypes emerge?**

Research provides several explanations to how prototypes emerge. One explanation offered in mathematics education literature points to the role of our visual-perceptual limitations (Hershkowitz, 1989). That is, features that we “see” frequently among the examples of a concept are the ones that emerge to form our prototypes (but these frequently seen features are not necessarily equivalent to the defining features of the concept). This aligns with a common explanation in the cognitive psychology literature whereby prototypes arise out of frequent use (Taylor, 2003): if an example is repeatedly activated with the concept, then the example becomes a prototype. But Rosch (1999) argued that the frequency explanation falls short in some cases (e.g., even though children see blue and black skies equally, they almost always draw a blue sky when asked to associate the sky with a color). Another explanation suggests that an example becomes a prototype if it bears properties that are most common among other popular examples. In this case, prototype status is granted to the example by already existing prototypes (Taylor, 2003).

**In what sense is an ‘algorithm’ a ‘mathematical concept’?**

We are aware that our use of the terms *concept* and *prototype*, and indeed our characterization of an algorithm as a concept may seem unconventional (not prototypical), so we offer a conceptual argument to justify this usage. Vinner (2014) refers to a *concept* as a generalization of instances that share certain things in common. Thomas (2014) defines an *algorithm* as “a step-by-step set of instructions in logical order that enables a specific task to be accomplished.” Under these two definitions, an algorithm can be viewed as a concept because it is a generalization of structured instances that enable solving a particular task. Furthermore, in our study, we do not look at students’ notions of an algorithm as an abstract entity. Instead, we are interested in the contextualized algorithms that students develop, algorithms that are proposed for a particular client with specific needs that can be derived from a contextualized narrative provided by the task.

## Method

### Participants, Research Setting, and Data Collection

The participants in this study were three students—Chad, Gil and Lome (pseudonyms)—who were enrolled in a pre-degree mathematics course in a large New Zealand university, and knew each other well as friends. None of the students had studied graph theory before, and they were studying high school level algebra when they participated in our research. Chad, Gil and Lome were recruited as part of a larger research project (Yoon, Chin, Griffith Moala, Choy, 2017) that involves over fifty undergraduate, secondary, and post-secondary/pre-degree students, and which explores student-mathematizing in tasks that present discrete mathematics concepts in contextualized narratives. Chad, Gil and Lome worked together on four discrete mathematics tasks in four one-hour sessions over the course of three weeks. These four sessions took place outside of class time and course requirements, and were audio recorded and video recorded. The group worked in the presence of an interviewer (the second author), who answered clarification questions about the wording of the task, but did not offer any mathematical hints.

### Task

We report on Chad, Gil and Lome's mathematical activity in the third discrete mathematics task they worked on: "The Jandals Problem" (Yoon, Griffith Moala, & Chin, 2016). The task begins with some warm up questions that familiarize students with diagrammatic representations of graphs (networks) within the context of friendship associations, where a node represents a person, and an edge between two nodes represents a friendship between two people. After the warm-up questions a scenario is posed: Xanthe, an American exchange student in New Zealand learns that the locals use the word *jandals* to refer to what she commonly calls *flip-flops*. Upon returning home, Xanthe wants to spread the word *jandals* throughout different networks of friends like the ones shown below in Figure 1 and Figure 2. Students are asked to:

> Create an algorithm (method) that Xanthe can use to figure out the first person whom she should share the word with first in each friendship network to ensure that the word gets passed on to everyone in the network as rapidly as possible. She assumes that a person will share the word with all of his/her friends on one day, and each of those friends will share it with their friends the next day. Ensure that your algorithm will work for any friendship network, not just the one given [Figure 1]. (Yoon, Griffith Moala, & Chin, 2016, p. 12)

Only Figure 1 was initially given to the students; Figure 2 was given to them at a later stage.

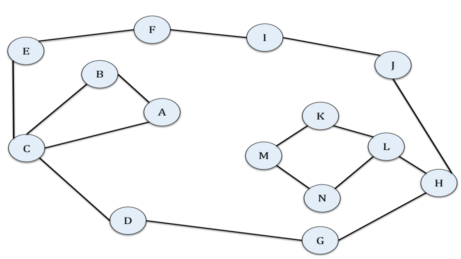

*Figure 1. Friendship Network 1*

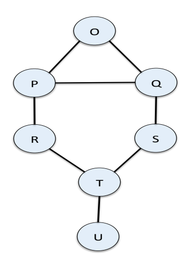

*Figure 2. Friendship Network 2*

This task asks students to develop “an algorithm (method) that Xanthe can use”. Throughout the session, the students and interviewer switched between ‘algorithm’ and ‘method’, and we preserve both when describing and analyzing their work.

**Data Analysis**

Due to the exploratory nature of the study, the aim of the analysis was not to confirm existing constructs but rather to explore aspects of the data that may be used to construct plausible explanatory models (Clement, 2000) for how features of an example come to be predominant in subsequent generated examples. Thus, the analysis involved an “open interpretation of the data” (Clement, 2000, p. 548), which is “useful for constructing initial explanatory models of cognitive processes” (Koichu & Berman, 2005, p. 171) inferred from the data.

Following the task description, we regard the target concept that guides the students’ mathematical activity to be “an algorithm (method) that Xanthe can use” with two defining properties: (1) it identifies the *quickest starting person*; (2) it must work for any friendship network. We searched the data for examples of the target concept that the students created, establishing the presence and predominance of a common feature among the examples. Then we followed the development of the examples (individually and collectively), looking for particular aspects of the group’s work that may have contributed to the emergence of the predominant feature.

## Findings

We present three episodes from Chad, Gil and Lome’s activity during the Jandals problem in which they create an example of the target concept of “an algorithm (method) that Xanthe can use”, and where a particular feature of this first example also appears in further examples that the students generate. Each episode begins with our *account of* (Mason, 2002) the group’s work (i.e., addressing what happened) followed by our analysis (addressing *why* particular things happened).

**Episode 1: A valid example of the target concept emerges**

After the group reads the task instructions, Gil says they need to find the person in the friendship network (Figure 1) that would spread the word quickly. Lome suggests they choose a person, count how many days it would take for the word to spread starting from the chosen person, repeat the process for all other persons, then share the word with the person that gives the least number of days. Lome refers to this entire process as “the elimination method.”

The students use the elimination method on the following persons in the first friendship network: *C, I, L, J, H, G, M*. They determine that the quickest of these is *H*, which yields four days, having incorrectly calculated that *G* yields six days, when in fact it also yields four days, making it another quickest starting person. Lome remarks, “I reckon we’ve solved it!” He then looks back at the task instructions, turns to the interviewer and says:

*Lome*: What’s an algorithm? This [*points to written parts of their elimination method*] is not an algorithm is it?

*Interviewer*: An algorithm is like a method. So it’s not your solution, it...

*Gil*: It’s like the way you got it.

*Interviewer*: Yeah, so that she can use it for any other network, because this is just one of many different friendship networks across the campus.

*Lome*: Can we say we just did elimination method?

*Interviewer*: You've got to explain it as well as you can so that Xanthe can use it for a different one that she is given.

When Chad says he is still unsure what they need to produce, Lome says, "she needs to be able to figure out the solution to any network, from our method." Gil then suggests a method: "Yeah, so it would be like, your method would be like, the [*starting*] person should tell three people because [*points to Figure 1*] if you told *H*, *H* would tell *L*, *G*, and *J*. And then, it spreads." Lome and Chad both nod their heads, and Lome says "Yeah, cool!"

**Analysis.** Two different methods emerge for the group in this excerpt: *the elimination method,* which is the exhaustive search procedure that the group uses to find the quickest starting person in the first network; and *Gil's method* (share the word with someone who tells three people) which is the method Gil suggests giving to Xanthe. Lome's question to the interviewer, "Can we just say that we did elimination method?" can be interpreted as asking whether the elimination method qualifies as a valid example of the target concept. The group's subsequent decision not to share it with Xanthe suggests they do not consider it to be a valid example (although it is indeed a mathematically valid algorithm for Xanthe's purposes). On the other hand, the group's enthusiasm towards Gil's method, indicated by head nods and "yeah cool!" suggests they regard Gil's method to be a valid example of the target concept. Thus, although both methods are put forth as potential examples of the target concept, only one of them (Gil's method) is accepted by the group as a valid example of the target concept.

**Episode 2: A feature of the first example is preserved in the generation of a second example and subsequent examples**

After Gil proposes his method at the end of Episode 1, the interviewer points to the task instructions and says:

*Interviewer*: Can I get you to read what the method needs to do?

*Lome*: So [*looks at Figure 1*] she should share it with someone who tells at least three people. But then mind you, if she starts at *L*, *L* tells three people but it doesn't work as fast.

*Gil*: Yeah, that's true.

*Lome*: So maybe [*points to H*] the starting person needs to tell three people [*points to L, J, and G*] but one of those three people [*points to L*] has to tell two other people.

*Gil*: Yeah [*nods head*].

*Lome*: Because this person [*points to C*] tells four people, but none of those people [*C's friends*] are connected to two other people. That's a method. I'll write it.

Lome writes down: "Share the word with a person who tells three people, and one of those three people must tell two other people." The interviewer asks, "Are you happy?" Chad, Gil and Lome reply, "Yes."

Later in the task, Gil revises Lome's method to "share the word with someone who tells three people, and each of those three people must tell one other person." Then, Chad revises Gil's second method to "Share the word with someone who tells three people, and two of those three people must each tell one other person." These methods are presented in Table 1 below.

**Analysis.** After the group notices a flaw in Gil's method, all of the methods they subsequently suggest nonetheless preserve a feature of Gil's method: *the quickest starting person tells three people*. What may be a plausible explanation for the preservation of this feature? We propose that the group may have noticed that their method needed to perform two functions: (i) it had to find the quickest starting person(s), and (ii) it had to *not* find non-quickest starting persons in a given network. In light of these two functions, the process whereby Lome's method above is obtained by building on Gil's, can be described as: keep the part of the current method that satisfies the first function, and change the part that violates the first function (note that *'change'* also includes adding other parts to it) so that the second function is also satisfied. We refer to this process as a 'patching process" due to its change-only-what-needs-to-be-changed nature. We observed the students using this patching process to generate the other examples (see Table 1).

**Episode 3: The elimination method is judged to be a non-example of the target concept**

After Lome writes down his method—share the word with a person who tells three people, and one of those three people must tell two other people—the interviewer hands the group a sheet of paper on which is printed a new friendship network (see Figure 2 above), and asks them to show how Lome's method would work on this new network. Rather than apply Lome's on this new network, the group uses the original elimination method to find five solutions: *P*, *Q*, *R*, *S*, and *T,* which all give three days (note, their solution set is incorrect; *R* and *S* are the quickest starting persons as they only give two days). Then Lome says:

*Lome*: Can you get four days? [*Chad demonstrates that it takes four days starting from person U*]. OK, so why wouldn't she tell *U* but tell *Q* instead? What's the method? Obviously *Q* will be quicker but why would she tell *Q* and not *U*?

*Gil*: Because, read your thing [*points to Lome's method*]. She has to tell someone who tells three people, so *Q* tells three people. If you tell *Q* first, *Q* tells *S*, *P*, and *O*. Then, the second person must tell at least two other people.

*Lome*: Yeah.

The group again agree that they need to produce a set of instructions and a method that Xanthe can use on any network. Then Lome remarks:

*Lome*: Say she has hundreds of these [*networks*] she doesn't want to do elimination method for every one. What if there's a network with a thousand people? She'll be there for ages counting!

**Analysis.** In total, the group created five methods for the task, which are summarized in Table 1, four of which they regard as examples of an algorithm they could give Xanthe.

*Table 1: The five methods created by Chad, Gil and Lome during the Jandals problem*

| *Name* | *Description of the method* | *Validity as example of target concept* |
|---|---|---|
| The elimination method | Choose a person, count how many days it would take for the word to spread starting from the chosen person, repeat the process for all other persons, then share the word with the person that gives the least number of days. | Non-example |
| Gil's method | Share the word with someone who tells three people. | Valid example until flaw is found |
| Lome's method | Share the word with someone who tells three people, and one of those three people tells two other people. | Valid example until flaw is found |
| Gil's second method | Share the word with someone who tells three people, and each of those three people tells one other person. | Valid example until flaw is found |
| Chad's method | Share the word with someone who tells three people, and two of those three people each tells one other person. | Final valid example |

While Lome was comfortable using the elimination method to find person *Q* as one solution for the friendship network in Figure 2, his questioning of why Xanthe should choose *Q* over *U* suggests he did not regard the elimination method as adequate justification for this choice: "obviously *Q* will be quicker than *U*, but why"? Gil cites Lome's method to justify choosing *Q* over $U$, which seems to satisfy Lome. For Lome then, the elimination method was prescriptive without being explanatory. This perceived feature, together with his characterization of the elimination method as tedious for large numbers of people may have dissuaded the group from perceiving the elimination method as a valid example of the target concept, even though it is indeed a mathematically appropriate algorithm. Rather, the group perceived the elimination method as a non-example of the target concept, which, in giving the group an idea of what a valid example should (not) look like, may have contributed to inclusion of the feature "tell someone who knows three people" in the examples they generated afterwards.

## Discussion and Concluding Remarks

The episodes that were presented in this paper provide an account of the recursive process that a group of students went through when engaging with a concept of algorithm. First, the group considered a method and decided whether it was an example or non-example of the targeted algorithm. The consideration was made against two functions that the group wanted their method to perform. Second, the group recognized that the method under consideration performed one of the functions, but not both. Lastly, a new method was generated in which feature from the previous method was preserved and a new feature was introduced so as to ensure that the resulting method performed both functions. We refer to this recursive process as 'a patching process' due to its change-only-what-needs-to-be-changed nature. This patching process eventuated in the preservation of a feature of the initial example in all the other examples that group generated, and hence the emergence of a predominant feature. We propose that this patching process is one instance of the processes that students might be engaged in when they abstract and preserve features of the concept examples—features that become predominant.

The patching process that we identified in our study puts forward the crucial role of the first concept examples that students encounter. This aspect aligns with the existing research on prototypes (e.g., Hershkowitz, 1989; Tall & Bakar, 1992). We, in our study, show that merely encountering examples is not necessarily sufficient, and that recognition of the example's status (as *an example of the* concept) is necessary. Indeed, the students in our study generated the elimination method, an algorithm that we, as researchers, wanted them to develop. Furthermore, to the best of our knowledge, there is currently no more efficient algorithm to cope with the tasks that were handed to our students. Yet, the group almost immediately labeled the elimination method as "not an algorithm," and its inappropriateness was not questioned in the data that we presented. Thus, it seems reasonable to propose that developing appropriate prototypes may come down to preserving appropriate features (and rejecting inappropriate features) of the examples; which in turn may depend on the processes (such as the patching process we found here) that students go through when abstracting and preserving certain features of the concept examples.

**Acknowledgement**

The data presented in this paper were collected as part of *a* two-year long research project funded by the Ministry of Education Teaching and Learning Research Initiative, and administered by the New Zealand Council on Education Research.

# Teaching Linear Algebra: Modeling One Instructor's Decisions to Move between the Worlds of Mathematical Thinking

| Sepideh Stewart | Jonathan Troup | David Plaxco |
|---|---|---|
| University of Oklahoma | University of Oklahoma | Clayton University |

*In this article, we report results from a year-long study in which a linear algebra instructor worked with the research team to document his instructional decision-making via journals and interviews as well as to code and analyze the data. This work supports the development of a more general model of the instructor's decision-making and provides a lens with which to make sense of the instructors shifts between representations from each of Tall's Three Worlds. With the introduction of the model, we include an example to show how the various codes interact in the instructor's decision-making. We also provide a detailed description of one incident that provides a second perspective on the instructor's decisions, helping to support a more robust understanding of the data.*

*Keywords*: Linear Algebra, Tall's Worlds, ROGs, decision-making

## Theoretical background

Over the past decade, research on linear algebra has revealed that many students struggle to grasp the more theoretical aspects of linear algebra which are unavoidable features of the course and are focused on students' thought processes (e.g. Stewart & Thomas, 2009; Hannah, Stewart &Thomas, 2013; Britten & Henderson, 2009; Wawro, Zandieh, Sweeney, Larson, & Rasmussen, 2011; Gol Tabaghi & Sinclair, 2013; Salgado & Trigueros, 2015). The research in recent years have mainly concentrated on students' difficulties and with a few exceptions (Hannah, Stewart & Thomas, 2011; 2013; Zandieh, Wawro, & Rasmussen, 2017; Andrews-Larson, Wawro, & Zandieh 2017), research on instruction in linear algebra is still scarce.

Research in instruction at the university level is fairly new. As Dreyfus (1991) suggested, "one place to look for ideas on how to find ways to improve students' understandings is the mind of the working mathematician. Not much has been written on how mathematicians actually work" (p. 29). Two decades later, Speer, Smith, and Horvath (2010) declare that "very little research has focused directly on teaching practice and what teachers do and think daily, in class and out, as they perform their teaching work" (p. 111). In recent years some mathematics professors have been more willing to examine and reflect on their own teaching styles, leading to a growing body of research in this area (e.g. Paterson, Thomas, & Taylor, 2011; Hannah, Stewart, & Thomas, 2011). The overarching goal of this study was to contribute to this gap in the literature by examining a linear algebra instructor's thought process and teaching decisions over an entire semester.

The theoretical aspects of this study are based on Schoenfeld's (2010) Resources, Orientations and Goals (ROGs). He claims that "if you know enough about a teacher's knowledge, goals and beliefs, you can explain every decision that he or she makes, in the midst of teaching" (2012, p. 343). By resources Schoenfeld focuses mainly on knowledge, which he defines "as the information that he or she has potentially available to bring to bear in order to solve problems, achieve goals, or perform other such tasks" (2010, p. 25). Goals are defined simply as what the individual wants to achieve. The term orientations refer to a group of terms such as "dispositions, beliefs, values, tastes, and preferences" (2010, p. 29). Although, the theory was originally considered as applying to research on school teaching, (Aguirre & Speer, 2000; Thomas & Yoon, 2011; Törner, Rolke, Rösken, & Sririman, 2010), it clearly has applicability to research on university teaching (e.g. Hannah, Stewart & Thomas, 2011; Paterson, Thomas & Taylor, 2011).

As a part of the theoretical framework described in this paper, we also employed Tall's three-world model of embodied, symbolic and formal worlds of mathematical thinking. Tall (2010) defines the worlds as follows: The embodied world is based on "our operation as biological creatures, with gestures that convey meaning, perception of objects that recognize properties and patterns...and other forms of figures and diagrams" (p. 22). Embodiment can also be perceived as giving body to an abstract idea. The symbolic world is the world of practicing sequences of actions which can be achieved effortlessly and accurately. The formal world "builds from lists of axioms expressed formally through sequences of theorems proved deductively with the intention of building a coherent formal knowledge structure" (p. 22). In Tall's view (2013, p. 18), "formal mathematics is more powerful than the mathematics of embodiment and symbolism, which are constrained by the context in which the mathematics is used". He believes that the formal mathematics is "future-proofed in the sense that any system met in the future that satisfies the definitions of a given axiomatic structure will also satisfy all the theorems proved in that structure. The formal mathematics can reveal new embodied and symbolic ways of interpreting mathematics." (p.18).

We believe that in many cases teachers and text books move between worlds of mathematical thinking very naturally and rapidly, not allowing students time to discuss and interpret their validities. They assume that students will pick up their understandings along the way. As Dreyfus (1991, p. 32) declares "One needs the possibility to switch from one representation to another one, whenever the other one is more efficient for the next step one wants to take… Teaching and learning this process of switching is not easy because the structure is a very complex one." We hypothesize that most students do not have the cognitive structure to perform the switch that is available to the expert. For example, Duval (2006) noted that to construct a graph, most students have no difficulties as they follow a certain rule "but one has only reverse the direction of the change of register to see this rule ceases to be operational and sufficient". (p. 113)

In this study, we employed Tall's three-world framework of embodied, symbolic and formal to follow a linear algebra instructor's movements between the worlds. Our research questions are: How did the instructor's ROGs inform his movements in the three worlds? When did he decide to move between the worlds and why?

## Methods

This narrative qualitative study examined an instructor's teaching journals. The study took place over an entire semester, during which the instructor (David) was teaching two sophomore-level linear algebra courses using the IOLA curriculum (Wawro et al, 2012). With some exceptions, the instructor kept a journal of teaching reflections throughout the semester and met with the research team (lead investigator, senior investigator, and undergraduate assistants) each week. The reflections and team meetings allowed for triangulation of data and gave multiple chances for the instructor to share his reasoning about his teaching decisions. The team then conducted a retrospective analysis of the journals following the methodology of narrative study (Creswell, 2013). Specifically, the team iteratively coded the data, beginning with open coding that each member of the team conducted and brought together to compare. Through comparison of open codes, the team developed a set of focused codes that were iteratively refined through collective discussion. The team then used these focused codes to categorize each sentence from the journals, disputing conflicts through an open discussion until each member of the team was satisfied. This process further refined the focused codes. These discussions resulted in a spreadsheet with each sentence from the journals coded for as many categories (themes) as the group deemed necessary for that section of transcript. Some of these codes are listed in Table 1.

The research team grouped similar codes with each other based on which aspects of the pedagogical process the instructor was discussing. The broad categories included: Teaching, which describes codes in which the instructor is describing what occurred in class; Math, which differentiates instances in which the instructor is explicitly talking about either the students' mathematics (Ms.) or his own (Mi); Reflection, which focused on the successes and failures of implementation toward the desired learning goals; and Tall's Three Worlds, which focused on which of the three worlds the instructor was drawing on in the moment. The codes that we focus on in this section are when the instructor discussed: teaching, focused on the tasks implemented in class (IOLA); teaching, focused on developing specific ideas in the class; teaching, when pedagogical decisions are made; statements about the instructor's mathematics; statements about the students' mathematics; and reflections specifically addressing the students' successes and struggles in developing the intended mathematics.

## Results and Discussions

After coding the instructor's journals, the team focused on identifying narratives that the codes supported. Through an examination of the codes, we identified several patterns that help explain specific instances of how the instructor made decisions in planning his lessons. One such pattern is diagrammed in Figure 1. In this pattern, statements about developing specific ideas in the classroom (Td) and making pedagogical decisions (Tp) inform the tasks (Tt) in which the instructor engaged the students. The instructor then reflected on the students' activity (Rs), and explicated the insight this allowed him to gain about their mathematics (Ms). Following this, the instructor then drew on his own mathematical understanding (Mi) to make sense of the students' mathematics in the context of his reflection on his own instruction (Ri). This act, in turn, informed the instructor's pedagogical decisions (Tp) and focus on which ideas to develop (Td) as well as a means of developing them through specific task (Tt). Although it is consistent with a few examples from the instructor's journal, this cycle is a generalization of how such a process might unfold and so we expect this process might be different for other instructors. Further, we find that shifts among these codes might provide some insight into how instructors make decisions regarding shifts between Tall's Three Worlds in their instructional decisions.

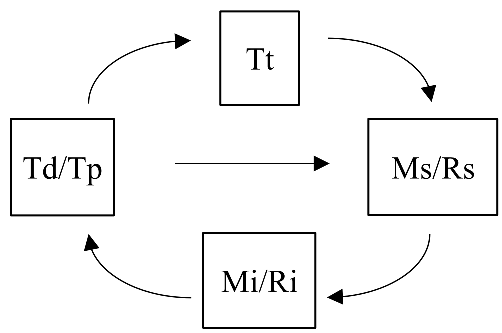

*Figure 1. Possible diagram of codes describing instructor's decision-making.*

We now provide an example (see Table 2) to show how this pattern of decision-making might unfold. The instructor began this episode by referring to the task that he wanted the students to complete, which comes from the IOLA curriculum intended to support students' development of linear independence, span, and basis (Tt). The instructor then reflected about the students' engagement in the task (Rs) and the mathematical understanding of linear in/dependence and span that they exhibited in their work (Ms). In these lines, he described what he had observed as the students' limitations in completing the table and conjectured why this might be the case, citing limitations of his own instruction in preceding class sessions (Ri). The instructor then responded to this by anticipating an approach that might address what he saw as an issue in his students' understanding. Specifically, he relied on an activity he had developed for himself (Mi) to make sense of the notion of basis. He then concluded that he would implement this task in the next class session (Tt, Td, Tp) and drew on his prior experiences using this task (Mi, Ri). Altogether, this sequence resulted in a shift from focusing on students' generation of examples set in the symbolic world to a focus on the students' embodied notions of linear independence. The instructor saw value in a different way of understanding and anticipated that focusing on this facet of understanding linear in/dependence would support the desired ways of thinking from the students.

*Table 2. An excerpt from the instructor's journal.*

| Excerpt | Tt | Td | Tp | Mi | Ms | Rs | Ri | TWe | TWs |
|---|---|---|---|---|---|---|---|---|---|

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| I wanted students to complete U1T4 from IOLA. | 1 | | 1 | | | | | | 1 |
| Each class finished the task, though some groups had some pretty serious reasoning deficiencies. | | | | | 1 | 1 | | | |
| For instance, very few groups in the first class realized the impossible cases. | | | | | 1 | 1 | | | |
| I think this is a result of rushing through the definition of LI/LD and my failure to support deep geometric thinking about linear dependence. | | | | | 1 | | 1 | 1 | |
| I think I can help fix this on Monday by having the students do the "building set" task while focusing on LI/LD. | 1 | 1 | 1 | 1 | | | | | |
| We've done this task when talking about span and so I think they'll be comfortable with it, I just need to give them time to feel comfortable with thinking about linear dependence spatially. | | | | 1 | | 1 | | 1 | |

**Moving between the three worlds**

In teaching two sections of linear algebra, David wished to get three fundamental points across. First, he wanted to help students discover that linear independence means there will be infinite solutions to the homogeneous equation. Second, he wanted to demonstrate that linear combinations of linearly independent vectors are unique. Finally, he wanted to help students reason about when and why matrices are invertible by connecting to the importance of basis and forming an appropriate connection between matrices and linear combinations.

David's teaching began smoothly enough, despite some minor complaints about time. Because of this shortage on time, he was unable to introduce the Elementary Row Operations (EROs) that the students had previously asked him about at this time, which disappointed him. He did however, introduce the vector space axioms (formal) and went over a few examples of vector spaces, at which point students finished their prescribed task quickly(Tt). David remarked that the second class seemed much less involved than the first class, perhaps because of the streamlining he did as a result of his experience from the first class (Rs). All groups converted a system of equations to obtain the same solution, though different groups chose different variables and David felt they were unaware of scaling solutions(Mi/Ri). He therefore synthesized the groups' classwork (Td/Tp), helping them focus on free variables (symbolic) and tying their work back to the "getting back home" problem (embodied). He utilized embodied reasoning here, envisioning traveling in a triangle, though perhaps due to rushing through some definitions, the students did not achieve the deep geometric thinking David would have preferred. In attempting to point out that linear combinations of linearly independent vectors are unique, David turned to symbolic reasoning by writing two separate equations for linear combinations of linearly independent vectors(Tt). This achieved the desired effect as students realized that the only way to obtain the zero vector from linearly independent vectors was to make the coefficients all zero, and some students, in David's words, had "really cool ways of thinking about why a=c," (Rs/Ms) and mentions that he wishes he had video of these in-class conversations.

In one particular interview from October 11, David described ways in which he helps his students learn the notion of linear independence. He leveraged the power of the embodied and symbolic worlds as resources to help students understand the formal world more completely. He stated his main goal was to help students understand that matrices are invertible if and only if their column vectors form a basis, that is, if and only if their column vectors are linearly independent (and span the field).

It seems that throughout the interview David utilized embodied reasoning as a resource to help students understand difficult concepts. Early on, he mentioned when students “can’t see” some concept he is teaching, he “takes it to a more familiar analog,” and furthermore shows pictures of vectors that challenge student intuition. At one point, David talked about helping a student in office hours refine their reasoning about linear independence through embodied use of markers pointing in particular directions. That is, he asked the student if she could get to various places on the desk traveling only in lines parallel to the two markers he had laid out pointing in specific directions. It seems David utilized the embodied world, supported by his example with the markers, to inform his student’s understanding about what the more formal terminology of “linear independence” meant.

Earlier in the interview, David stated his wish to help students develop math based on the representations they’re already using, as well as their own natural tendencies (orientation). To this end, he asked students in class for their thoughts on a formal idea they’re discussing as a class. For example, he wrote “What does it mean to be invertible?” on the board at one point, but rather than having students memorize the formal definition, he asked them for input and wrote the facts they suggested on the board. In this process, he guided them toward the idea of linear transformation which they had already covered, in order to use their previous embodied and symbolic reasoning to inform this new formal idea they were moving towards.

Finally, David suggested he used symbolic work to help reinforce formal ideas. In answer to an interviewer probe, David agreed that he felt that “pictorially” students were fine, but had trouble with representations that “were not just a symbol” but were more strongly “rooted in the definition”. In response to this question, David gave an example of another student he asked, “If $\begin{bmatrix}1\\0\end{bmatrix}$ goes to $\begin{bmatrix}1\\0\\1\end{bmatrix}$ and $\begin{bmatrix}0\\1\end{bmatrix}$ goes to $\begin{bmatrix}1\\1\\2\end{bmatrix}$, where does $\begin{bmatrix}x\\y\end{bmatrix}$ go? The student took an algebraic approach and felt this was intuitive, but still missed the connection to linear dependence. With some help from the instructor, however, sometimes this symbolic reasoning can still inform this formal definition. In doing similar problems, this student answered quickly but her work was disorganized, and therefore confused her. David reorganized the symbolic calculations into a single line with reasoning about linear dependence and transformations informing this symbolic flow of logic. It seemed that David once again utilized symbolic reasoning to help the student cross a bridge from the symbolic world into the beginnings of formal reasoning.

Thus, David builds upon students’ prior mathematical knowledge, and utilizes first embodied reasoning to inform the formal definition. Once students are comfortable with embodied reasoning, David begins utilizing tools from the symbolic world to further inform student reasoning, switching back to embodied reasoning (see markers example, or Geometric Sketch Pad (GSP) usage) when students experience further difficulty in reasoning. In class, David successfully led students to symbolically reason about the uniqueness of linear combinations of linearly independent vectors, his second of three main goals.

Not all such teaching was smooth however. One serious reasoning deficiency was that students did not realize some of the cases were impossible, such as writing down three linearly independent vectors in $\mathbb{R}^2$. David first attempted to fix this by helping students think about a matrix times a vector as a linear transformation via a “building set” task they had previously completed while thinking about span rather than linear independence (Tt). He also wanted students to be able to think about the product as a linear combination of column vectors(symbolic), so that students would realize the importance of basis in conjunction with the invertibility of matrices, as well as in conjunction with linear transformations. In particular, column vectors must form a basis for the matrix and the associated transformation to be invertible(formal). However, students had a hard time understanding David's point that a matrix isn't a transformation until you do something with it, and that bases have to be named. He was just trying to explain to them the difference between a simple symbol and the activity that is sparked by that symbol(Ri/Mi)—the difference between symbolic and embodied reasoning. As he felt this point was lost on them, in his second attempt he used GSP (embodied) to actually demonstrate the distinction between symbols and the action the symbol is taken to signify. Asking students to name a vector led them to realize they needed to see axes in order to name a vector(Rs/Ms). David was then able to start with the standard basis axes, then distort them with GSP to a different basis and ask students to come up with a linear combination for the same vector once again. Through embodied work with GSP, students came to understand that with a different basis, a completely different matrix can stand for the same linear transformation, and that a matrix isn't a linear transformation until the bases are established. Thus, GSP in conjunction with David's directed teaching successfully effected a transition in the students from embodied to symbolic reasoning. Showing students (embodied) the difference proved much more effective than just trying to explain the difference(symbolic/formal).

## Concluding Remarks

In both accounts, it appears that David roughly followed the cycle laid out in Figure 1, where he utilized developed tasks to draw out or further refine students' existing mathematics. This affords him the opportunity to utilize his own knowledge of mathematics to reflect on his instruction and make inferences about his students' mathematics. Armed with this knowledge, he can then make more appropriate pedagogical decisions and ideas within the classroom. While David notes that students were not typically comfortable shifting between Tall's three Worlds (i.e., formal was most difficult for them while embodied was most accessible, with symbolic somewhere in the middle), in contrast, David himself shifted between worlds regularly in an effort to teach his students. As seen in the October 11 interview, it appeared that David also utilized the embodied world as a resource to help develop the symbolic world, and then used both of these as resources to begin to approach the formal world. Thus, Tall's three worlds functioned as a resource to help David meet his goal of instructing students about the relationship between linear independence and invertibility.

This work provides a foundation for further investigations into linear algebra instructors' decisions, especially those decisions about shifting between representations in each of Tall's three worlds. This research also provides insight into how we might frame instructional decision making more generally – beyond the context of linear algebra instruction. For instance, the decision-making diagram in Figure 1 could be used in any context, though we found it useful in this study to help focus on shifts between Tall's three worlds.

# Could Algebra be the Root of Problems in Calculus Courses?

Sepideh Stewart Stacy Reeder Kate Raymond Jonathan Troup
University of Oklahoma University of Oklahoma

*Calculus serves as the gateway for most STEM degrees. Due to students' challenges successfully completing calculus, more than half of students are deterred from a career in STEM. Our preliminary investigation indicates that students' difficulties with algebra cause significant problems in many first-year math courses. The aim of this paper is to investigate in what ways the difficulties with algebra impact students' success in calculus.*

*Keywords*: Algebra, Calculus, common errors, accommodation

## Introduction

Calculus occupies the position of gatekeeper to disciplines in STEM since at least one calculus course is required for all STEM majors. "For too many students, this requirement is either an insurmountable obstacle or—more subtly—a great discourager from the pursuit of fields that build upon the insights of mathematics" (Bressoud, Mesa, & Rasmussen, 2015, p. v). Research has shown that negative experiences encountered in gatekeeper or introductory math and science courses are a major factor in the national problem of significant attrition (more than half) of declared STEM majors (Crisp, Nora, & Taggart, 2009; Mervis, 2010). Studies by Stewart & Reeder (2017a; 2017b) suggest that college students' weaknesses with high school algebra play a major role in their success in their first-year math courses.

Although research on students' difficulties with algebra in school has been well documented (e.g. Kieran, 1992; Hoch & Dreyfus, 2004), research on these difficulties and their impact at university level are scarce. Stacey, Chick, and Kendal (2004) discussed the main problems of algebra in school algebra, little was mentioned in the way of consequences for college level mathematics. Research has catalogued common errors in computation and algebra (Ashlock, 2010; Booth, Barbieri, Eyer, & Pare-Blagoev, 2014; De Morgan, 1910). Our findings parallel these categorizations and document that these errors continue to persist in college level mathematics work, potentially complicating student success in college mathematics courses (Stewart & Reeder, 2017b). As Author (2017, p. vii) points out: "Many college instructors are facing this dilemma every day. Students who seemingly follow more complex mathematical concepts, are unable to proceed as problems, for example involving fractions, will soon let them down." We suggest that challenges students have with the high school algebra content that is embedded in calculus problems are a major cause of failure for many Calculus students.

The goal of our research is to understand how students' difficulties with algebra impact their work in calculus problems. For this study, Calculus students were given algebra tasks and calculus tasks with algebra embedded to help answer the following research questions: (a) What were the most common algebra problems in both the algebra and calculus tasks? (b) What were the students' perceptions of their challenges with algebra and calculus related to these tasks?

## Theoretical framework

Piaget's (1952) theory of accommodation and assimilation as a theoretical framework was employed for this study. A schema (mental structure) serves two purposes: "It integrates existing knowledge, and it is a tool for acquisition of new knowledge" (Skemp, 1971, p. 39). When new situations and experiences are encountered, the human brain deals with it by either accommodation or assimilation; the structure of the schema must change to adapt to the new situation, "this may be difficult; and if it fails, the new experience can no longer be successfully interpreted, and adaptive behavior breaks down- the individual cannot cope" (p. 44). In this way, how we understand concepts is constantly changing and adapting as we are presented with new information, experience things, and learn new concepts. While assimilation is easier and often produces a feeling of mastery, accommodation is difficult. Vinner (1988) stated that "very often (and specially in mathematics) the cognitive structure of the learner is not suitable for incorporating the new material" (p. 594). He believed that acquisition of new mathematical concepts in more advanced settings requires accommodation, since "a concept which seems quite simple to the mathematician can be difficult for the student to accommodate" (p. 606). He further believed that the lack of attention to accommodation will lead into situations where "certain concepts are not conceived by the students the way we expected" (p. 593). Skemp (1979) introduced two further notions: *expansion* and *reconstruction*. He clarified that "our schemas grow by expanding existing concepts and by forming new ones" (p. 126). Sometimes, however, we may encounter a situation for which we have a relevant schema which is not adequate. If we are unable to avoid such situations, we need to re-construct our schema. This is "disruptive, unwelcome, and difficult: because while this is going on, we are unable to use our schemas effectively for directing our actions" (p. 126). We suggest that success in calculus requires expanding and reconstructing schemas about algebra in order to make sense of the calculus contexts in which they appear.

## Method

This qualitative research study involved 275 Calculus I students at a university in the Southwest US at the end of their 16-week course. Students were asked to solve three common Calculus I tasks and four algebra tasks, identify what caused them the most challenge, algebra or calculus, and provide a brief discussion about what challenged them while solving the tasks (see Table 1). The algebra tasks were designed such that they focused on the algebra students would encounter while solving the calculus tasks. Students were asked to solve the calculus tasks first (30 min) and were given the algebra only after their calculus problems were completed (20 min). The open response question was provided last.

Once all data were collected, it was de-identified and incomplete data sets were removed. The result was N = 84 complete sets of data. The research team (four individuals) met to analyze each problem to develop an initial codebook. The initial codebook was used by researchers to code ten sets of data independently for both calculus mistakes in the calculus problems and algebra mistakes in both the calculus and algebra problems. A second meeting of the research team focused on establishing the code book and inter-coder reliability. With an established codebook (see Table 2), each set of problems were analyzed and coded independently by two members of the research team. Each team met to review the codes and establish 100% agreement.

## Results

Our first research question focused on determining the most common errors students made while completing the algebra tasks and calculus tasks while our second question focused on the students' perceptions of their challenges with algebra and calculus. As such, the results are presented in two sections: Research Question 1 and Research Question 2.

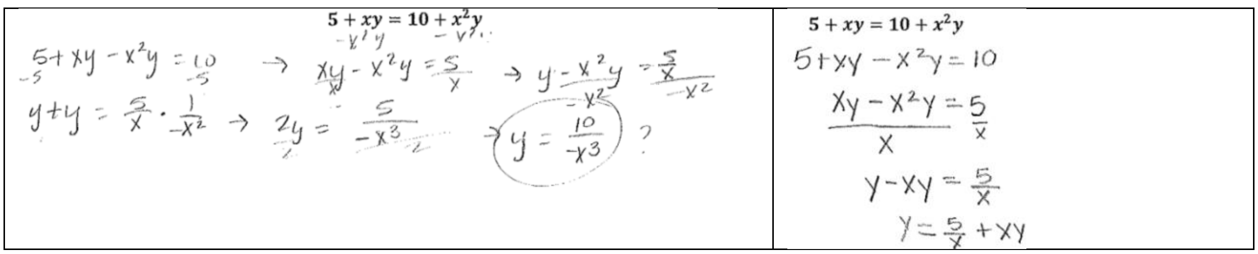
### Research Question 1

Analysis of the algebra and calculus tasks revealed that the student errors were numerous and significant with algebra in both sets of tasks and calculus related errors were frequent in the calculus tasks as well. The most common algebra errors made in both sets of tasks were problems working across the balance point in equations, cancelling, operations with radicals, appropriate application of the distributive property, and incomplete algebra (work that was not completed due to confusion). While the students' work with the calculus tasks were replete with algebra errors, they also made many calculus errors. The most common among these were correctly taking the derivative implicitly, using the product rule properly, failing to identify undefined points as critical, incorrectly taking the limit, and avoiding algebra.

#### Analysis of Algebra tasks

The first algebra task directed participants to solve for y. This problem required collecting like terms and then factoring to isolate the variable *y*. The most common mistakes illustrated that participants had an incomplete conceptual understanding of what it meant to solve an equation, either because they did not isolate the *y* variable or because they did not recognize factoring as a strategy that could help isolate the variable. Figure 1 illustrates two examples of these types of mistakes by different students.

The initial mistake by the first student occurred when s/he attempted to divide each side of the equation by - $x^2$ (see Figure 1(a)). Clearly, the student was attempting to rewrite the left side of the equation in a form which would allow the terms containing *y* to be combined; based on the incorrect work, the student combined these terms. The mistake was failing to recognize that factoring would accomplish this goal while performing operations on both sides of the equation would not. The second student compounded the errors as s/he tried to find a way to combine the two *y* terms. In other words, the student either failed to recognize that manipulating terms was no longer a viable option, or was unable to determine another viable strategy for solving equations. Likewise, the student whose work is presented in Figure 1(b) reached the point where s/he should have shifted strategies from manipulating both sides of the equation to factoring the left side of the equation, but continued to manipulate both sides of the equation instead, which resulted in an equation that was not solved for *y*.

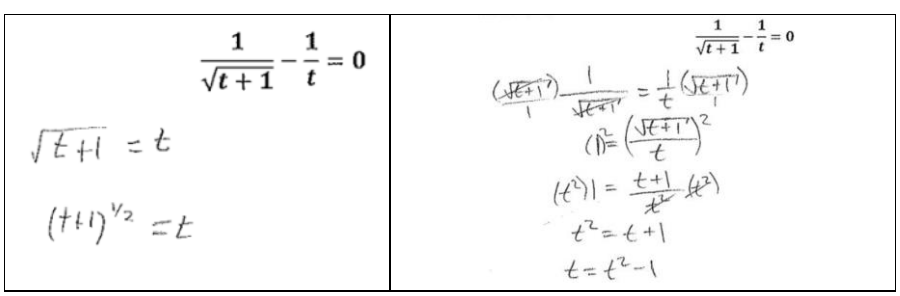


(a) (b)

*Figure 1: (a) Student did not recognize factoring as a strategy for solving equations, (b) Student did not isolate y.*

In the second algebra task, students had similar issues determining what strategies to use and when to move between strategies to solve the equation. Even when students successfully solved the problem, it sometimes appeared as if strategies were chosen at random and students seemingly solved the equation through determination and perseverance. Because of the multitude of technically correct, but unhelpful strategies that can be employed for task two, more mistakes were made with this task than any of the other algebra tasks.

The difficulty students faced in the third algebra task centered around points at which they needed to change strategies. Determining a strategy that allowed the equation to be rewritten without a radical and a strategy to use to solve the resulting quadratic equation challenged many students (see Figure 2). Interestingly, students were much more likely to simply stop working on task three when they reached one of these decision points than they were to stop working on task one or two.



(a) (b)

*Figure 2. (a) Student was not able to work with the radical, (b) Student was unable to determine a strategy for solving the quadratic equation.*

Operations with radicals proved to be a major difficulty for students in problem four. Not only did students have difficulty determining how to eliminate the radical, but students were also more likely to make mistakes in earlier algebraic concepts when wrestling with them in conjunction with radical. For example, one student (see Figure 3) properly eliminated the radical through multiplication, but failed to distribute the negative through the resulting binomial; a mistake fortuitously corrected by his/her next mistake. In addition, the student failed to recognize that the two $y^2$ terms could be combined, and incorrectly assumed that a radical could be, for lack of a better term, distributed to each term within it. It is important to note that many students who correctly applied the distributive property and correctly combined like terms in earlier problems routinely misapplied these procedures in task number four when radicals were involved. As students learn mathematics they build new schema, assimilate and accommodate new information, and expand and reconstruct existing schema. If these schemas are formed around misconceptions or incomplete understandings of mathematical concepts then as they are expanded and reconstructed through the ongoing process of accommodation, students will have continual problems in mathematics.

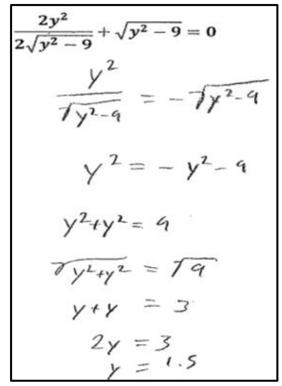


*Figure 3. Difficulties with radicals.*

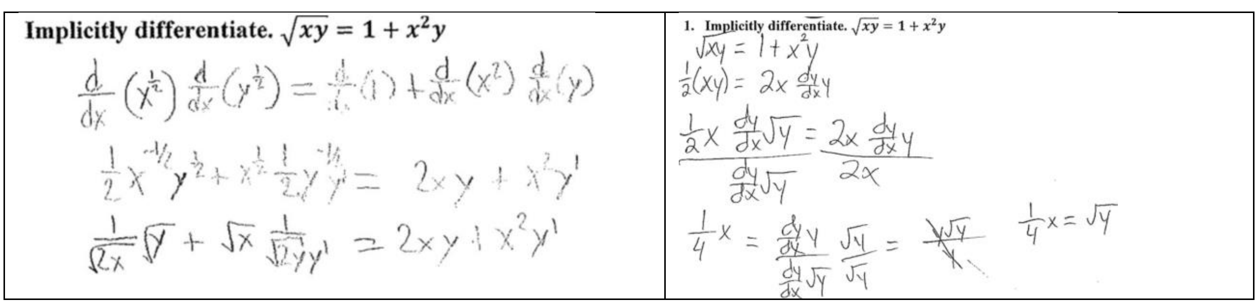
### Analysis of Calculus tasks

In the first calculus task, the most common errors students made were correctly taking the derivative implicitly, using the product rule properly, and failing to complete the necessary algebra correctly. For example, one student (see Figure 4 (a)) incorrectly differentiated each variable separately on both sides of the equation in the first line, and then did not finish solving for $y'$. Note, that despite the incorrect notation of the first line, the second line appears to contain the correct derivatives.



(a) (b)

*Figure 4. (a) Incomplete Algebra (b) Incorrect Chain Rule and Product Rule with disappearing derivative.*

In contrast, another student (see Figure 4(b)) did not apply the chain rule properly on the left side or the product rule properly on the right side. Also note the strange algebra in the second and third lines lead to the $\frac{dy}{dx}$ term disappearing, making it impossible to solve for $y'$ as required, so this again is incomplete algebra. Four students total were completely correct for Question 1 as

61 of the 84 students either could not differentiate implicitly did not correctly apply the product rule, or did not solve for $\frac{dy}{dx}$.

In the second calculus task, the typical errors were failing to identify undefined points as critical, incorrectly applying the product rule or failing to apply it altogether, and failing to complete the calculus portion of the task. For example, one student could not complete the calculus due to difficulty with the product rule (see Figure 5). However, it is notable that s/he successfully identified the mistake and gave reasonable instructions for how the problem *should* be solved. Note s/he finds two of the critical points ($\pm 2$), but this is somewhat accidental, as s/he finds these by setting his incorrect derivative to 0, when the points $\pm 2$ should be obtained from finding the points at which the derivative is undefined. The points obtained from setting the correct derivative to 0 should be $\pm\sqrt{2}$. Only two students correctly solved task two.

The two most common errors in the third calculus task were incorrectly taking the limit and avoiding algebra (i.e., actively avoiding rationalizing the numerator). One student (see Figure 6 (a)) used the quotient rule in an inappropriate scenario (perhaps conflating with L'Hopital's Rule) to simplify the limit. S/he followed this very well executed quotient rule with an improper cancellation of one of the *t*'s, which led her/him to assume that the limit does not exist, despite still having *t*'s in both numerator and denominator. A few students (see Figure 6 (b)), incorrectly utilized a limit law to separate the two terms to separate the limit. While this strategy works well if both resulting limits converge, it does not here because the two separate limits both diverge. Note that while this student did not claim that the limit does not exist, s/he appears to have stalled out and never attempted to evaluate the limit. This task resulted in the more correct work from students (7 of 84) but provided the most variation in the types of errors students made.

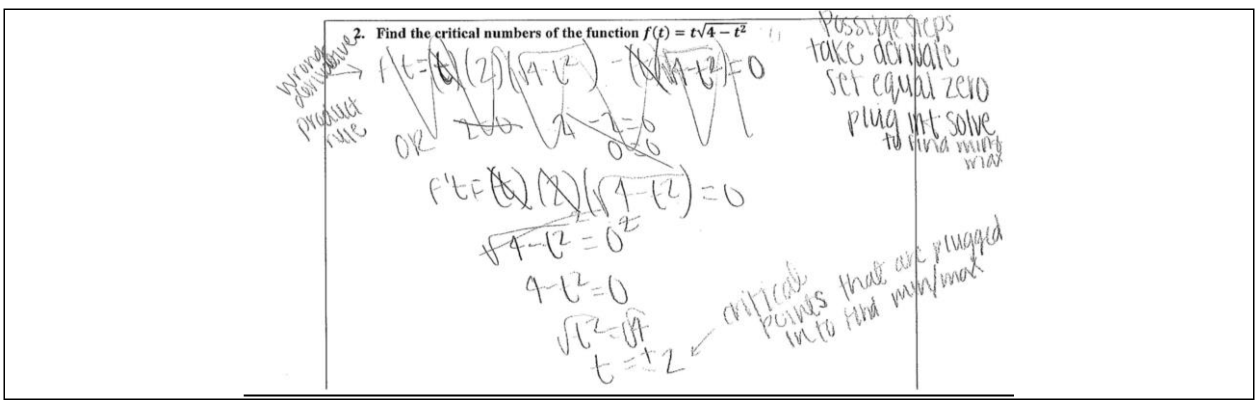


*Figure 5. Instructions for how problem should be solved.*

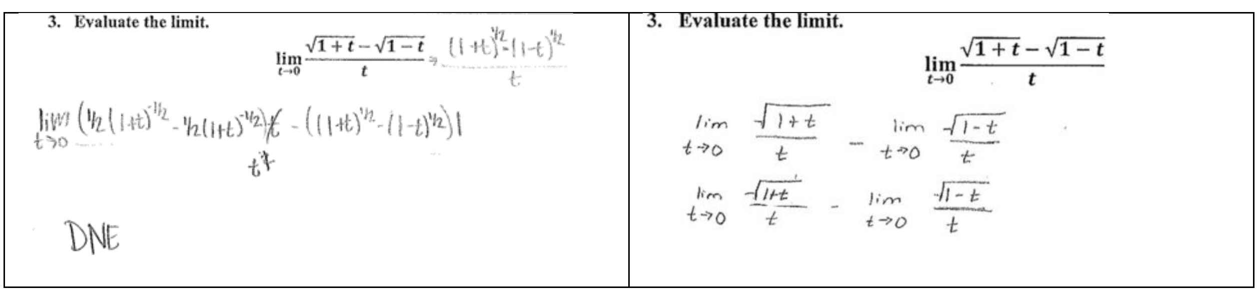

(a) (b)

*Figure 6. (a) Out-of-context Quotient Rule (b) Incorrect limit law.*

As students encounter new concepts in calculus they are no doubt building new schema to accommodate for the news ideas and new mathematics. However, in the midst of dealing with new ideas they must also rely on schemas they developed for algebraic manipulations in the setting of the new concepts they are learning in calculus. If the schema for their algebra understanding are incomplete, then they may present significant challenges for the students as they rely on them to develop understandings of new concepts.

**Research Question 2**

**Analysis of Students' Comments**

Our second research question aimed to provide insight on the students' perceptions about their abilities with algebra and calculus as presented in the tasks they were asked to solve. During the one-hour data collection session, students solved three calculus tasks and four algebra tasks and while pressed for time, 73 of the 84 chose to provide a response to our short-answer item. When asked to simply select which gave them more challenge, algebra, calculus, or both, 57% indicated algebra, 31% indicated calculus, while 12% indicated both. Their comments overwhelmingly expressed recognition that algebra causes them difficulties, frustration, anxiety, and in some cases, hopelessness about their abilities to succeed in mathematics. An excerpt of student comments below capture this well:

- *Square roots and fractions can make algebra difficult and confusing. Calculus can be difficult too but there are more steps either before or after the calculus that involve algebra and that can either "make or break" the problem and solution.*
- *I've had a very weak base in Algebra, ultimately leading to a dysfunction in Calculus.*
- *I struggled the most on the algebra portion of the test. However, I struggled with both portions of the test. I felt as if I hadn't learned anything or retained anything in my course of math. I want to be better at math, but I don't know how.*

## Concluding Remarks

We hypothesized that students would solve algebra problems largely correctly when these problems were in isolation from calculus, but make predominantly algebraic mistakes in the context of calculus problems with algebra problems embedded. However, we found that our sample of students had difficulty in all aspects of both the algebra and calculus tasks. Students routinely struggled with the isolated algebra tasks as well as the calculus tasks. While the work with the tasks presented students challenges with both calculus and algebra the student responses overwhelmingly indicated they had frustration and concerns with their algebra abilities. In the words of one student "I knew how to start the problem, but couldn't finish because of the difficulty of the algebra involved." This presents a challenge for those of us teaching undergraduate mathematics. Our students may have the prerequisite knowledge, but it may not be strong enough to function as a versatile tool in calculus as expected or required. Certainly, further research is needed to examine students' abilities with algebra and its' impact on their success in undergraduate mathematics. We are in the process of designing further studies by interviewing students and mathematics professors in order to gain a better appreciation of students' difficulties. Ultimately, we would like to create a model of intervention to remedy calculus students' struggles with algebra.

# The Counter-storytelling of Latinx Men's Co-Constructions of Masculinities and Undergraduate Mathematical Success

Luis A. Leyva
Vanderbilt University

*While Latinxs complete undergraduate engineering degrees at lower rates than Whites and Asians, Latinx men trail behind Latinx women who recently earned over half of engineering and science degrees conferred to Latinxs. With multiple semesters of mathematics required in engineering majors, qualitative analyses of undergraduate Latinx men's strategies of persistence and success in engineering can illuminate ways to inform more socially-affirming postsecondary educational opportunities and thus increase retention in STEM (science, technology, engineering, and mathematics). This report presents findings from a phenomenological study that characterized variation in two undergraduate Latinx men's negotiations of their masculinities with pursuits of mathematical success as engineering majors at a large, predominantly White four-year university. Findings illuminate the Latinx men's strategies of managing risks of mathematics classroom participation, building academically and socially supportive relationships with faculty members, and negotiating pursuits of STEM higher education with their gendered sense of commitment to family.*

*Keywords:* equity, gender, identity, intersectionality, Latinx

Analyses of academic success among Latinxs[1] in undergraduate STEM education have shed light on disparities between Latinx women and Latinx men (Chapa & De La Rosa, 2006; Cole & Espinoza, 2008; Simpson, 2001). Cole and Espinoza (2008), for example, highlighted how undergraduate Latinx women in STEM have higher grade point averages and degree completion rates than Latinx men. At the same time, Latinx women demonstrated lower levels of confidence and weaker academic self-concept often shaped by the masculinized nature of undergraduate engineering and mathematics spaces perpetuated through issues of representation and valued norms of engagement (Camacho & Lord, 2014; Cole & Espinoza, 2008). Despite the masculinization of engineering spaces, Latinx women outnumber Latinx men as recipients of undergraduate engineering degrees in the United States (U.S.; NSF, 2017).

Engineering is a mathematics-intensive field of study. The socially exclusionary nature of mathematics, therefore, raises considerations about how different constructions of masculinity are privileged or marginalized in undergraduate mathematics, including those among Latinx men pursuing engineering majors. In mathematics education, Latinx students have "seldom been asked for their perspectives on their classroom mathematics experiences" (Varley Gutiérrez, Willey, & Khisty, 2011, p. 27), especially in relation to how they negotiate mathematical success with multiple intersections of their race, gender, and other identities. This points to the promise of intersectional analyses of mathematical success among undergraduate Latinx men pursuing engineering degrees that focus on their negotiations of academic pursuits with constructions of their masculinities.

This report presents findings from a study that detailed the variation of mathematical success

[1] The term *Latinx* decenters the patriarchal nature of the Spanish language that groups Latin American women and men into a single descriptor *Latino* denoting only men. The "x" in *Latinx* allows for gender inclusivity among Latin Americans (including those identifying as gender-nonconforming) compared to *Latina/o* implaying a gender binary.

among two Latinx men pursuing engineering majors at a large, predominantly White four-year university. A three-tiered analytical framework was adopted to address the following question: What institutional structures, interpersonal relationships, and ideological discourses shaped the two undergraduate Latinx men's co-constructions of masculinities with mathematical success?

## Relevant Literature

Two bodies of literature are reviewed in this section. The first body of literature details insights from intersectional studies on Latinx students' co-constructions of mathematics and social identities in undergraduate mathematics as a socially exclusionary space. The second explores undergraduate Latinx men's constructions of masculinities in their pursuits of higher education. Insights across these bodies of literature provide conceptual points of consideration for the study's exploration of how undergraduate Latinx men co-construct mathematical success as engineering students with their sense of masculinity.

### Undergraduate Mathematics as a Socially Exclusionary Space for Latinx Students

Mathematics has been well documented as a gendered and racialized space for marginalized populations, including women as well as Black and Latinx students (Boaler, 2002; Leyva, 2016; McGee & Martin, 2011; Mendick, 2006; Oppland-Cordell, 2014; Stinson, 2008; Varley Gutiérrez et al., 2011). Issues of gender and race, however, have largely been studied separately in extant mathematics education research and with conceptualizations of gender as a female-male binary rather than socially constructed (Leyva, 2017). This leaves the field with minimal insight on varying forms of mathematics experience among underrepresented student populations at different intersections of gender and other social identities.

Intersectional analyses, thus, allow for the detailing of within-group differences in how individuals make meaning of gendered, racialized, and other socially exclusionary experiences in their pursuits of mathematical success (Martin, 2009). Much of the foundational mathematics education research on Latinxs largely focuses on the importance of validating Latinx students' cultural backgrounds through use of the Spanish language and home experiences as resources for mathematical learning (Khisty & Willey, 2013; Moschkovich, 2013). Thus, there is room for exploring how other social identities including gender intersect with Latinx culture to shape variation in Latinx students' experiences of navigating mathematics as a socially exclusionary space. Below I present findings from studies in undergraduate mathematics education that adopted such intersectional analyses of Latinx students' co-constructions of mathematics and social identities at predominantly White universities.

In a study focusing on the experiences of two undergraduate Latinx women in their first year of pursuing mathematics-intensive majors (Leyva, 2016), I examined self-report data (including interviews, a focus group discussion, and mathematics autobiographies) to capture variation in strategies for negotiating their *familismo* (Marín & Marín, 1991; Suárez-Orozco & Suárez-Orozco, 1995), or a sense of loyalty or responsibility to the Latinx family unit, with pursuits of STEM higher education. Both Latinx women discussed managing gendered cultural discourses of Latinx women becoming young mothers and wives rather than being college-bound.

Oppland-Cordell (2014) coupled self-report and classroom observation data to detail how a Latinx woman's and Latinx man's emerging mathematical and racial identity constructions (EMRICs) contributed to shifts in their participation as learners in an undergraduate calculus workshop. While intersectional analysis revealed how gender was only relevant in the Latinx woman's participation shift related to perceptions of her and her peers' mathematical ability, Oppland-Cordell (2014) detailed how socioeconomic status, particularly having access to more meaningful and socially-affirming mathematical learning opportunities in the workshop than K-12 education, played a role in the Latinx man's workshop experience. These different social influences on the Latinx woman's and Latinx man's identity constructions and workshop participation illustrate the "complex intersectional nature of Latina/o students' EMRICs in mathematics classrooms" (Oppland-Cordell, 2014, p. 51). Considering how such variation of experience exists even within intersectional subgroups as noted in my study involving Latinx women, the coupling of self-report and observation data like in Oppland-Cordell's (2014) analysis allows for more situated insights into variation of how Latinx students, at different intersections of social identities, make meaning of their classroom experiences to inform the future design of more socially-affirming undergraduate mathematics learning opportunities.

**Social Constructions of Latinx Masculinities**

Latinx men is an example of a marginalized subgroup in STEM whose mathematics experiences have been minimally explored, especially using intersectional analyses of gender. However, research insights from higher education and psychology on Latinx masculinity ideologies and constructions of manhood can be leveraged to understand how Latinx men negotiate their masculinities with pursuits of mathematics-intensive STEM degrees like engineering. Compared to Black and White men, Latinx men more readily internalize and endorse traditional, culturally-specific norms of masculinity (Abreu, Goodyear, Campos, & Newcomb, 2000; Vogel, Heimerdinger-Edwards, Hammer, & Hubbard, 2011). Latinx masculinities are largely shaped by notions of *machismo* from Mexican culture that has a negative side (or *traditional machismo*) and a positive side (or *caballerismo*) (Arciniega, Anderson, Tovar-Blank, & Tracey, 2008; Torres, Solberg, & Carlstrom, 2002). Traditional machismo is associated with aggression, emotional restrictedness, hypermasculinity, avoidance of the feminine, and sexism including gender-role dominance (Arciniega et al., 2008). Caballerismo is characterized by ethnic acceptance, chivalry, family-centeredness, nurturing qualities, and problem-solving coping strategies (Arciniega et al., 2008).

It has been documented that Latinx men with high levels of caballerismo and high levels of perceived academic racism produce motivation for success to achieve their aims of protecting and providing for their families (Liang, Salcedo, & Miller, 2011). Latinx men with high levels of caballerismo and low levels of perceived academic racism placed less restrictions on emotional behaviors with other men, thus reflecting a reduction in feeling the need to validate their sense of Latinx masculinity in academic contexts (Levant & Fisher, 1998; Liang et al., 2011). In addition, self-confidence and traditional gender norms were commonly observed among Latinx men (particularly Mexican-American) of more recent generational status and lower socioeconomic status respectively (Ojeda, Rosales, & Good, 2008). Family plays a major role in Latinx men's college persistence as a source of motivation (e.g., parental encouragement) or distraction (Ojeda et al., 2011, Sáenz, Bukoski, Lu, & Rodriguez, 2013; Sáenz, Mayo, Miller, & Rodriguez, 2015). In alignment with the notion of caballerismo, Latinx men's pursuits of higher education can be interpreted as being framed by notions of *familismo* (Marin & Marin, 1991; Suarez-Orozco & Suarez-Orozco, 1995) with aims of ultimately supporting their families.

Undergraduate Latinx men minimally engage in help-seeking behaviors in times of struggle to avoid being perceived as vulnerable, less self-reliant, and thus feminine (Cabrera, Rashwan-Soto, & Valencia, 2016; Gloria, Castellanos, Scull, & Villegas, 2009; Sáenz et al., 2013; Sáenz et al., 2015). Cabrera and colleagues (2016), for example, detailed constructions of self-defeating masculinities among Latinx men at a predominantly White university that brought them to downplay the significance of academic and racial stressors, internalize responsibility for managing these struggles, and refuse seeking help because it was an affront to their masculine pride as well as a manifestation of fear and vulnerability. Such avoidance of help-seeking was a performative strategy that protected the undergraduate Latinx men's masculinity while also jeopardizing their academic success. Focusing on persistence and success in community college, Sáenz and colleagues (2013, 2015) documented how Latinx men managed gender role conflicts with their pursuits of higher education. Machismo operated as both a barrier to academic success and a "quasi-positive" source of motivation for success, mainly by way of competition with Latinx women (Sáenz et al., 2013). Caballerismo guided Latinx men's management of fears about academic failure by positioning full-time employment after high school and higher education at odds with one another, the former representing a "cultural marker of manhood" (p. 91) for the advancement of supporting their families (Sáenz et al., 2013). The positioning of employment as a form of successful Latinx masculinity shaped the discouragement that Latinx men received about going to college from hometown peers as well as discourses of Latinx women as smarter and more destined for higher education than Latinx men (Sáenz et al., 2015).

## Theoretical Framework

This study synthesized various perspectives into a theoretical framework that guided data analysis. Critical race theory (CRT) in education is a perspective that "foreground[s] and account[s] for the role of race and racism" (Solórzano & Yosso, 2002, p. 25) to disrupt racism and other intersecting systems of societal oppression (e.g., sexism, classism) in schools and classrooms. Intersectionality (Crenshaw, 1991), a tenet of CRT, refers to the constitution of unique systemic forms of oppression experienced at intersections of race, class, gender, and other identities. As a "close cousin" to CRT, Latinx critical race theory (LatCrit) was adopted to examine the intersectionality of experience among Latinxs in relation to culture, immigration, and language that often go unaddressed in CRT (Bernal, 2002). The intersectionality tenet of CRT and LatCrit focused this analysis by exploring variation in participants' strategies for negotiating mathematical success with different intersections of their social identities.

## Methods

This yearlong study took place at a large state university in the northeastern U.S. Less than 15% of the 2011-2012 graduating class was Latinx. These Latinx graduates earned only 10% of the university's conferred STEM degrees. Latinx study participants were purposefully recruited based on criteria informed by extant scholarship on successful underrepresented students in STEM (Cole & Espinoza, 2008; McGee & Martin, 2011; Stinson, 2008). Five Latinx participants (2 women and 3 men) were recruited from the university's chapter of the Society of Hispanic Professional Engineers (SHPE), a national organization aimed at empowering the Hispanic community in realizing its potential in engineering through STEM outreach and professional networking. The analysis presented in this report focused on two Latinx men: Brian (a third-year, Peruvian electrical engineering student who had transferred from a community college and immigrated to the U.S. when he was twelve years old) and Daniel (a fourth-year, Dominican- and Ecuadorean-American mechanical engineering student).

Phenomenology informed the study's methodology of collecting and critically examining multiple "texts of life" (Creswell, 2013) to detail the phenomenon of mathematical success among the two Latinx men as engineering majors at the university. Under the CRT perspective, these "texts of life" informed the analytical construction of the two Latinx men's *counter-stories* (Solórzano & Yosso, 2002). Counter-storytelling is a methodology used to tell the stories of marginalized individuals in society that "aims to cast doubt on the validity of accepted premises or myths, especially ones held by the majority" (Delgado & Stefancic, 2001, p. 144). The coupling of CRT with LatCrit framed the study's cross-case, phenomenological analysis of mathematical success as an intersectional endeavor across the two Latinx men's counter-stories.

Four types of data were collected: (i) mathematics autobiographies, (ii) fields notes from classroom observations, (iii) semi-structured interviews, and (iv) a focus group. Observations in the participants' mathematics classrooms and engineering department offered situated insights to complement participants' reflections of experience captured in other data sources for the study.

The mathematics autobiography, completed prior to the first interview, allowed participants to adopt a storytelling role by writing a story of 3-4 paragraphs chronicling major experiences in mathematics. Field observations were completed in participants' college mathematics classes, including three 80-minute lectures and three 80-minute recitations or problem-solving workshops per semester. These observations detailed the instructional and relational spaces of the mathematics classrooms as well as participants' engagement noted in terms of interactions and participation (e.g., answering and asking questions) or lack thereof.

Throughout the academic year, participants completed three 60-minute, semi-structured individual interviews. All interviews were audiotaped and transcribed verbatim. The interviews were opportunities for participants to share and explore what being Latinx and mathematically successful meant to them across different contexts (e.g., classroom, home, SHPE meetings). Interview questions were structured in an open-ended manner, allowing participants to describe varying levels of consciousness of their different social identities across these contexts such as the mathematics classroom (Bowleg, 2008).

In addition, participants completed a focus group centered on three stimulus narratives of events from their mathematics lectures and recitation/workshop sessions. These narratives related to dynamics explored in extant literature of students taking up classroom space (Hand, 2012), stereotypes of mathematical ability (Shah, 2017), and faculty-student relationships (Battey, Neal, Leyva, & Adams-Wiggins, 2016). Participants were probed on the extent to which they observed such dynamics in mathematics classrooms and whether or not they saw themselves in similar situations. The focus group was audiotaped and transcribed verbatim.

Phenomenology guided data analysis by focusing on patterns across participants' mathematics experiences to detail the phenomenon of mathematical success and how it was negotiated with their social identities (Creswell, 2013). Open codes were used to identify the institutional, interpersonal, and ideological influences on mathematical success while axial codes examined the intersectionality across participants' mathematics experiences (Bowleg, 2008; Creswell, 2013). While some axial codes were specific to individual social identities (e.g., race, gender), other axial codes corresponded to different intersections of these identities such as race-gender (Bowleg, 2008). Implicit instances of intersectionality were made explicit through analytical consideration of subtexts in participants' narratives of experience (Banning, 1999).

Validity was reinforced through triangulation of collected data, memoing, and member checking. I brought awareness of my positionality to pursue data analysis with strong subjectivity to develop nuanced understandings of the undergraduate Latinx engineering students' mathematical success. In addition, I developed positive rapport and mutual trust with participants supported by our mutual identification as Latinx STEM majors.

## Findings

Three themes emerged in the cross-case analysis of Brian's and Daniel's counter-stories: (i) managing risks of mathematics classroom participation, (ii) building academically and socially supportive relationships with faculty members, and (iii) negotiating pursuits of STEM higher education with their gendered sense of commitment to family. This section presents the variation in the two Latinx men's co-constructions of their masculinities and mathematical success as engineering students with respect to these three analytical themes.

First, the Latinx men's experiences capture how the university's mathematics classrooms constructed racialized hierarchies of ability (Martin, 2009) along which Latinxs were positioned lower than their White and Asian classmates who were more regularly invited to participate. The Latinx men discussed how such racialized positioning resulted in managing risks associated with classroom participation to protect their status of mathematical ability from negative judgment. Brian described the classrooms' "tense and competitive" atmosphere where he "didn't have the guts" to respond to professors' questions like his White classmates did and avoided possibilities of "feel[ing] embarrassed" if professors thought he did not know the content well. Daniel reflected on "closed off" opportunities from connecting with higher-status peers "who go above and beyond" in participation, unlike him who remained silent because "no one want[ed] to be wrong." Unlike Daniel, Brian felt ease connecting with classmates of any race because they were in the "same position" as him in being successfully admitted to the university. Brian "got used to" being underrepresented in mathematics classrooms and viewed all classmates as "experiencing the same stuff [he was] experiencing" as university STEM students. Limited classroom participation and perceptions of sameness among peers capture the Latinx men's strategies for managing the racialized dynamics of undergraduate mathematics classrooms. However, such nonparticipation and erasure of social differences are problematic as they perpetuate ideologies of whiteness in mathematics that position Latinx students as less mathematically able and mathematics as a neutral, cultureless domain (Battey & Leyva, 2016).

Secondly, the Latinx men reflected on the importance of building academically and socially supportive relationships with professors in and out of the classroom. Brian and Daniel valued professors who established relational spaces in classrooms that welcomed student participation, prioritized mathematical understanding, and were characterized by supportive teacher-student interactions. These influential faculty members' support went beyond coursework assistance, including office hour conversations that were emotionally-reaffirming "turning points" in the Latinx men's academic trajectories as engineers. Brian recalled a meaningful "big talk" with an Argentinian engineering professor at the community college who acknowledged his ability as a mathematics minor and encouraged him to pursue an engineering major. As a fellow Latinx man, the professor's advice was informed by his awareness of Latinxs' marginalized position in society, thus describing an engineering pathway as an opportunity for Brian to apply his ability in challenging deficit views by "be[ing] one of those persons who tries to make yourself look good and also your community." Daniel's relationship with a Honduran calculus professor, Benjamin, played a role in his "metamorphosis" as a calculus student when he began sitting toward the front of lecture halls, voluntarily attending office hours, and feeling like he "could become an engineer." He described Benjamin as a "uncle-grandfather hybrid" who, in speaking Spanish with him during office hours and sharing childhood stories during class, brought him to feel "more comfortable" than with other university professors who "felt like robots." These professors' blending of academic and social support can be likened to notions of apoyo (moral support, Auerbach, 2006) and consejos (culturally-specific forms of advice; Delgado-Gaitan, 1994) that Latinx children receive from family members for educational advancement. I argue that, while both professors in these examples were Latinx men, such family-like forms of support can be adopted by faculty members from other backgrounds with a critical awareness of Latinx men's marginalized positions in higher education and society to inform more equitable educational practices.

Lastly, Brian's and Daniel's counter-stories captured how the Latinx men's familismo shaped how they made meaning of their pursuits of mathematical success and engineering careers as masculine endeavors. Brian's low-income, immigrant family background shaped his perceptions of STEM higher education as an opportunity to pursue a "good career" as an engineer, allowing for social mobility in the U.S. and to "help [his] parents out with economic problems." He viewed his STEM pursuits at a four-year university as being tied to a sense of responsibility of becoming "someone to look up to" in his hometown community. Daniel approached his engineering degree pursuits by associating academic failure with a sense of guilt about letting down his family. Graduating and becoming an engineer were ways that Daniel saw himself "represent[ing]" for his family and meeting his brother's gendered expectations that "you're not a man until you live alone [and] pay your bills." Brian and Daniel, therefore, similarly engaged in forms of caballerismo -- a construction of Latinx masculinity characterized by family-centeredness – through their views of undergraduate mathematical success and engineering career pursuits as ways to contribute to the advancement of their respective family situations. The Latinx men also reflected on having encountered implicit forms of racism in relation to their mathematical ability as engineering students. While Brian reflected on his encounter with a hometown police officer who appeared "a little bit shocked" after learning about his engineering degree pursuits, Daniel interpreted Asian American peers asking for his grade on a mathematics exam as them adopting a "subtle change of words" to essentially ask if he failed. Being mathematically successful, as a result, served as a way for the Latinx men to show that "we're [Latinxs] not stupid" (Brian) as well as "not fall victim to the stereotypes" (Daniel) of racialized mathematical ability. They saw their STEM higher education pursuits as ways of them not becoming a "delinquent or deviant person" (Brian) as well as "not be[ing] a statistic" (Daniel), thus challenging discourses about Latinx men as criminals and underrepresented in higher education respectively. Brian's and Daniel's counter-stories, therefore, illustrate how their family-centered sense of caballerismo shaped their persistence as engineering students and coping strategies for managing interpersonal slights about their academic ability as Latinx men.

## Implications for Educational Practice

Findings from this study raise implications for educational practice. The Latinx men's strategic management of risky classroom participation and limited opportunities for establishing classmate connections highlight undergraduate mathematics educators' important role in designing instruction and participation structures that disrupt racialized and other socially exclusionary status of mathematical ability. With public forms of help-seeking perceived as an affront to successful constructions of Latinx masculinity, it is important for mathematics educators to consider the extent to which they extend opportunities for student support rather than solely expect students to initiate contact. Brian's and Daniel's appreciation of faculty support, likened to notions of apoyo and consejos in Latinx families, illustrates the value of culturally-affirming teaching in undergraduate mathematics toward increasing retention and inclusion among underrepresented groups in STEM. With Brian and Daniel left largely on their own in negotiating engineering pursuits with their commitment to family as well as oppressive discourses about Latinx men, it is important for higher education institutions to carve spaces that bring Latinx men together for collective forms of coping and support in managing the racialized-gendered burdens of such experiences.

# Schema Development in an Introductory Topology Proof

Ashley Berger
University of Oklahoma

Sepideh Stewart
University of Oklahoma

*This is an exploratory study into schema development of introductory topology students. We discuss Skemp (1987) and Dubinsky and McDonald's (2001) definitions of schema and how they fit with Piaget and Garcia's (1989) triad framework. We employed these theoretical instances on the idea of schema to analyze students' responses to a final exam problem about a basis for the product topology on a product space. Our analysis indicates that the majority of the students were still in the beginning stages of schema development by the end of the semester in a topology course.*

*Keywords:* schema, Topology, basis

## Theoretical background

Advanced mathematics courses are often difficult for undergraduate students to transition into and research on student difficulties on advanced courses, especially on topology, are scarce. The overarching goal of this project is to build a theoretical framework investigating the differences between expert mathematicians and novice undergraduate students' schemas in topology. We also would like to be able to investigate how students' schemas develop (Piaget's accommodation) and how interactions with peers and instructors affect that development. In this case study, we embark on this journey by examining undergraduate students' proof attempts involving a basis for the product topology on $X \times Y$.

We will employ the idea of schema to gain more insight into the transition towards advanced mathematics, specifically towards topology. Although there are multiple definitions of schema currently in the literature, in this study we will mostly focus on Skemp's version. In 1962, Skemp argued for the need of a valid learning theory that was developed in classrooms:

> A theory is required which takes account (among other things) of the systematic development of an organised body of knowledge, which not only integrates what has been learnt, but is a major factor in new learning: as when a knowledge of arithmetic makes possible the learning of algebra, and when this knowledge of algebra is subsequently used for the understanding of analytical geometry. (p. 133)

Skemp (1962, p. 133) defines schema as the "organised body of knowledge" that integrates existing knowledge and is a major factor for new learning. Additionally, he defines and compares schematic learning to rote learning (non-schematic learning). Unsurprisingly, he finds that "Schematic learning has a triple effect: more efficient current learning, preparation for future learning, and automatic revision of past learning." (p. 140)

Skemp (1987) gives a more detailed definition of schema in his chapter, "The Idea of a Schema". He describes a system where concepts are embedded in a hierarchical structure of other concepts, where levels in the structure are classifications of concepts. For example, a train can be classified as a mode of transportation and can contribute to one's concept of transportation. We can also pair concepts together, giving a relation between them, which we can also classify. Additionally, we can look at transformations of concepts, which can be combined to make other transformations. What makes this hierarchical structure of concepts, relations, and transformations so deep and complex is the fact that these classifications are not unique, giving way to multiple hierarchical structures, which can be interrelated. When components of these conceptual structures come together to make a structure that would not be realized by only looking at the individual components, we call this resulting structure a schema. Skemp (1987) claims that a schema integrates existing knowledge, serves as a tool for future learning, and makes understanding possible. Without a suitable schema, students will have difficulty in understanding or making sense of new concepts. Skemp (1987) used topology in his work for the reason that "the relevant schema can be quickly built up, whereas most mathematical ones take longer." (p. 30) Although this study focuses on a more advanced topology question than Skemp did, we still believe that topology offers ideal topics to observe schema development with since most students do not encounter topology until late in their undergraduate work.

Another definition of schema is embedded in APOS Theory (Dubinsky & McDonald, 2001). Actions, processes, and objects are used to define a schema. Actions are external transformations of objects that become processes once internalized. After an individual becomes aware of a process and the transformations that can act on it, the process has become an object itself. Dubinsky and McDonald (2001) continue on to define schema:

> Finally, a schema for a certain mathematical concept is an individual's collection of actions, processes, objects, and other schemas which are linked by some general principles to form a framework in the individual's mind that may be brought to bear upon a problem situation involving that concept. This framework must be coherent in the sense that it gives, explicitly or implicitly, means of determining which phenomena are in the scope of the schema and which are not. (p. 3)

Clark et al. (1997) discussed an application of Piaget and Garcia's (1989) triad framework, Intra, Inter, and Trans, to the chain rule in Calculus. This triad is a theory for schema development within the context of APOS. Before a schema is coherent, it must go through these three stages. In the Intra stage, an object is thought of in isolation from other actions, processes, or objects. Once relationships are seen between the object and other actions, processes, objects, and schemas, the individual is in the Inter stage, also known as a pre-schema. In the Trans stage, a coherent structure begins to underlie the relationships from the Inter stage, and there now exists a schema for the original object in question.

As an example, consider the development of a schema for a topology. Working purely within the definition of a topology and considering basic examples is in the Intra stage. The schema enters the Inter stage once connections between the definition and previous knowledge are made. This includes more complex examples and possibly basic proofs. Viewing a topology as how open sets are defined for a topological space and being able to apply that in more complicated proofs demonstrates ideas in the Trans stage. This triad will be used as a place to begin analyzing schema development for a proof in an introductory topology course.

We view Piaget and Garcia's (1989) triad framework as a continuous spectrum for developing a schema. Dubinsky and McDonald's (2001) definition of schema overlaps with only the Trans stage since that is when a coherent structure appears. In comparison, Skemp's (1987) definition of schema not only overlaps with the Trans stage, but all stages of the triad framework. In our view, an idea does not have to be fully developed or correct in order to be a part of a schema. Our research question for this project is "With respect to the triad spectrum, how developed are introductory topology students' schemas for a basis for a topology?"

## Method

This is a case study into introductory topology students' thinking about a basis for a topology. Eleven final exams were collected and de-identified from a senior-level undergraduate topology class at a research university in the Southwest US. This study focuses on the first of the nine exam questions, shown in Figure 1.

1. (a) Let $(X, \mathcal{T}_X)$ and $(Y, \mathcal{T}_Y)$ be two topological spaces. Define the product topology $\mathcal{T}$ on $X \times Y$.

   (b) Show that the projection map $p_X : X \times Y \to X$ defined by $p_X(x, y) = x$ is an open map.

*Figure 1. Question 1. Define and use the product topology on a product space.*

We chose this question for a couple of different reasons. First, it is structured such that students who are in-between the Intra and Inter stages of their schema development for a topology generated by a basis can still answer part a. Then part b requires students to be at least in the Inter stage of schema development. This question quickly reveals students whose schemas are still in the Intra stage.

Compared to other questions on the exam, this problem is more consistent with content from a typical introductory topology class. It would be unusual if the product topology on $X \times Y$ and the use of a basis did not appear in a beginning topology course, and therefore this problem is one that can be considered for use in future expansions of this study. This problem was also the first on the exam and therefore all of the students made an attempt on it.

The data was initially coded by identifying the types of errors made in each part of the problem (see Table 1). We then went through a second round of coding for consistency and grouped the responses together based on these errors and attempted to analyze them with the triad spectrum.

*Table 1. Types of errors.*

| Code | Description | Percentage of Students with Error |
|---|---|---|
| B | Left blank or contributed no original thoughts | 9.1% |
| IN | Issues with notation | 36.4% |
| IL | Issue of beginning proof with conclusion/other incorrect logical statement | 45.5% |
| NB | No reference to a basis | 63.6% |
| LC | Lacking clarity | 72.7% |
| LL | Lacking logical flow | 18.2% |
| LD | Lacking direction | 9.1% |

## Results and Discussion

The product topology on $X \times Y$ can be defined using the collection $\beta = \{U \times V | U \in \mathrm{T}_X, V \in \mathrm{T}_Y\}$ as a basis. The proof for part b involves three main components:

A. Noting that all open sets can be written as a union of basis elements (this part may be considered part of the definition of a basis depending on how it was presented in class)
B. Noting that the projection of a union is a union of projections
C. Showing the projection map is an open map for basis elements

We understand it is up to each instructor as to how detailed students' proofs should be, but these three components should at least be noted somehow in the proof. Figure 2 gives an overview of the proof schema. The arrows in the figure indicate previous knowledge that is needed in order to complete parts of the problem.

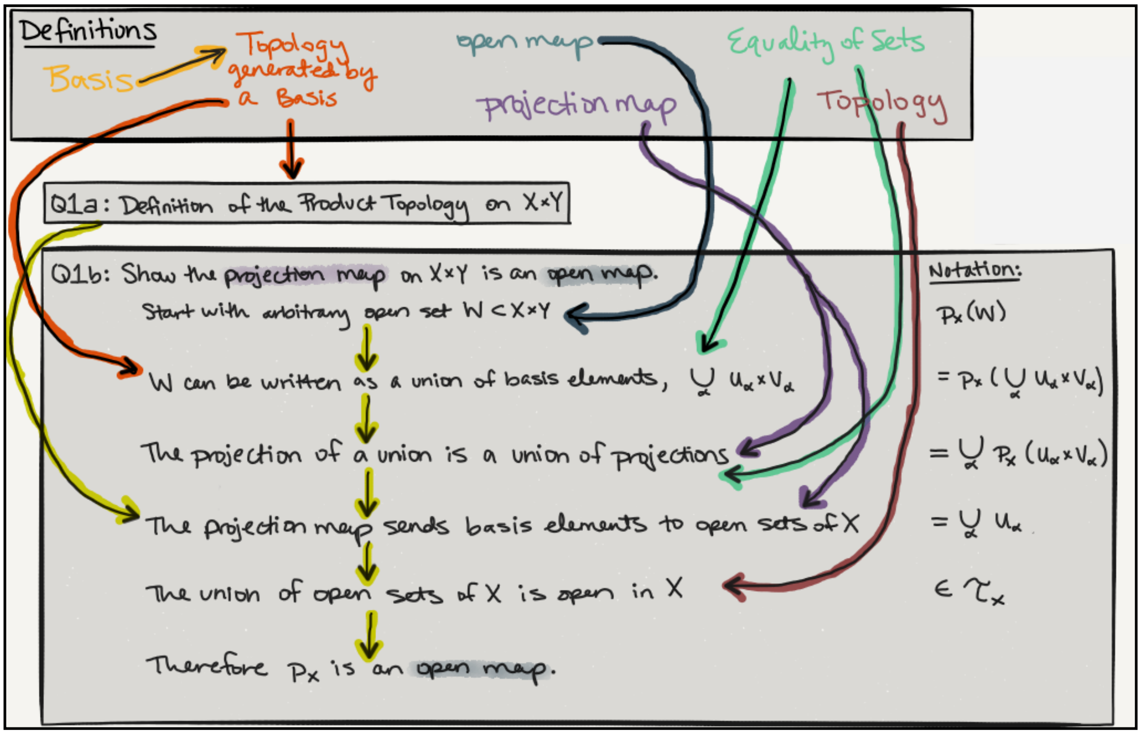

*Figure 2. A proof schema for the problem.*

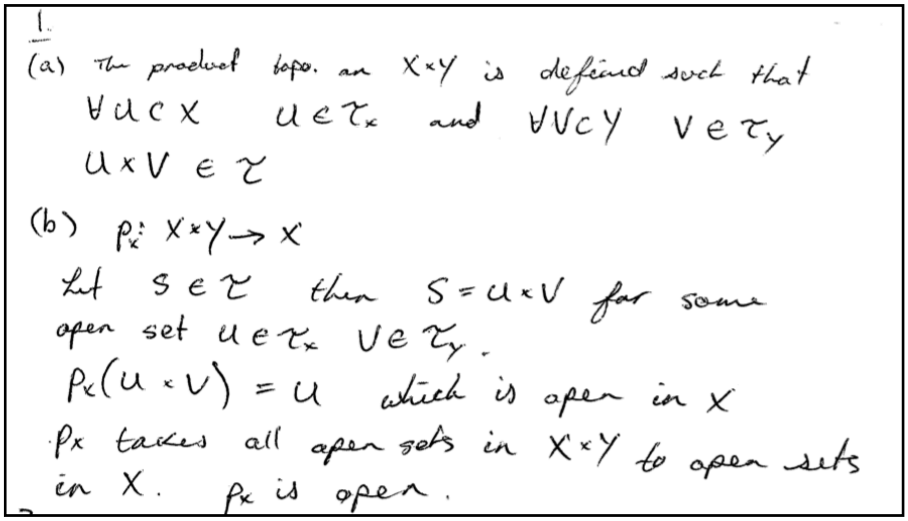
Seven of the eleven students did not use a basis to define the product topology on $X \times Y$ and six of those seven students claimed that the topology on $X \times Y$ is $T_{X \times Y} = \{U \times V | U \in T_X, V \in T_Y\}$. A typical response of this type is shown in Figure 3.

The following argument demonstrates why this response cannot be the topology on $X \times Y$ and why a basis is needed. Let $\beta = \{U \times V | U \in T_X, V \in T_Y\}$ be the basis for $T_{X \times Y}$. $U_1 \times V_1$ and $U_2 \times V_2$ are both elements of $\beta$ and therefore are also elements of $T_{X \times Y}$. By the definition of a topology, $(U_1 \times V_1) \cup (U_2 \times V_2)$ is also an element of $T_{X \times Y}$. Note, however, that the union is not of the same form as elements of $\beta$ and cannot be in $\beta$, as shown in Figure 4. So $\beta$ cannot be the entire topology on $X \times Y$.

Since the proof for part b depends on the use of a basis, the seven students who did not use a basis in part a were unable to write a complete proof for part b. They often showed component C of the proof but did not include components A or B. The students who had this type of response may not see the need for a basis, when it is appropriate to use one, or how to make use of it. There is a disconnect between this problem and the definition of a topology generated by a basis. Therefore these students' basis schemas are, at best, in the Intra stage of schema development. They have not reached the Inter stage since they are unable to connect a basis with other knowledge.



1.

(a) The product topo. on $X \times Y$ is defined such that
$\forall U \subset X$ $U \in \tau_x$ and $\forall V \subset Y$ $V \in \tau_y$
$U \times V \in \tau$

(b) $p_x: X \times Y \to X$
Let $S \in \tau$ then $S = U \times V$ for some
open set $U \in \tau_x$ $V \in \tau_y$.
$p_x(U \times V) = U$ which is open in $X$
$p_x$ takes all open sets in $X \times Y$ to open sets
in $X$. $p_x$ is open.

*Figure 3. A response that is not past the Intra stage.*

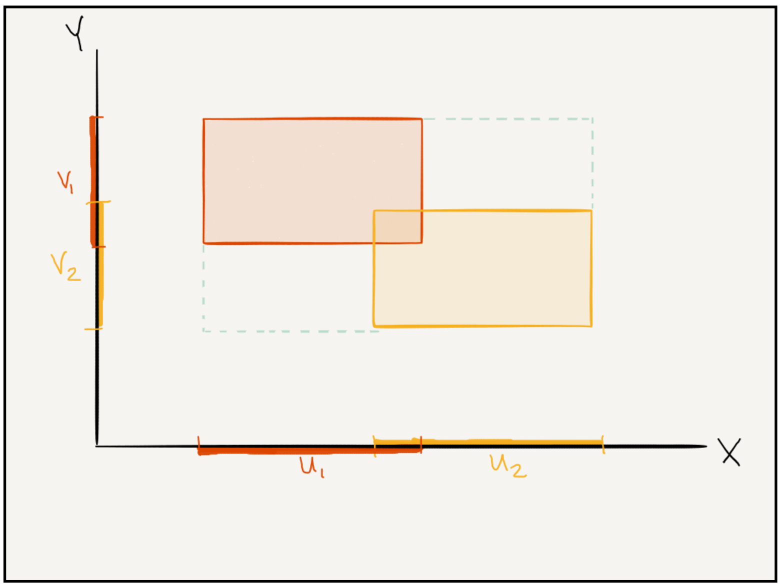


*Figure 4. A visual representation of the need for a basis.*

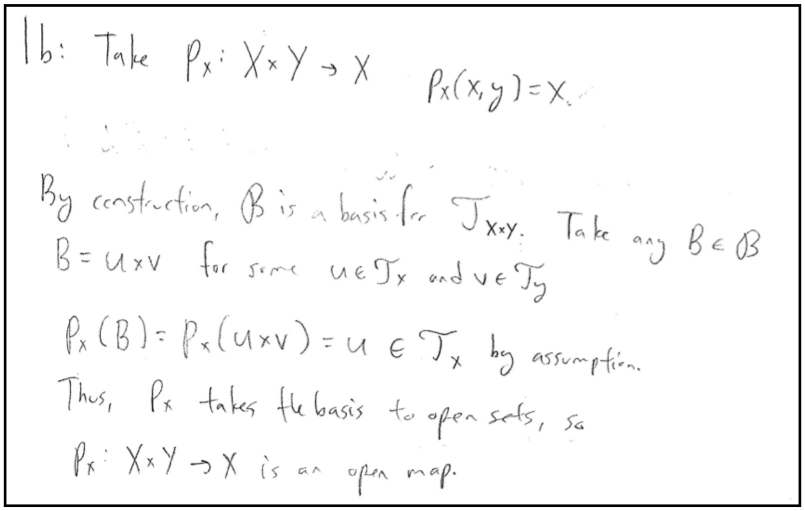
The four students who did make use of the basis had problems with incomplete proofs and notation. They would write the proof for basis elements only and then immediately jump to the conclusion of the proof without addressing components A or B of the proof. Such an example is in Figure 5. Whether or not the proof is considered to be correct depends on the instructor and the classroom norms. For this study, however, we are not as concerned about the validity of the proof as much as what it does (or in this case, does not) tell us about the student's schema of a basis. The use of the word "basis" can be used as a substitute for component A of the proof, but we cannot assume that the student did or did not understand this. The same goes for component B, which may or may not have been considered trivial in the class. We can say that this student has reached the Inter stage of basis schema development since they could relate a basis with other actions, processes, and objects, but due to the minimal amount of details in their proof, we cannot make any conclusions past this stage about their level of understanding.

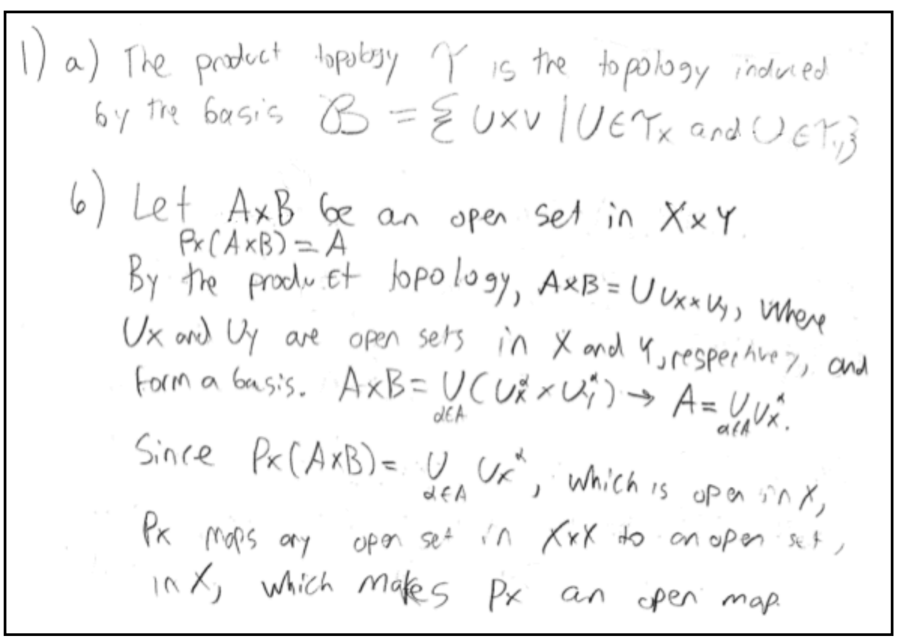


1b: Take $p_x : X \times Y \to X$ $\quad p_x(x,y) = x$.

By construction, $\mathcal{B}$ is a basis for $\mathcal{T}_{X\times Y}$. Take any $B \in \mathcal{B}$
$B = U \times V$ for some $U \in \mathcal{T}_X$ and $V \in \mathcal{T}_Y$
$p_x(B) = p_x(U \times V) = U \in \mathcal{T}_X$ by assumption.
Thus, $p_x$ takes the basis to open sets, so
$p_x : X \times Y \to X$ is an open map.

*Figure 5. A response that has reached the Inter stage.*

There were four students who had notational issues and nearly all students could have made their arguments more clear. An interesting example of this is in Figure 6. The student in this example incorrectly used $A \times B$ as their arbitrary open set of $X \times Y$, yet still included component A of the proof by saying that $A \times B$ is a union of basis elements. This indicates that the student had an understanding of the need for component A in their proof schema, but they did not understand how to denote the arbitrary open set. The student has a coherent proof structure here, but their argument could be improved with some corrections in notation. This student's response shows that they have reached the Trans stage, but there are still some notational gaps to fill in in their overall schema.



1) a) The product topology $\Upsilon$ is the topology induced by the basis $\mathcal{B} = \{U \times V \mid U \in \Upsilon_X$ and $V \in \Upsilon_Y\}$

b) Let $A \times B$ be an open set in $X \times Y$
$P_x(A \times B) = A$
By the product topology, $A \times B = \bigcup U_x \times U_y$, where $U_x$ and $U_y$ are open sets in $X$ and $Y$, respectively, and form a basis. $A \times B = \bigcup_{\alpha \in A} (U_x^\alpha \times U_y^\alpha) \to A = \bigcup_{\alpha \in A} U_x^\alpha$.
Since $P_x(A \times B) = \bigcup_{\alpha \in A} U_x^\alpha$, which is open in $X$, $P_x$ maps any open set in $X \times X$ to an open set, in $X$, which makes $P_x$ an open map

*Figure 6. A response that has reached the Trans stage.*

## Concluding Remarks

The three examples discussed in this study demonstrate three different places along the triad spectrum where student's schemas could be. Even though this problem came from a final exam at the end of the semester, a majority of the students surprisingly were still `at the Intra stage or lower in their schema development for a basis. We cannot comment on why this is since we did not collect any data regarding the norms of the class that these participants were in. This also means that we cannot know what was considered to be trivial in the course, making it difficult to analyze student's responses that are similar to Figure 5. These schemas may or may not include the components that were replaced with equivalent, but highly simplified, statements. We also do not know how much the instructor emphasized the need for a basis for certain topologies or whether or not the students had seen this problem on a previous homework assignment, both of which would affect the students' schemas.

The other limitation to this study is that it is impossible to physically see the schema of another person, so at best we can only make conjectures about participants' schema development, especially since we analyzed written proofs. Interactions with participants will be more informative in future work.

The next steps for expanding our project include interactions with the participants, data collection that occurs at the beginning and the end of a semester, and interactions between participants in either a partner or group setting. We hope to have participants explain their schemas out loud to us or a peer and to observe progress in the development of their schemas over time. We also will be asking a wider variety of questions over introductory topics to gain a better sense of which topics are more challenging for undergraduate students.

Generalizing in Combinatorics Through Categorization

Zackery Reed Elise Lockwood
Oregon State University

*In this report we discuss students generalizing within a combinatorial setting. To facilitate reflection on prior activity, we prompted students in a teaching and a design experiment to categorize a myriad of problems they had previously engaged in. We will discuss the combinatorial underpinnings behind the students' generalizations according to Lockwood's (2013) model for combinatorial understanding. We saw that the students were able to produce generalizations of various basic combinatorial problems while each maintaining different understandings of the combinatorial structures. We conclude by discussing uniformity in the students' reasoning pertaining to combinations and the productive nature of such discussions.*

Key words: generalization, combinatorics, combinations, permutations

## Introduction

The activity of generalization is integral to mathematical thought, reaching all education levels (Amit & Klass-Tsirulnikov, 2005; Lannin, 2005; Peirce, 1902). While there is a growing body of literature on student generalization, we still have much to learn about fostering productive generalizing activity in various contexts. Through a multi-phase study, we sought to better understand students' generalizing activity in a combinatorial setting. Combinatorics provides a natural setting for generalization, as counting problems are often accessible yet challenging (Kapur, 1970; Tucker, 2002). These accessible problems provide a natural structure from which students may generalize. In this report, we discuss the results of student engagement in a categorization task designed to facilitate reflection on prior work with various counting problems. The students collectively produced sophisticated generalizations while individually maintaining unique combinatorial understandings. We discuss the various nuances of their understandings as well as some affordances of attending to certain combinatorial structures.

We will discuss the students' generalizing activity in accordance with Lockwood's (2013) model for combinatorial thought. Such an analysis provides a deeper understanding of the potential source material for students' generalizations in combinatorics. We seek to answer the following research question: What do students attend to combinatorially as they generalize?

## Literature Review

### Generalization

Generalization has been recognized as a key aspect of mathematical activity by both researchers (Amit & Klass-Tsirulnikov, 2005; Davydov, 1990; Ellis, 2007b; Vygotsky, 1986) and policymakers (Council of Chief state School Officers, 2010). While much of the literature on student generalization focuses on algebraic contexts (Amit & Neria, 2008; Becker & Rivera, 2006; Carpenter, Franke & Levi, 2003; Ellis, 2007a/2007b; Radford, 2006/2008; Rivera, 2010; Rivera & Becker, 2007/2008), more recent studies have looked at undergraduate student generalizations in calculus (Dorko, 2016; Dorko & Lockwood, 2016; Dorko & Weber, 2014; Fisher, 2007; Jones and Dorko, 2015; Kabael, 2011) and combinatorics (Lockwood & Reed, 2016). Lockwood and Reed (2016) first investigated generalization in combinatorics by demonstrating two students that produced similar generalizations while holding vastly different meanings for their constructs. This report contributes to the growing body of literature by providing instances of generalization being rooted in various nuanced combinatorial understandings.

### Combinatorial Reasoning

Though combinatorics provides accessible and deep tasks (Kapur, 1970; Tucker, 2002), students struggle reasoning combinatorially (Batanero, Navarro-Pelayo, & Godino, 1997; Eizenberg & Zaslavsky, 2004; Hadar & Hadass, 1981; Lockwood, Swinyard, & Caughman, 2015b). Our hope is that through investigating how students reason combinatorially, we may discover ways to foster productive thinking in combinatorics. Studies that have been conducted in this spirit include multiple reinvention studies (Lockwood, Swinyard & Caughman, 2015a; Lockwood & Shaub, 2016) where students generated basic counting principles and formulas. One such productive way of thinking that emerged from research is a set-oriented perspective (Lockwood, 2014), where students consider the set of outcomes as integral to the solving of counting problems. Other studies have developed and tested instructional interventions (Lockwood, Swinyard & Caughman, 2015b; Mamona-Downs & Downs, 2004). Our study contributes to this literature base by implementing generalization as a means to develop deep understanding of basic counting phenomena. We offer analysis of a task through which students construct the general formulas for basic counting operations such as arrangements and combinations. By analyzing their combinatorial understandings as they generalize, we learn more about the nature of students' combinatorial thought in these basic settings.

## Theoretical Perspectives

### Generalization

For purposes of describing students' activity as they generalize, we adopt Ellis' (2007a) taxonomy of generalizing activity. Ellis describes three main categories of generalizing actions, those of *relating, searching* and *extending*. *Relating* occurs when "a student creates a relation or makes a connection between two (or more) situations, problems, ideas, or objects" (p.235). Through *relating*, students organize mathematical phenomena they experience based on commonalities. The commonalities may be nuanced, and can take on different forms such as symbolic, structural, activity and more. The relationships formed may then become the source material for further generalizations.

Students also may engage in *searching*. *Searching* occurs when students perform "the same repeated action in an attempt to determine if an element of similarity will emerge" (p. 238). In this activity, students are seeking out regularity in the mathematical operations they perform. While *searching*, students may have some potential regularity they seek to verify, but also they may have yet to discover the regularity they hope to emerge via repeated action.

Finally, students generalize through *extending*. When *extending*, a student "not only notices a pattern or relationship of similarity, but then expands that pattern or relationship into a more general structure" (p.241). This may indeed be the activity most closely associated with generalization. While *extending*, students draw upon known mathematics and then apply them in a more abstract setting. This activity accounts for the learning of more abstract mathematics than previously encountered. This taxonomy allows us to organize students' activity as they generalize.

## Combinatorial Reasoning

We also wish to describe the nuances of students' combinatorial understanding as they generalize. To do this, we utilize Lockwood's (2013) model for the different kinds of reasoning in combinatorics. Lockwood describes three unique and separate ways students reason about combinatorics problems. First, students may attend to the *formula* or *expression* of the combinatorial problem. Attention of this manner includes the symbolic form of the final answer, rather than the final numerical value. Students may also attend to the *counting processes* of a combinatorics problem. Students who reason via *counting processes* attend to the carrying out the process described by the problem. In doing so, they carry out the activity (either mentally or physically) to generate a solution to the problem. Finally, students might attend to the *sets of outcomes*. An outcome is a specific collection of the objects being counted. In considering this set, students attend to the particular structural organization of the outcome-set as a whole. This final way of reasoning is in line with Lockwood's (2014) *set-oriented perspective*, where the set of outcomes becomes a cornerstone of reasoning about any particular counting problem. Students reason in this way by viewing "atten[tion] to sets of outcomes as an intrinsic component of solving counting problems" (p.31). Further research has identified the productivity of attending to the sets of outcomes as well (Lockwood, 2013; Lockwood & Gibson, 2016).

## Methods

The data for this report draws from two larger studies in which we investigated the nature of student generalization in combinatorial settings. To do this, we conducted one paired teaching experiment consisting of fifteen hour-long sessions followed by a design experiment consisting of nine ninety-minute sessions with four students. The students from both studies were recruited from vector calculus courses, and were selected from an initial set of applicants based on a selection interview process. Each of the students in these studies had not taken a discrete or combinatorics course before so that their activity and generalizations were indeed spontaneous rather than implementations of extant schemes.

This study reports on the generalizing activity of the students during the third session of each experiment. The goal of this session was to facilitate reflection on the students' prior activity from the previous sessions, culminating in the construction of general statements of certain combinatorial structures such as the permutation and combination. To do this, we presented the students with various problems they had previously solved either in the first two session or in the selection interviews and prompted them to separate the problems into groups. They were not given any specific instructions on how to group the problems so that distinctions they found relevant would be revealed. The problems included those whose solution methods were arrangement of $n$ objects ($n!$), permutation of $k$ objects from $n$ objects $\left(\frac{n!}{(n-k)!}\right)$, selection of $k$ objects from $n$ objects $\left(\frac{n!}{(n-k)!k!}\right)$, and $k$ repeated selections from a set of size $n$ ($n^k$). Once the students agreed on the categories for the problems, they were asked to describe a general formulation of each category, and then to construct a general formula for the solution to each problem type. Both groups successfully categorized all problems into their respective four groups.

The sessions were video and audio recorded so that the records could later be reviewed for data analysis. The audio was also transcribed. Analysis consisted of reviewing the transcripts and the video files for episodes of generalizing activity. Relevant segments were further analyzed and coded according to Ellis' (2007a) framework and Lockwood's (2013) model.

## Results and Discussion

The categorization task allowed students to both reflect on combinatorial structures and to meaningfully generalize from prior activity. In terms of generalization, we saw students relate and extend commonalities in the combinatorial situations with which they had previously engaged. Further, we saw students demonstrate a fluid ability to reason with and communicate across various components of Lockwood's (2013) model. Through this categorization, the students were able to generate multiple abstract combinatorial situations that demonstrated inherently different structures. Moreover, the students showed understanding of nuanced differences between the combinatorial structures. These understandings resulted from various generalizations rooted in reflection on activity. In this results section, we will both discuss the students' generalizing actions and combinatorial reasoning. This allows for a discussion of generalizing actions motivated by underlying combinatorial understanding.

The students engaged in meaningful relating activity while categorizing the different combinatorics problems. Through the relationships created, they were then able to make general statements reflecting the combinatorial structures. For instance, when first categorizing the problem types, Carson described a collection of problems involving selection with repetition that he had just arranged. Note that in this quotation he is describing multiple problems in front of him:

> This [referring to a specific collection of problems] is independent events. So, [first problem he describes] there are eight questions but the outcome of one doesn't affect the others. [Second problem he describes] There are six characters, but the outcome of one doesn't affect the others.

Here he was relating that each question described a combinatorial structure in which there was no dependence between selections. Indeed, while his language was in terms of outcomes, he described the outcomes not affecting other outcomes in the process. From this we infer Carson held a *process*-oriented perspective. Similarly, Josh then identified two more selection with repetition problems still not categorized:

> *Instructor*: . . . and why did those two go with those [the original collection Carson grouped together]?
> *Josh*: Those two also deal with independent events and finding all the possibilities in those events depend on something raised to some power.
> *Instructor*: Okay, okay, good.
> *Josh*: Like the number of choices that you have raised to the number of choices that you make.

Note here the difference between Josh and Carson's language as they engaged in the generalizing activity of relating. While Josh was responding to Carson's attention to independent events, Josh chose to identify these problems as similar according to the formula for the answer. According to Lockwood's (2013) model, Josh is attending to *formulas/expressions* while Carson is attending to *counting processes*. This diversity in combinatorial language was common during these discussions. Indeed, students often collaboratively generated the categories while appealing to individually different combinatorial details. For instance, while categorizing the same type of problem, the students in the teaching experiment had the following exchange:

*Sanjeev*: And then you want to paint 6 different houses on your block and there are 3 acceptable paint colors you can pick —
*Rose*: Would that one come down here? Because that would be —
*Sanjeev*: You have 6 houses and —
*Rose*: 3 to the power of 6?
*Sanjeev*: you have 3 different paint colors for each, yeah. So this [problem] would be this one [referring to the collection of selection with repetition problems]?

Notice that Sanjeev and Rose were attending to different components of Lockwood's (2013) model during this exchange. Sanjeev adopted a *process*-oriented perspective by attending to the process of picking paint colors. Rose, in turn, attended to the *formula* of the answer as a means of relating the houses problem to other selection with repetition problems she experienced. This further demonstrates the students' abilities to communicate and generalize across varying combinatorial language. While it may not be surprising that students are able to communicate efficiently while demonstrating various combinatorial understandings, we can witness a variety of cognitive material as the source for generalizations. For instance, Rose and Josh both demonstrated attention to common representation (*formula/expression*) of the solutions to the problems. As a contrast, Sanjeev and Carson demonstrated *process*-based relating amongst combinatorial situations. These students continued to attend to such nuances throughout the categorization task.

While there was, as noted, variety in the students' generalizations and combinatorial understandings throughout the task, we found a surprising uniformity of language pertaining to combinations. Indeed, all students demonstrated attention to the structure of the *sets of outcomes* when discussing combinations. The discussions about differentiating combinations from other combinatorial processes revolved around taking care not to count two similar outcomes as different. For instance, when separating the permutations and the combinations, Rose and Sanjeev said the following:

*Rose*: It's [referring to the collection of permutation problems they categorized]— it's how many — it's basically how many ways to put certain amount of items into fewer spots where 1, 2, 3 and 3, 2, 1 are different. And this [the collection of categorized combination problems] is how many ways you put a certain amount of things into fewer spots where 1, 2, 3 and 3, 2, 1 are the same.
*Sanjeev*: On these ones [referring also to the collection of permutation problems] you've got combinations [not referring to the combinatorial sense of the word. Literal combinations of outcomes]. So 1, 2, 3 - 3, 2, 1 would be different combinations. With this one [a combination problem], for example, if you have identical lollipops you can label them 1, 2, 3 or you can just label them 1, 1, 1. So 1, 2, 3 and 3, 2, 1 would be the exact same thing, because 1, 2 and 3 are all the same.

We note that while they mentioned permutations during this exchange as well as combinations, their previous discussion of permutations involved only discussing either the *formula* or the *process* involved in their construction. The distinction of making $\{1, 2, 3\}$ and $\{3, 2, 1\}$ the same was brought up as a means of separating the combination from permutation. Indeed, while there was a variety of combinatorial language used during categorization, students would always use set-based language when discussing combinations. We find attention to outcomes in this way as productive, as it allows for careful consideration of what is being counted. Further, it is interesting that combinations were the only problems in which there was uniformity in the combinatorial language that the students used.

As another example, we saw similar discussions of combinations emerge from the design experiment. Initially, when describing the difference between combinations and permutations, Ann-Marie remarked:

> Yeah, so in those two problems [a pair of combination problems] you divide by two factorials to cancel out the duplicate answers whereas in the other ones you don't have to do that.

Notice that her response also included *formula*-driven language. Indeed, Ann-Marie confessed that she primarily thought of the formula representation when thinking of the problem types. Ann-Marie made the distinction of "two factorials" in this case to contrast division by "one factorial" in the permutation group. What we see here is that within her formula driven remarks, she also used outcome-based language to describe the need for the extra division by a factorial. Also, later when explaining why the formula for $\binom{n}{k}$ adds on a division by $k!$, Aaron explained:

> Well, because you're trying to get rid of all the combinations that you're not looking for that you can make out of those three slots because they're all the same. So, that just accounts for it.

Indeed, most descriptions of combinations involved *outcome* - based language so that they could be differentiated from permutations. Often, the design experiment students described "dividing by redundancies" when performing combinations. It is interesting that among the students we worked with, combinations were uniformly a source of *outcome* - based language. Returning to the teaching experiment, we see Rose also using *outcome* - based language when describing why a subset selection problem is grouped with other combinations. After negotiating the particulars of the problem involving finding subsets of a set of numbers, Rose said the following:

*Rose*: and if that was the case then we'd want to put it over into this group [the collection of combination problems].

*Int*: Okay. And how come?

*Rose*: Because now you don't want — you just want unique combinations. And if you're getting rid of all the — the repeated subsets, then you're just finding the unique combinations.

Here, we see Rose clarified that the desired outcomes were indeed "unique combinations". The uniqueness was generated by getting rid of repeated subsets, which indeed would emerge from a standard permutation. Thus, we see that Rose diverged from her typical *formula*-centered language to attend to unique outcomes. Finally, when also discussing the subset selection problem, the design experiment students had the following exchange:

*Carson*: . . . and these [their initial collection of permutation problems] you're arranging a given number of things in smaller number of spaces than there are things.

*Josh*: Is this one [the subsets problem] really the same as the others though because you're only looking for the four number set?

*Carson*: So, every number in the four limit subset is unique, right? So, there's no repeated

numbers.
*Josh*: There can be repeated numbers.
*Ann-Marie*: But like zero, one, two would be the same as one, zero, two.
*Carson*: Right and you can't have zero, zero, zero.
*Josh*: Oh, yeah.
*Carson*: So, that would be an arrangement one as well just with the caveat that there are only four of them.

Here we see two types of outcome - differentiation occurring. We see the students describing that ordering the numbers in the subset should not create a different outcome. This is consistent with the set-oriented perspective the students took on combinations. We also see Carson noting that an outcome cannot have multiples of a number in the subset. While this is not unique to combinations, it is another example of *set-oriented* language. The above discussion naturally centered around whether or not certain outcomes would be considered as distinct. Indeed, the students in both groups consistently attended to the set of outcomes while discussing combinations.

While much of the above discussions centered around the activity of relating, we also saw students engage in extending. The students were prompted to generate statements and formulas that reflected the categories they had created. The following statement the teaching experiment students wrote for the collection of combinations further reflects the *outcome*-centered underpinnings of their generalizations. Rose and Sanjeev produced the following characterization of combination problems:

3) $\uparrow_2$ *... and divide by the factorial of the given spots to delete repeated sequences because any arrangement of the same given elements is considered the same combination.*

Note that the arrow marked with a 2 at the beginning is referring to their previous statement of a permutation process. This characterization suggests that the structure of a combination involved constructing a permutation followed by the further operation of division as described above. We bring attention to their *outcome*-oriented justification for their addition to the permutation. This further demonstrates that their understanding of a general combination process involves accounting for multiple arrangements of a particular outcome. We again note that such distinctions are productive, and allow for deeper understanding of the combinatorial objects.

## Conclusions

We see that the categorization task allowed the students to generalize their prior work on individual counting problems into more general contexts in which different combinatorial structures could be illuminated. The students productively engaged in relating and extending, both activities underpinned by the nuances of the combinatorial settings, as described by Lockwood's (2013) model. We saw meaningful generalizations being underpinned by all three aspects of Lockwood's model. Moreover, there was a uniformly *set-oriented* approach to generalizing combinations. Further, such distinctions between permutations and combinations demonstrated productive understandings of the combinatorial objects. Such a perspective allows for specific criteria with which students can evaluate whether a combination or permutation applies to a counting situation. Thus, we see that through engagement in categorizing and reflecting on prior work, students meaningfully generalized while gaining a better understanding of the combinatorial objects.

# Generalizations of Convergence from $\mathbb{R}$ to $\mathbb{R}^2$

Zackery Reed
Oregon State University

*Sequential convergence is a powerful tool in the field of real analysis. Though its structure persists throughout various metric spaces, students initially understand sequential convergence as it manifests on the real line. Students often do not encounter more generalized forms until advanced analysis courses. As part of multiple teaching experiments, students were given the opportunity to generalize sequential convergence from $\mathbb{R}$ into the $\mathbb{R}^2$. This report will demonstrate various generalizations rooted in reflective abstraction of convergence in $\mathbb{R}$. We will also discuss students generalizing by reduction, reflecting on the utility of distance as a map between spaces.*

Key words: generalization, real analysis, convergence, limits, advanced calculus, vectors

## Introduction

Convergence is a phenomenon encountered at all levels of mathematical practice. A utility of sequential convergence is its persistent structure throughout metric spaces. Students studying introductory real analysis encounter the convergence of real number sequences and also of continuous functions. These contexts for convergence may be leveraged to facilitate understanding of convergence in more abstract spaces through generalization. These spaces create unique opportunities for students to generalize their understandings in productive ways.

During the selection interviews for multiple teaching experiments, students were given an opportunity to generalize convergence of real numbers to the convergence of real vectors in two dimensions. Their work revealed multiple instances of generalization rooted in abstraction of real number convergence. In this report I seek to answer the following research question: How do undergraduate students leverage convergence of real numbers when defining convergence in more abstract spaces?

## Literature Review

### Student Understanding of Convergence

While student understanding of limits and convergence has been thoroughly investigated, there is still much to learn about how students understand convergence beyond introductory contexts. Early studies investigated student initial understanding of limits, problems that may result from students' initial understandings, and intuitions behind the limit concept (Bezuidenhout, 2001; Cornu, 1991; Cottrill, Dubinsky, Nichols, Schwingendorf, Thomas, & Vidakovic, 1996, Davis & Vinner, 1986; Oehrtman, 2003/2009; Roh, 2008/2009; Tall, 1992; Tall & Vinner, 1981; Williams, 1991). Many of these studies focused primarily on student understanding of informal limiting processes, leaving room for investigations of formal limiting processes.

In 2011, Swinyard began investigating students' formal understanding of limits via a teaching experiment in which two students reinvented the formal definition of a limit. Useful constructs for describing student formal understanding of limits emerged from this experiment. Studies that followed expanded on his work, proposing strategies for fostering useful understanding of limits and also reinventing the formal definition for sequential convergence (Swinyard & Larsen, 2012; Oehrtman, Swinyard, & Martin, 2014).

Other studies have also examined student understanding of formal limiting processes. Adiredja investigated how students make sense of the relationship between the multiple limit-controlling variables (Adiredja, 2013/2015; Adiredja & James, 2013/2014). Also, Roh and colleagues (Dawkins & Roh, 2016; Roh, 2009; Roh & Lee, 2016) implemented interventions such as the "Mayan Activity" and the "$\epsilon$ -strip activity" designed to illuminate the logical structure of formal convergence. Finally, Reed (2017) examined a student's understanding of the logical structure of point-wise convergence for functions. These studies examine the nuances that accompany the logical statement of convergence.

### Generalization

While the activity of generalizing has been investigated in many contexts, such studies have not yet examined students generalizing formal mathematics. Generalization has been deemed a relevant mathematical activity both by researchers (Amit & Klass, 2005; Lannin, 2005; Pierce, 1902; Vygotsky, 1986) and educators (Council of Chief State School Officers, 2010). Indeed, generalization has been thoroughly investigated in algebraic and other elementary contexts (Amit & Neria, 2008; Becker & Rivera, 2006; Carpenter, Franke, & Levi, 2003; Ellis, 2007a/2007b/2011; Radford, 2006/2008; Rivera, 2010; Rivera & Becker, 2007/ 2008).

More recent investigations have begun to explore student generalizations at the undergraduate level. Researchers have studied student generalizations in both single and multi-variable calculus (Dorko, 2016; Dorko and Lockwood, 2016; Dorko & Weber, 2014; Fisher, 2008; Kabael, 2011; Jones and Dorko, 2015) as well as combinatorics (Lockwood and Reed, 2016). For instance, Jones and Dorko (2015) considered different ways in which the multivariable integral is understood as a generalization of notions that students held for single variable integrals, such as generalizing from an "area under the curve" model in single variable calculus. While these studies investigate the nature of generalizing activity in various advanced contexts, the research so far has not investigated generalization of formal mathematics.

This report contributes both to the literature on convergence and to the literature on generalization by observing students generalize the concept of convergence in a formal context.

## Theoretical Perspectives

### Generalization

We wish to characterize the activities students engage in while generalizing. To do this, we consider student activity according to Ellis' (2007a) taxonomy of students' generalizing activity. This examines generalization from an actor-oriented perspective (Lobato, 2003).

Ellis described three broad categories of generalizing activity in which students engage: *relating, searching* and *extending*. In *relating*, "a student creates a relation or makes a connection between two (or more) situations, problems, ideas, or objects" (p. 235). Generalizing activity can manifest as an organizing of similar situations which then become the source material for further generalizations.

The next activity students engage in is to search for a pattern or relationship. This is where students perform "the same repeated action in an attempt to determine if an element of similarity will emerge" (p.238). The distinction here is that the student repeats an activity to uncover some regularity.

Finally, students engage in *extending*. This occurs when a student "not only notices a pattern or relationship of similarity, but then expands that pattern or relationship into a more general structure" (p.241). This extension can be done in multiple ways that expand the source material to new abstraction. *Extending* moves beyond the observance of relationships or patterns, and involves the creation of new mathematical objects that reflect the source of the generalization in some way. These three categories provide us language with which to observe and discuss the generalizing activity of students in any mathematical setting.

**Abstraction**

We find Piaget's notion of *abstraction* (Piaget, 2001; Glasersfeld, 1995) to be complementary to studying student generalization. Indeed, through *abstraction* Piaget describes the cognitive mechanisms through which activity is reorganized and extended. Specifically, we are concerned with facilitating *reflective abstraction* (Glasersfeld, 1995). In *reflective abstraction*, an operation (mental activity) "developed on one level is abstracted from that level of operating and applied to a higher one" (Glasersfeld, 1995, p. 104). Indeed, *reflective abstraction* accompanies generalization as it can describe mathematical activity being organized at higher levels of thought. *Reflective abstraction* is characterized in two parts. The first is a réflexion, or reflection, of the operations from their original context (p. 104). This indeed highlights the importance of salient activity from which to abstract. The second part of reflective abstraction is a réfléchissement, or projection, of the borrowed operation to a higher level of thought (p. 104).

Thus we see *reflective abstraction* involving the borrowing of activity to then be applied at higher levels of thought. In mathematical contexts, this indeed can be used to characterize the generalization of operations. Using *reflective abstraction* as an underpinning for generalizing activity allows us to use mathematical activity as a direct source of generalization. This indeed will be useful in describing the generalizations of students as they engage in extending their mathematical understandings.

**Mathematical Discussion**

Convergence is a generalizable concept that obeys the same structure in various real spaces. Convergence of real number sequences and other seemingly more complex objects, such as uniformly convergent function sequences, are indeed the same because of the metric structure associated with each space. Consider the formal definition for convergence of real numbers: A sequence $\{x_n\}$ of real numbers converges to a real number $x$ if $\forall\epsilon>0$, $\exists N \in \mathbb{N}$ such that $\forall n \geq N$, we have $|x_n - x| < \epsilon$. The mathematical structure of such convergence stems from the definition of convergence within any general metric space: A sequence $\{x_n\}$ in a metric space $(M, \delta)$ with a metric $\delta$ converges to $x$ if $\forall\epsilon>0$, $\exists N \in \mathbb{N}$ such that $\forall n \geq N$, we have $\delta(x_n, x) < \epsilon$. Such is the case for real vectors in $\mathbb{R}^2$. Indeed, the only alteration to make in each metric space is the notion of distance. On the real line, distance is measured using the absolute value norm. While many equivalent metrics may be applied in the plane, perhaps the most natural is the metric given by the Euclidean distance. Indeed, when the distance between vectors is measured using the Euclidean distance, the convergence of a sequence of real vectors may be characterized as follows: A sequence of vectors $\{\vec{x_n}\}$ in $\mathbb{R}^2$ converges to a vector $\vec{x} \in \mathbb{R}^2$ if $\forall\epsilon>0$, $\exists N \in \mathbb{N}$ such that $\forall n \geq N$, we have $\sqrt{(x_n^1 - x^1)^2 + (x_n^2 - x^2)^2} < \epsilon$. Note that in this notation $x^k$ represents the $k$-th component of the vector $\vec{x}$.

Similarly, the characterization of Cauchy sequences is uniform throughout metric spaces: A sequence $\{x_n\}$ in the metric space $(M, \delta)$ with metric $\delta$ is Cauchy if $\forall\epsilon>0$, $\exists N \in \mathbb{N}$ such that $\forall n, m \geq N$, we have $\delta(x_n, x_m) < \epsilon$. This allows for Cauchy sequences to be characterized on the real line by: A sequence $\{x_n\}$ of real numbers is Cauchy if $\forall\epsilon>0$, $\exists N \in \mathbb{N}$ such that $\forall n, m \geq N$, we have $\delta(x_n, x_m)<\epsilon$, and on the real plane by: A sequence of vectors $\{\vec{x_n}\}$ in $\mathbb{R}^2$ is Cauchy if $\forall\epsilon>0$, $\exists N \in \mathbb{N}$ such that $\forall n, m \geq N$, we have $\sqrt{(x_n^1 - x_m^1)^2 + (x_n^2 - x_m^2)^2}<\epsilon$.

## Methods

This study reports on the selection interviews and the first sessions of multiple teaching experiments (Steffe and Thompson, 2000) being conducted for my dissertation. Two of the teaching experiments conducted were for pilot purposes, and consisted of six hour-long sessions each with one student. The other two teaching experiments consisted of ten 90-minute sessions, one with a pair of students and one with an individual student. The students reported on were each mathematics majors at a large university. Each were recruited out of the advanced calculus sequence, and had finished at least one course in the sequence before the interviews were conducted.

The sessions were semi-structured and task-based (Hunting, 1997) so that student activity could be observed and understanding could be inferred. The goal of these episodes was to facilitate reflection on real-number convergence and the characterization of the absolute value as a measurement of distance. Thus, the interviews began with discussions of real number convergence and distance measurement on $\mathbb{R}$ and $\mathbb{R}^2$. The students were prompted to write down and explain their definitions of real number convergence, and then to demonstrate that a specific sequence converges. Once details were discussed, and distance measurement was thoroughly discussed, the discussion turned to convergence of vectors. The students were prompted to characterize convergence of a sequence of vectors, and similarly demonstrate that a specific sequence of vectors converges. Any further discussion negotiated nuances of their multiple characterizations of convergence.

The interviews were video recorded, and the records have been reviewed multiple times looking for episodes of student generalization to be analyzed using Ellis' (2007a) framework and Piaget's (2001) construct of reflective abstraction.

## Results

### Convergence on $\mathbb{R}$

Each interview began with a review of the known distance and convergence concepts on the real line. I will describe an understanding commonly held by the students that was relevant for their generalizations of convergence.

When prompted to characterize convergence of a sequence of real numbers, each student gave the standard $\epsilon$-N definition described above in the mathematics section. The discussion that followed allowed the students to further explain their understanding of the characterization. For instance, Kyle said the following while describing distance measurement via the absolute value function while characterizing a Cauchy-convergent sequence:

> Well we end up measuring the distance between two subsequent points. That's what we're doing here-we're saying that the absolute value of $a_n - a_m$ is the distance between these two points in the sequence. So you're trying to measure, as your $n$ is getting arbitrarily large, what's happening between this point in the sequence [$a_n$] and this point in the sequence [$a_m$].

The absolute value as a distance measurement on the real line similarly emerged in all of the interviews. For instance, using $1/n$ as an example, Jake said the following while explaining why we take the absolute value to characterize Cauchy-convergent sequences:

> If we had this instead of $1/n$ be $-1/n$ ... we're just concerned with the width between the numbers not where they are relative to the $x$-axis ... 'cause we're always concerned with the relative distance of the two. Not if it's, you know, below of above the $x$-axis. The absolute value takes care of that.

Similar discussions of real number convergence were had with all students in the study. Each student displayed a sophisticated understanding of sequential convergence on the real line. These discussions then influenced the students' generalizations of convergence to $\mathbb{R}^2$

**Convergence on $\mathbb{R}^2$**

Following discussions of convergence on the real line and characterizations of distance in $\mathbb{R}$ and $\mathbb{R}^2$, the students were prompted to develop a characterization of vector convergence. Two distinct generalizations emerged from the students' characterizations of vector convergence. Both generalizations result from reflections on real number convergence.

The first generalization involves considering vectors on the real plane component-wise and isolating real number sequences in each component. This generalization manifested differently among the students, each instance demonstrating unique understandings. Laura and Kyle considered vectors in terms of their components separately, and described a sequence of vectors as a pair of real-number sequences. This allowed for convergence of the sequences to rely on convergence of the components. Below, Laura described the sequence of vectors converging in the following manner:

> If this [a sequence of vectors $\{\vec{v_n}\}$] converges, then that means your x-component has to converge and your y-component has to converge. Which is realistically seeing if - two independent sequences converges - you have some sequence $\{x_n\}$ and some sequence $\{y_n\}$ that make up your vector, then it's basically like doing the convergence thing twice but you have to fit it for both $x$ and $y$.

Here Laura extends convergence of real numbers to a vector setting by making note that a sequence of vectors forms two sequences of real numbers, and asserts that controlling the convergence of each component will result in a convergent sequence of vectors. Note that here, Laura is using the known structure for convergence of real numbers.

Jerry, Jake and Christina produced similar component-wise characterizations, however their approaches differed subtly from Kyle and Laura. Specifically, Jake and Christina attempted to bound the sequence of difference vectors by an "error vector". When generalizing convergence to two dimensions, Christina initially wrote out again the definition of real number convergence, and used the same notation as real-number convergence, while noting the caveat that in this case $|A_n - A|$ denoted a distance between vectors. Moreover, she described making the distance vector "smaller" than some error vector $(a, b)$:

> So, this [$A_n^1 - A^1$] is describing the horizontal distance that will be traveled, and then this [$A_n^2 - A^2$] is describing the vertical distance that will be traveled. And the whole entire thing describes a vector that would create that translation, and it's going to be - I guess less than would actually be smaller than - the $\epsilon$ vector.

Christina went on to describe that in this context “less than” does not necessarily mean an ordering, but instead referred to the sizes of the vectors. From this, she reduced convergence to comparing the components of the difference vector $\{A_n - A\}$ and the ”error vector”. She then reduced the vector comparison to a component-wise comparison and arrived at a similar characterization as above. Similarly, Jake wrote a characterization for Cauchy-convergence of vectors that was identical to Christina’s up to notation. Motivated by the behavior of a sequence when the y-axis is constant, Jake said the following:

> And you do the same with the $x$-axis. You get an analogous statement with the $x$-components [where keeping the x-components constant yields a real number sequence in the y-components]. But we have the difference between the $x$-components and the $y$-components both decrease below some arbitrary $\epsilon$. Otherwise you could have convergence with respect to the $y$-axis but having it oscillate back and forth in the $x$, or increase without bound on the $x$ or vice versa.

So for Jake, while the problem of convergence was to capture varying vectors, the variation could be simultaneously handled in both components.

Thus we see these students were able to reduce the problem of vector convergence into a form that they are familiar with, namely convergence on the real line. In this case, they reflected that they could iterate real number convergence a finite amount of times (in this case twice), and that convergence of each component implied convergence of the vector as a whole. Mathematically, these characterizations are interesting because multiple geometries can result from considering the component-wise absolute value distances, including the $\ell_1$ and $\ell_\infty$ distances.

The final generalization we will discuss differs from the generalizations above in that it involves reflection on the role of measuring distance in convergence, rather than taking advantage of the repeatability of real number convergence. It involves reflection on structures that are more consistent with a general metric. After being challenged to find a characterization of convergence that involves a single calculation rather than multiple calculations, Jerry and Christina together used the Euclidean distance formula to create a sequence of the distances between vectors in the sequence and the convergent vector. These distances formed a sequence of real numbers that would converge to 0. After formalizing the convergence of the sequence of distances, Jerry made the following statement:

> I like this ‘cause it seems like we reduced the problem to something that was like, that we already know, so I feel like this is on the right track So we now have this number that we can check for every single vector in our sequence and that generates a sequence of real numbers which we already know the rules of convergence for. And that’s something we can check.

Jake constructed a similar generalization of a Cauchy-convergent sequence of vectors. These generalizations allow for direct comparison between vectors involved in the convergence process via a distance calculation. As the students indicated, this calculation allows for the convergence to be stated in terms of a varying set of real numbers, namely the sequence of distances between the elements of the set of vectors converging. This transforms the problem into one of a known operation, namely the convergence of real numbers. This, in fact, is the logical structure of convergence in abstract metric spaces. In contrast, the students’ first generalization is indeed also generalizable, but only within finite dimensional vector spaces, as the requirement of checking convergence in each component is only possible a finite number of times.

## Discussion and Conclusion

### Reflective Abstraction

Within these episodes we see multiple instances of reflective abstraction when generalizing sequential convergence from the real line to $\mathbb{R}^2$. While both generalizations involve reflection on the structure of convergence along the real line, the réfléchissement of such reflection is manifest in two qualitatively different ways. I infer that the component-wise construction involves abstractly projecting the action of taking a limit on the real line. In observing that vectors can be expressed via components of real numbers, and formulating the sequences of vectors to reflect real number sequences, the students project convergence of real number sequences to two simultaneous iterations of real number sequences that converge in conjunction with one another. This involves reflection on the process of real number convergence, and then projection of this to each component in the vector structure.

### Generalizing through reduction

While the second generalization also may be characterized via reflective abstraction, it also reveals a new form of generalizing by extending. Within this episode we also see instances of students generalizing a more abstract phenomenon by reducing aspects of the problem to a known setting. Jerry and Christina, as well as Jake, utilized the Euclidean distance formula as a map from $\mathbb{R}^2$ to $\mathbb{R}$ that reduced the problem from one that involved 2-dimensional geometry back to the convergence of real numbers. Thus, the students manipulated the structure of the problem at hand to match a familiar structure. The use of a mapping in this way is entirely consistent with productive activity in multiple areas of mathematics. As an example, the integral can be similarly used to reduce problems of functional variation to problems of varying real numbers via special limiting processes. These are interesting instances of generalization, as they involve coordinating of an abstract process via simplification. This is indeed reminiscent of Jerry's final comment. Moreover, while Jerry and Christina were challenged to perform a single calculation, their characterization of the problem in terms of a sequence of real-number distances involved constructing an explicit relationship between the vectors that varied in the sequence and the known structure of $\mathbb{R}$.

### Conclusions

In this report we see two distinct generalizations rooted in sophisticated understandings of real number convergence. By reflecting on convergence as an activity, the students generated two generalizations unique from each other mathematically and cognitively. The generalization characterizing vector sequences as pairs of real numbers reflectively abstracts the repeatable operation of checking real number convergence. Further, the generalization utilizing the Euclidean distance involves reducing the more abstract mathematical phenomena of vector convergence to the simpler and more familiar setting for convergence, that of the real numbers. These findings begin to illuminate the nature of student thought an generalization in more formal mathematical settings. Specifically, we see students attending to natural relationships in real space to facilitate meaningful generalizations of known analytical phenomena. Further research will investigate student generalization in more abstract spaces.

Examining a Mathematician's Goals and Beliefs about Course Handouts

Sepideh Stewart
University of Oklahoma

Clarissa Thompson
Kent State University

Noel Brady
University of Oklahoma

*In this qualitative narrative study, we employed Schoenfeld's theory of Resources, Orientations and Goals (ROGs) to analyze a mathematician's beliefs and goals in creating handouts for his students. Some of the instructor's primary goals in creating the handouts were: (1) to help students gain an intuition about Algebraic Topology, (2) to provide a resource for students to revisit the difficult material outside of class, and (3) to prompt students to complete exercises so that they could monitor their own mastery of the course content. As part of this study, one of the students in class took daily journals. These journal entries revealed that he appreciated the time and careful preparation that was necessary to create the handouts, particularly the pictures that the instructor drew in the margins to help students gain an intuition. However, one obstacle that the student faced was struggling to appreciate the instructor's goal of expecting students to monitor their mastery of content outside of class time through completion of ungraded exercises in the handouts.*

*Keywords*: Algebraic Topology, handouts, beliefs, goals

## Theoretical background

Giving out handouts is a common practice in many mathematics classrooms. In his book, *Mathematics Teaching Practice: A Guide for University and College Lecturers*, Mason (2002) shares a variety of reasons why mathematics instructors give handouts to students (see Table 1). In his view, "people have a mixture of aims, and so use different approaches at different times" (p. 64). Mason differentiated among handing out complete notes, writing everything on the board, and giving no notes during the lectures. In the case of providing complete notes, students may not see the need to attend lectures; in the case of writing everything on the board, students will turn into transcribers; in the case of providing no notes, students have nothing to fall back on to make sure they are gleaning the important points from the lecture. Teaching is a complex activity and clearly designing handouts and successfully implementing them in lectures requires careful thought.

*Table 1. Pedagogical insights in using handouts in lectures (Mason, 2002, p. 64).*

| Aims | Expected Actions by Students | Styles of Handouts |
|---|---|---|
| Cover (explain, teach, transmit, or convey) the definitions, theorems, proofs, and techniques | Study (not just read) notes mathematically; work mathematically on set exercises | Complete notes as if in a book (available in advance or after the lecture)<br>Definitions, theorems, and sample worked examples |
| Inspire | Appreciate overall flavour; pick up details from carefully working on notes and perhaps texts, not just working through exercises | Notes with headings but details left as spaces for students to fill in as you work through the exposition |

| | | |
|---|---|---|
| | | Explicit references to standard texts<br>Extra suggestions not mentioned in the lecture |
| Work at understanding, making connections between topics or theorems | Re-construct topics for themselves from lecture notes and text, and, increasingly, independently from text alone | A succinct mathematical summary, perhaps with worked examples or challenging questions to explore |
| Teach how to carry out required techniques and solve sample problems | Work on ‘worked’ examples; justifications and theory found in text | Elaborated worked examples displaying choices, wrinkles, and use of theorems |

The current qualitative narrative study is a part of a larger study with the main goal of understanding the mind of a working mathematician as he made pedagogical decisions (Stewart, Thompson, & Brady, 2017). In this paper, we describe what motivated a Geometer to design and employ 35 handouts in an Algebraic Topology course. In our holistic approach to investigate this instructor’s teaching, we examined his handouts, his weekly teaching journals, and discussions that occurred during weekly meetings with a team of researchers. Additionally, we examined one student’s daily journals to get the student’s perspective on the instructor’s handouts. We do not aim to prove or disprove whether handouts are ideal educational resources, rather, our ultimate goal is to understand the mind of the working mathematician by investigating what motivated him to create detailed handouts. To analyze the Geometer’s motivations, we employed Schoenfeld’s (2010) Resources, Orientations, and Goals (ROGs) theoretical framework. This theory helped us identify the knowledge and materials at the instructor’s disposal, his values and beliefs, and what he wanted to achieve with the handouts. Schoenfeld claims that “if you know enough about a teacher’s knowledge, goals, and beliefs, you can explain every decision that he or she makes, in the midst of teaching” (2015, p. 229). Resources, or knowledge, include “the information that he or she has potentially available to bring to bear in order to solve problems, achieve goals, or perform other such tasks” (Schoenfeld, 2010, p. 25). Orientations are “dispositions, beliefs, values, tastes, and preferences” (Schoenfeld, 2010, p. 29). Goals are what the individual wants to achieve. Although, the theory was originally applied to middle and high school teaching, (Aguirre & Speer, 2000; Thomas & Yoon, 2011; Törner, Rolke, Rösken, & Sririman, 2010), it has more recently been applied to university teaching (e.g. Hannah, Stewart, & Thomas, 2011; Paterson, Thomas, & Taylor, 2011).

Our current research questions are: What were the instructor’s ROGs in making the handouts? Was the student aware of the instructor’s goals for creating the handouts, and what were his reactions toward the handouts?

## Method

In this qualitative narrative study (Creswell, 2013), our research team analyzed a Geometer’s thought processes and pedagogical decisions while he taught a course in Algebraic Topology. The research team consisted of four members: a mathematics education researcher; a Geometer (the course instructor); a cognitive psychologist; and a mathematics postdoc. The Algebraic Topology course was the first in a two-semester sequence of courses; eight students were enrolled. During class meetings, the instructor (Noel Brady) passed out handouts to help students follow along with the topic of the day. Students actively solved problems together in groups, or individual students were called to the board to complete problems.

One source of data we analyzed was a series of teaching journals that contained the instructor's reflections on his preparations for class, what happened during class, as well as some descriptions of the events that took place during office hours. The research team read his daily journal entries and discussed them during weekly research meetings. During these meetings, the research team asked the instructor further clarification questions, and he often drew additional pictures as he described the course content. These meetings were audio recorded, and the meeting transcripts were also used as a source of data. Our team also analyzed data from a student in the instructor's class, who wrote daily journals. These student journals provided an additional perspective into the events that took place in class. The final source of data was 35 handouts that the instructor created for his students.

The data were analyzed thematically, meaning we mainly considered the key issues that emerged in this study. One of the main themes that emerged from this instructor's journals was "teaching". Forty-six percent of all instances from his journals were coded with the "teaching" code and 20% of those codes fell into the sub-category of "handouts/notes." More details about data coding and analysis is described in Stewart, Thompson and Brady (2017).

## Results and Discussion

The instructor's resources included: (1) his knowledge of mathematics and the subject area, (2) many years of teaching experience, (3) course notes from when he was a student, (4) the textbook (Hatcher, 2001), and (5) many hand-drawn images. Analysis of the instructor's 35 handouts illuminated his motives. These handouts gave the research team a more authentic glimpse into the mind of the mathematician than his teaching journals. The instructor noted that he was self-aware when he wrote the journals, as he knew the research team would subsequently analyze and discuss them. On the other hand, he created the handouts solely for his students.

Apart from the usual dose of definitions, theorems, and proofs, the instructor's mostly handwritten handouts included headings such as, "intuition," "motivation," and "application," which are often lacking in textbooks. Table 2 summarizes the essence of the instructor's goals and beliefs as indicated in his teaching journal entries.

*Table 2. The instructor's pedagogical goals and beliefs about handouts.*

- Presented the information in a conversational tone
- Accompanied class activities
- Inspired by notes from his own graduate courses
- Contained relevant examples and exercises that referenced his published research
- The chosen textbook (Hatcher, 2001) gave a "muddled discussion" when the topic was "highly non-trivial and non-obvious" for the students
- Referenced alternative discussions of difficult topics that other mathematicians had posted on their websites
- Inspired by assigned homework
- The instructor wanted to present his students with "ultra-detailed" arguments that had taken him at least an hour to develop.
    - The handouts helped the instructor feel organized and not scattered.

|  |
| --- |
| - He was able to add onto existing handouts from semester-to-semester.<br>- If he wanted to be particularly precise, he used LaTeX to type up the handout, but those handouts were time-intensive to create.<br>• Some handouts synthesized information for the students. The instructor synthesized this material on his own when he was a student.<br>• When the instructor was unable to cover all of the material that he wanted to in his lectures, he created handouts on the topic.<br>- Handouts gave the instructor the license to go through the material more quickly because the students could revisit the information at their own pace outside of class time.<br>• Helped students build intuition<br>- The instructor drew images by hand that represented the complex mathematics.<br>- The instructor noted that some students may be learning about the topics for the first time.<br>• Handouts were helpful when the material was particularly complex.<br>• The proof of the E-S axioms (for singular homology) was a component of the course. The textbook withholds the axioms until the end of coverage for singular homology, but the instructor decided to present them first. He believed that the axioms could serve as a framework, or table of contents, for the topic.<br>• The instructor created a summary handout to give students a preview of what was to come in the second course on Algebraic Topology. He expected that the students would attempt to solve some of the problems when they were on break between the Fall and Spring semesters. |

In this section, we will discuss some of the instructor's goals and beliefs in more detail and match them to the student's comments.

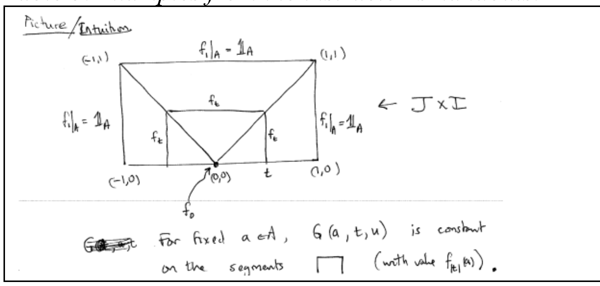
**Helping Students to Build Intuition**

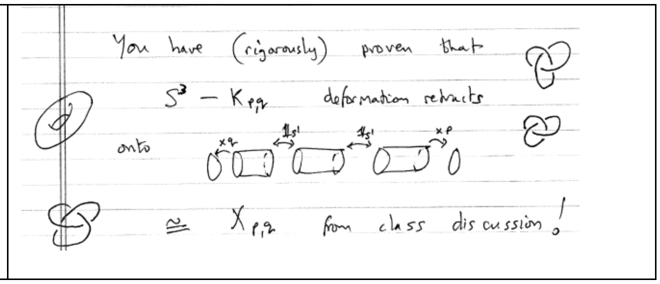
One of the instructor's main pedagogical goals was to help students build intuition. The instructor mentioned this goal often during the research meetings, which indicated his strong belief in and the importance he placed on helping his students build intuition. He drew images by hand (see Table 3) that represented the complex mathematics to help students who were learning about the topics for the first time. Research team members noticed that the instructor often used phrases such as "carefully and slowly" and "careful proof" in his teaching journals. These phrases indicated that he wanted to make sure students followed the arguments as they unfolded.

| The instructor's comments | The student's comments |
| --- | --- |
| "Did some examples carefully and slowly, but told them that they have to get used to computing boundaries quickly and efficiently."<br><br>"They still had difficulty going from an intuition to a formal proof, and I gave some | "I've so far enjoyed reading Dr. Brady's notes in the handout, which are rife with helpful commentary and ultimately very user-friendly. I've noticed how careful he is with building some of these mathematical concepts from the ground up." |

| | |
|---|---|
| handouts that sort of went through stuff fairly carefully." | "His pictures in the margins are abundant and very helpful, and there's always a nice subject line or topic sentence for each section along the lines of "here's what our ultimate goal is for the next few pages and here's how we're going to do it." |

*Table 3. Examples from the instructor's handouts.*





## Giving Students a Resource to Revisit

The instructor's orientation was to place a value on providing students with detailed notes that they could revisit outside of class time. The instructor viewed the textbook as wonderful in many ways, but was "a bit fast and loose" with the coverage of some topics, so he decided to create handouts to supplement the textbook.

| The instructor's comments | The student's comments |
|---|---|
| "Even with the handout here, I have to say this is cool, but me telling you it is cool, or me going in there and writing very quickly on the board and showing this is not going to work. You need to go and figure out why it is cool yourself."<br><br>"There are topics here that I think they should read, and they should read it carefully enough—meaning maybe a couple of paragraphs they need to spend several hours on teasing them out and then present it to their peers for 50 minutes."<br><br>"We need to get our hands dirty to do this." | "Overall, I'm happy with the handout, as it works through several examples entirely, with plenty of marginal remarks by Dr. Brady as always. I always know that, given a handout, Dr. Brady has license to cruise through the material in that lecture even quicker than usual, but that I have it right there with me to review by myself later." |

## The Instructor Believed the Students Should Master the Material on their Own Time

The instructor noted that some of the handouts helped students draw connections across course content, and these were connections that took him quite some time to realize when he took the course himself. Therefore, the instructor's goal was to provide these connections for his students to facilitate their "a-ha" moments. This goal is aligned with Mason's (2002, p. 64) statement that students should "re-construct topics for themselves from lecture notes and text, and, increasingly, independently from text alone". Hence, the handouts were no substitute for the students putting in the time and effort outside of class to master the content. In the comment below, we noticed that the student did not realize the instructor's motivation for asking his students to complete ungraded assignments in the handouts.

| The instructor's comments | The student's comments |
|---|---|
| "It had exercises for them to verify things. I am not grading it. It is up to them to make sure they understand it, and they come up and chat with me if they want." | "I can't remember exactly when our last homework assignment was, but it must have been weeks ago. Since then the course has consisted only of lectures and unofficial "I suggest you do these" exercises assigned by Dr. Brady. I have to admit that I haven't attempted all of them, partly because there are so many and partly because the lack of incentive (that they won't be graded)." |

## Concluding Remarks

This qualitative narrative study investigated a mathematician's ROGs through his handouts, teaching journals, and conversations that occurred during weekly research team meetings. Additionally, we analyzed one of his students' journals to investigate whether the student understood the instructor's goals for creating the handouts.

Analysis of the instructor's teaching journals and transcripts of the weekly team meetings revealed that the Geometer noted a myriad of reasons why he created handouts for his students. We focused on three goals: (1) helping students to build intuition, (2) giving students a resource to revisit, and (3) assisting students with mastery of the course content outside of class time, and we also provided quotes linking the instructor's and students' thoughts about the handouts.

The student appreciated the detailed handouts, particularly the hand drawn images that helped students understand the gist of the topics before the formal proofs were introduced. In one of his journals, he mentioned: "The immense amount of effort Dr. Brady must put into class preparation shone through again with this handout." However, the student was keenly aware that the handouts allowed the instructor to "cruise" through the material faster than he might otherwise. Further, the student may not have recognized the value in completing the ungraded exercises that the instructor suggested in the handouts. To put this into the instructor's words, the students had to grapple with the handout. It was not enough just to read it over once. They had to "get their hands dirty" and work on it on their own time.

We suspect that many other mathematics instructors share similar pedagogical goals. Creating handouts can be time-intensive, but once the handouts are created, they can be adapted from semester-to-semester. We would like to make some pedagogical recommendations for the inclusion of handouts in advanced courses. First, instructors may consider alerting their students to their goals for creating the handouts. For instance, instructors could let their students know that they will be covering the material more quickly than if they did not have a handout prepared, but the students can revisit the handouts outside of class to more fully grasp the content. Second, handouts can provide an avenue that helps instructors show how concepts unfold step-by-step to help their students grasp an initial intuition about the content. The instructor that we studied also noted that when he created handouts, it helped him to feel like he had a plan and was not scattered for his lecture. Third, if instructors recommend that students complete ungraded exercises, they could explicitly state why they believe these exercises will benefit the students' learning, even though they are not incentivized with course points.

As members of the mathematics community, we are constantly faced with challenges of finding the best ways to maximize our students' understanding. Making the right pedagogical decisions that are aligned with our goals and beliefs are not always trivial. Although, we recognize that we only examined one student's journals in this study, it is rewarding to know that some of our instructional decisions and efforts are effective and appreciated by our students.

# Factors Supporting (or Constraining) the Implementation of DNR-based Instruction in Mathematics

Osvaldo D. Soto
University of California, San Diego

Guershon Harel
University of California, San Diego

Brandon Olszewski
International Society for Technology in Education

*DNR-based instruction in mathematics (Harel, 2008a, 2008b, 2008c) is a theoretical framework for the learning and teaching of mathematics. DNR-based professional development is a long-running program spanning seven years with multiple cohorts of in-service secondary mathematics teacher participants. This report investigates teacher change among five key variables: facilitating public debate, using holistic problems, attending to students' intellectual need, attending to the meaning of quantities and use of students' contributions. Commitment to change and perseverance, the nature of available curricular materials and teachers' view of the role of curriculum, a view of students as partners in knowledge construction, institutional context, collaboration and content knowledge were identified as factors that afford or constrain DNR implementation. This work has implications for the design of future professional development efforts and the development of a more robust theory of teacher change.*

*Keywords:* Teacher change, DNR-based instruction, Intellectual Need, Professional Development, In-service

In their review of 106 articles reporting findings on mathematics professional development programs between 1985 and 2008, Goldsmith, Doerr and Lewis (2014, p. 21) point out that "existing research tends to focus on program effectiveness rather than on teachers' learning," while much less has been said about "*how* teachers develop knowledge, beliefs, or instructional practices". Understanding how teachers' development entails also understanding factors that facilitate or inhibit desired forms of development. In this report, we also strive to answer similar research questions: *How effectively are aspects of a professional development guided by a particular theoretical framework adopted by teachers and integrated into classroom teaching? And what factors challenge or support teachers in implementing this framework in the classroom?*

For the purposes of this report, the first question is seen as merely a starting point. The second questions, is in line with Goldsmith et al's (ibid) observed gap in the literature base. However, we argue that a crucial step in understanding how teachers develop is identifying factors that afford or constrain implementation of the targeted forms of knowledge, beliefs or practices. We are not alone in this goal. Indeed, Hill et al (2008) also sought to identify factors that support or hinder teachers' use of mathematical knowledge for teaching in practice as part of a larger research agenda. Similarly, Schoenfeld (2010), seeking to construct models of teachers' decision-making, found it "necessary and sufficient" to characterize teachers' knowledge, goals, orientations (i.e., belief, values, preferences, etc.) and decision making in order to construct their models. A natural extension to this work is understanding factors that afford and constrain teachers' ability to reach their goals or enact their stated beliefs.

## Theoretical Perspective

*DNR-based instruction in mathematics* (*DNR,* for short; Harel, 1998, 2000, 2008a, 2008b, 2008c, 2013a, 2013b) is a theoretical framework for the learning and teaching of mathematics—

a framework that provides a language and tools to formulate and address critical curricular and instructional concerns. *DNR* can be thought of as a system consisting of three categories of constructs: *premises*—explicit assumptions underlying the *DNR* concepts and claims; *concepts*—constructs defined and oriented within these premises; and *claims—*statements formulated in terms of the *DNR* concepts, entailed from the *DNR* premises, and supported by empirical studies.

As the above list of references indicates, *DNR* has been discussed extensively elsewhere, and so in this paper we only reiterate briefly the definitions of the concepts pertaining to the concern of this study.

*Assigning Holistic Problems:* A holistic problem is one where a person must figure out, from the problem statement, the elements needed for its solution (Harel and Stevens, 2011). It does not contain hints or cues as to what is needed to solve it. In contrast, a non-holistic problem is broken down into small parts, each of which attends to one or two isolated elements. Often each of such parts is a one-step problem.

*Intellectual need:* Do students have a need for understanding the mathematics the teacher intends to teach? Does the teacher appeal to a problematic situation that puzzles students when introducing new mathematics?

*Attention to meaning*: When a problem has a context, unknown quantities have meaning with respect to that context (e.g. units related to quantities). Does the teacher attempt to attend to the meaning of quantities within the context of the problem?

*Public debate*: Is there evidence to believe that the whole class is following the discussion? Is the teacher making a successful effort to engage the whole class in debate through questioning and solicitation of contributions? Public debate also includes the need to evaluate mental images and their validity and efficiency.

*Taking student contributions seriously*: A student's contribution is considered to be taken seriously when it is allowed to live in the public space for discussion without immediate teacher evaluation. When taking contributions seriously, teachers solicit ideas and mental images from students, and facilitate public debate about these ideas to highlight and critique both underlying mathematics.

DNR-based professional development (DBPD) is a long-running program spanning seven years with multiple cohorts of in-service secondary mathematics teacher participants. This report investigates teacher change among five key variables: facilitating public debate, using holistic problems, attending to students' intellectual need, attending to meaning, and use of students' contributions. Collectively, these key variables have previously been identified as crucial teaching practices in student-centered classrooms targeting the development of students' mathematical content knowledge compatible with the Common Core's standards for mathematical practice (e.g., University of Michigan, 2006; Harel, Fuller and Soto, 2014; Shoenfeld, 2013). In his attempt to articulate the complexities constructing the TRU Math Framework and presenting the framework itself, Schoenfeld (2013, p. 613)) identified similar teaching actions, identifying them as, "known in the literature to be important" (ibid, p. 610).

## Methods

DBPD consisted of two related support structures: (1) summer institutes and mid-year follow-up sessions and (2) on-site professional development. Both efforts targeted teachers' knowledge of mathematics, knowledge of student learning, and knowledge of pedagogy. This report examines DNR implementation for 33 teachers in a major urban area of the southwestern United States. DBPD included a focus on the five teaching practices: *public debate*, *holistic* *problems*, *intellectual need*, *attention to meaning*, and *taking contributions seriously* as defined above.

Repeated classroom observations of teacher participants were conducted and used to evaluate participants' implementation of DNR and to chart changes in participants' teaching over time. Two forms of data were generated using these observations. First, researchers examined whether or not a particular teaching practice was demonstrated in each participant's classroom during an entire classroom observation across two later years of the program's existence. Rather than relying exclusively on quantitative results for groupings, the authors triangulated available data sources (including their own experiences with the participants as well as formal debrief interviews) in order to maximize reliability associated with the classifications, thus reflecting the change in each of the participating teachers over time. Second, researchers looked more closely at interview data with participants conducted after classroom observations that could be used to give insight into factors that afford or constrain implementation. A summary of findings follows.

## Results

### How effectively are aspects of DBPD adopted by teachers?

Teachers were observed at least twice over the course of a four-year period, yielding data that describe change over time for each participant. In order to explore overall changes in teaching over time, the evaluator created a factor score that aggregately considered implementation of each of the five DNR parameters (public debate, use of holistic problems, attention to intellectual need, taking student contributions seriously, and attention to meaning) as one normally distributed score. This factor score, calculated using the principal factors method across all five DNR parameters, yielded a clear one factor structure, and thus served as an estimate of DNR implementation. Observed levels of implementation of each of the five DNR parameters were coded as absent or present during observations, and coded in duration by seconds, yielding a data structure that was capable of examining proportion of class periods where various levels of DNR implementation were observed. Across the sample for this study, the mean level of DNR implementation was calculated at 1.51, with a pooled standard deviation of 0.34. Results of a panel regression analysis examining whether or not average implementation of DNR increased over time for the entire group yielded a non-significant $p$ value for the variable "time", indicating that average level of DNR implementation did not increase. However, this lack of aggregate results masks important variation within the population.

Analysis of change within subjects/by teacher revealed five distinct groups:

*Evolvers:* These teachers exhibited noteworthy increases in their DNR implementation score over time, an increase of one standard deviation or more over time (specifically, from first recorded observation to last observation).

*Decliners:* These teachers exhibited a decreased DNR implementation score of one standard deviation or more over time.

*Consistent high implementers:* These teachers exhibited DNR implementation score changes of less than one standard deviation, but were consistent in their high DNR implementation score, scoring at least one standard deviation above the mean at some time.

*Consistent moderate implementers:* These teachers exhibited DNR implementation score changes of less than one standard deviation, but were consistent in their moderate DNR implementation score, scoring within one standard deviation of the mean at both times.

*Consistent low implementers:* These teachers exhibited DNR implementation score changes of less than one standard deviation, but were consistent in their low DNR implementation score, scoring at least one standard deviation below the mean at some time.

Triangulated classifications are used for this publication, and are presented below as a table of frequencies across the five categories.

*Table 1. Frequency table for categories of DNR implementation by DBPD participants.*

| Categorization | Number of Participants |
|---|---|
| Consistently Low | 6 |
| Decline | 8 |
| Consistently Medium | 4 |
| Evolvers | 9 |
| Consistently High | 6 |

Closer examination of these groups (and specifically, of the stories these teachers provided through interviews) revealed important details about factors that both facilitate and inhibit DNR implementation. Finally, we noticed that affordances were simply the opposite of the constraints. Therefore, we report findings thematically, describing how a particular side of each theme (such as presence of absence of collegiality in the work environment) related to DNR implementation. In this same vein, we look at conditions that facilitated successful teachers, and conversely, those that facilitated disengagement with the DNR mission and a failure to implement in the classroom.

**What factors challenge or support teachers in implementing DNR in the classroom?**

Participant interview data identified commitment to change and perseverance, the nature of available curricular materials and teachers' view of the role of curriculum, a view of students as partners in knowledge construction, institutional context, collaboration and content knowledge as factors that afford or constrain DNR implementation. However, given the current space constraints and the qualitative nature of the data analysis, we report here one example of an observed factor, commitment to change and perseverance.

**Commitment to Change and Perseverance**

Across groups, risk-taking and willingness to take initiative emerged as common traits among consistently high implementers and evolvers. Similarly, the absence thereof characterized consistently low implementers and decliners. Three participants describe sharply contrasting points of view which explain their rationale for choosing to implement (or not) two different aspects of DNR-based instruction, holistic problems and public debate.

P1: They're trying to get us all to do the Euclid unit, and I'm just not on board - I was going to do it, but my school was not into it! Then I decided against it. There is a lot of construction and proofs, and that's what our students struggle with the most. The problems in there are geared for teachers, so you'd have to re-write everything to be more appropriate for students.

DBPD participants experienced the unit P1 refers to as "The Euclid Unit" (see Harel, 2014 for a description) over two summers. P1 described an initial willingness to implement this curriculum. Ultimately, she decided against implementing the unit for the following reasons: (a) lack of support at her "school" – where "school" may refer to departmental colleagues, students, parents or administrators, (b) a belief that construction and proving problems are beyond what her students' are capable of appreciating and productively struggling with, and (c) a need to lower the level of the questions, generating work beyond the scope of her capacity. We save constraints (a) and (b) for discussion in subsequent sections while focusing on constraint (c) here.

In contrast to P1, P2 and P3 illustrated how a commitment to change supported implementation, regardless of their experience with the same kinds of constraints faced by P1. That is, these participants knowingly chose to search for ways to overcome existing constraints because of their belief systems.

P2: The students were not buying into public debate – they always just want to know the steps. That's a struggle, especially with the advanced classes. Same story over and over. I believe in what I'm doing, but the resistance is always there. Most students are buying in, doing great, will publicly debate and challenge themselves. They understand that the methods and strategies we're applying [are] good for them… A lot of times the students work in groups of four where they talk to one another a lot already. I don't do direct instruction as much as any other teachers around here. That takes a lot of coaching every time – basically the months of September and October where I really have to drill the process into them, including training the kids and talking to the parents about why I do it like this.

P2 discussed how her belief in the role of public debate drove her to persevere in the face of student and parental pressure. P1 also cited a constraint regarding lack of support among important stakeholders (i.e., her "school"). Also in contrast to P1, P2 describes an actual, rather than a perceived, form of resistance. However, her belief in the benefits of public debate in the learning process led her to persist in her implementation.

P2 also describes a time frame in which she knows she will have to endure this resistance along with an understanding that communication with parents and powerful student learning experiences can combat this resistance despite the amount of effort it will take. We note that at one point in time P2 confronted and overcame these constraints before developing confidence that resistance eventually fades, and usually after the first two months of class. In the end P2 developed a sense for how long resistance will last and the benefits of persistence.

Also in contrast to P1, P3 describes below how a valuable experience at the DBPD summer institutes led to implementation of a particular holistic problem.

P3: Anytime I get a holistic problem, I try and spot some of the techniques they've used…like, the teacher-researcher gave us a problem where a sweeping line was covering some area…and I used that type of thing with my students. I thought, I can make that

> simpler and thus appropriate for 9th graders… You have to have faith that the kids will learn something valuable.

We first note potential differences in beliefs between P1 and P3. P1 reported feeling pressure to implement an entire DNR-based curriculum. P3 described a desire to bring a particular problem to his students, an approach emphasized during the summer institutes. P3 also described a desire to find and implement a general principle. Both participants felt a need to translate problems introduced at the DBPD to their students' level. P3's choice was supported by a belief in students as partners in knowledge construction saying, "You have to have faith that kids will learn something valuable." Consequently, P3's commitment to change surpassed constraints of the amount of work needed to translate a DNR concept (holistic problems) in his classroom.

Regardless of implementation level, participants reported that generating holistic problems was difficult and time consuming. On many occasions we observed, and participants reported, that they needed to try several versions of these problems before finding one that elicited productive student images useful in advancing the teacher's mathematical agenda. This was expressed nicely by one high implementer who noted after several years of implementation, "Almost all the problems I use I make up…". Another high implementer reported, "I'm always writing the material on my own. The book that we have doesn't support DNR-type instruction at all … I have very limited time. So, curriculum is a big need." While both of these comments also point other factors to be discussed later, we emphasize that this factor, commitment to change and perseverance, was a necessary ingredient in these participants' *eventual* shift toward the development of a curriculum consisting of a large number of holistic problems.

Assigning holistic problems, facilitating public debate and attempting to attend to students' intellectual need are high risk behaviors with the potential for high rewards or catastrophic failure. A common theme among low implementers and decliners was the observation that that assigning holistic problems could lead to high student frustration, especially from students who had little experience with them. This was often cited as a reason they did not implement key aspects of DNR, while high implementers and evolvers demonstrated a commitment to change and perseverance in implementation. Nearly all participants expressed fear of complaints from parents (and students) who might not understand the intention of a problem, why teachers were not providing algorithmic approaches in advance or why teachers might record an incorrect solution on the board. As one participant said, "A challenge is the resistance from parents and students when DNR or Common Core Standards are implemented since they are used to being told what to do."

In addition to targeted DBPD, change in teaching practice or sustaining the forms of teaching practice compatible to DNR-based instruction requires a concerted effort. Successful implementation of DNR requires teachers to see teaching as a mission – a mission of implementing and evangelizing innovative mathematics instruction – rather than a job.

## Discussion/Summary

We summarize what we have learned, what remains open and what implications for instruction/future programs.

### What have we learned?

Echoing the findings of other mathematics educators (e.g., Schoenfeld, 2010; Harel, Fuller & Soto, 2014; Ball, Hill & Bass, 2005), we are still far from understanding the inner workings of how teacher change their practice, especially "*how* teachers develop [and change existing] knowledge, beliefs, or instructional practices". It takes a professional with an exceptional commitment to change and perseverance in the face of the many obstacles that constrain teaching practice. Choosing a holistic problem for students is a non-trivial task, especially in light of the current culture of textbook school mathematics where the decisive majority of problems are non-holistic. We have found that successful implementers of DNR believe that students are partners in knowledge construction. Even when teachers do hold this belief, they may still struggle to solicit student thinking, anticipate student difficulties and bring the whole class conversation to a meaningful closure in a reasonable amount of time. There are many institutional pressures that constrain DNR-compatible teaching.

A constant theme among DBPD participants, regardless of implementation level, was a desire for a DNR-based curriculum. This large task requires a large set of resources, both human and fiscal. Nevertheless, DBPD participants repeatedly pointed out that curriculum would be a practical way to make inroads with colleagues, administrators, parents and students.

Another lesson learned is the importance of collaboration among teachers involved in DBPD. In order for DNR-based professional developers to influence instructional practice, participants must have access to first-hand experiences in which DNR-based instruction is demonstrated first-hand with actual students at the level of the participants. One important finding was that DNR-implementation was actually independent of the level of student being taught. While this result seems to contradict our finding that teachers needed to experience DNR-based instruction with students, in actuality it is more of a statement about teacher perception rather than fact.

Finally, we note that our participants enjoyed doing mathematics together. Successful implementers found ways to parlay their content knowledge into the selection or refinement of holistic problems for their students, the goals they set for public debate, the ability to make better sense of what students were saying and meaning, and the ability to make something out of those statements. Thus, giving their students a sense of ownership over mathematical ideas in the classroom.

**Questions for further research**

These findings point out that high implementers demonstrated a set of beliefs about learning and teaching coupled with particular dispositional traits (e.g., sees teaching as a mission, demonstrates perseverance/adherence to the belief that learning can only be accomplished through problem-solving, views content knowledge as central to good teaching). Were these participants selected for these traits or did DBPD influence them in some ways? If so, how?

We cited many institutionally related constraints here (and there are certainly others). How can DBPD providers attend to these in the future? For example, two participants at the same site, with the same preparation period, taught the same content and they seemed to benefit most from the DBPD. Another question concerns curriculum. How much will teachers feel is sufficient to support DNR implementation? An entire year? A particular grade band? All grades?

Relationships between Precalculus Students' Engagement and Shape Thinking

Derek A. Williams
North Carolina State University

*This study examines relationships between community college precalculus students' understanding and engagement to link mathematical success to a malleable construct, and offer new insights for addressing consistently poor success rates in community college precalculus (Barnes, Cerrito, & Levi, 2004). Two-part interviews, consisting of a task and debriefing, were conducted with 8 students to investigate their shape thinking (Moore & Thompson, 2015), and engagement, conceptualized through flow theory (Csikszentmihalyi, 1975). Results suggest that students can be highly engaged in mathematics tasks regardless of understanding and that students exhibiting different ways of thinking about graph construction tended to experience different forms of engagement.*

*Keywords:* Student engagement, Shape thinking, Precalculus, Community college

This study represents a portion of the author's dissertation in which community college precalculus students' engagement, understanding of precalculus concepts (e.g., covariation) and relationships between the two were investigated to address consistently poor success rates in community college precalculus (Barnes, Cerrito, & Levi, 2004). Others have demonstrated that student engagement is positively associated with academic achievement (e.g., Finn & Rock, 1997; Finn & Zimmer, 2012; Newmann, Wehlage, & Lamborn, 1992; Reschly & Christenson, 2012; Skinner & Belmont, 1993) and success in mathematics (e.g., Barkatsas, Kasimatis, & Gialamas, 2009; Lan et al., 2009; Martin, Way, Bobis, & Anderson, 2015; Rimm-Kaufman, Baroody, Larsen, Curby, & Abry, 2015; Robinson, 2013), where achievement and success are typically measured by students' performance on high-stakes assessments and student engagement is frequently reported by teachers or observers. Studying student engagement remains a focal point for educational research; this study contributes to that body of literature by investigating community college students' engagement and associations between engagement and understanding – as opposed to achievement on standardized tests. This study focuses on exploring relationships between student engagement and understanding of covariation. Information on such relationships would extend our understanding of the importance of fostering student engagement in community college precalculus classrooms.

## Framework

### Student Engagement

Student engagement is a metaconstruct consisting of emotional, behavioral, and cognitive components (Fredricks, Blumenfeld, & Paris, 2004). Flow theory (Csikszentmihalyi, 1975, 1990) is a valid framework for conceptualizing student engagement because both flow and engagement are comprised of similar components, both are described as states of intense concentration and investment in a task or activity, and both are intrinsically motivating (Steele & Fullagar, 2009). From the perspective of flow theory, student engagement is comprised of interest, enjoyment, and concentration (Shernoff, Csikszentmihalyi, Schneider, & Shernoff, 2003), where interest and enjoyment are elements of emotional engagement and concentration constitutes behavioral and cognitive engagement.

## Covariation

Among other precalculus concepts (e.g., quantity/quantizing and function), covariational reasoning is paramount for success in future undergraduate mathematics courses (e.g., Carlson, Jacobs, Coe, Larsen, & Hsu, 2002). Moore and Thompson (2015) suggest that shape thinking provides perspective for describing students' covariational reasoning in the context of graphs. They describe students' shape thinking as static or emergent, where "static shape thinking involves operating on a graph as an object in and of itself" (p. 784). Monk (1992), defined iconic translations as a way of thinking in which perceptual features from a situation are associated with the shape of a graph for that situation. Also, Thompson (2015) explains that students may use thematic associations by regarding features of a situation as being necessary elements of the corresponding graph. Stevens and Moore (2016) elaborate that both iconic translations and thematic associations are examples of static shape thinking because both ways of thinking rely on perceptual features of an event for reasoning about a graphical representation; hence, operating on a graph as an object. On the other hand, "emergent shape thinking involves understanding a graph *simultaneously* as what is made (a trace) and how it is made (covariation)" (Moore & Thompson, 2015, p. 785, emphasis in original).

# Methods

The purpose of this study is to explore and describe any relationships between community college precalculus students' engagement and shape thinking in the context of a task-based interview. The following research question is addressed. Is there a relationship between student engagement and shape thinking, and if so, what are characteristics of this relationship?

## Setting and Participants

Data collection for the dissertation study took place during Fall 2016 at two Southeastern community colleges, where 15 precalculus instructors and 101 students participated. As part of the larger study, three instructors were selected for classroom observations, and their students were considered to take part in task-based interviews. Eight students from these three classrooms were selected based on their self-reported levels of engagement (i.e., interest, enjoyment, and concentration) during the first five weeks of the semester. These students were consistently more engaged during class time than their peers. Students with relatively high levels of engagement were selected to take part in interviews to increase the researcher's opportunity to "see" student engagement so any relationships between engagement and shape thinking could be explored.

Seven of eight students were enrolled full-time and all but two (Richard and Suzy, pseudonyms) were taking precalculus for the first time as college students.

## Data Collection and Analysis

Data collection took place during interviews with students. Each interview consisted of two parts. The first part was task-based, where students worked through the *Taking a Ride* task, which has been used by Moore and colleagues to investigate students' shape thinking and other graphing activities (e.g., Stevens & Moore, 2016). The second part of each interview was a debriefing, where participants were asked to reflect on their interest, enjoyment, and concentration (i.e. engagement) while working the task. The data consist of video recordings, transcripts, and student artifacts.

Interview transcripts and artifacts produced during the task-based portion of interviews were coded for indicators of students' shape thinking based on definitions provided above. Transcripts from the debriefing portion of interviews were open coded to describe themes in participants' descriptions of their interest, enjoyment, and concentration while working the task. Finally, students' various ways of thinking coupled with themes emergent in their engagement are used to identify and characterize any relationships between student engagement and shape thinking.

**Task description.** In the Taking a Ride task, students are prompted to watch an animation of a Ferris wheel perpetually rotating clockwise and "graph the relationship between a rider's total distance traveled *around* the wheel and the rider's distance from the ground" (emphasis in original). Following this, participants view a second animation of a Ferris wheel; however, in this animation the ride stops periodically. Participants are then asked to discuss the relevance of their original graph to the new situation.

## Results

This section is organized to first present results on students' shape thinking, and then describe themes in students' engagement.

### Shape Thinking

Three students exhibited static shape thinking: Richard, Paula, and Sally. Though, all three students did not associate perceptual features of the animation and their graphs in the same way. Richard interpreted the image of the Ferris wheel as a coordinate system and explained how he envisioned such a coordinate system working. He explains the image/graph was structured with x's that were all zero "because the fact that every um lines over there [*pointing to the image in the animation*] kind of direct me straight to the middle [of the ride]." He used the image of the ride to establish radial coordinates, like those of a polar coordinate system, which he described as heights. Richard labeled his horizontal axis "time," which was constant at zero "because everything points at zero." Two visuals of Richard's coordinate system are provided in Figure 1.

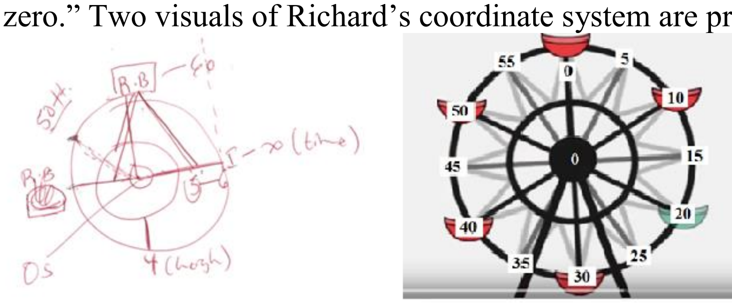

*Figure 1. Richard's sketch (left) and a reconstruction (right) of his coordinate system.*

Paula and Sally also demonstrated static shape thinking in their work on this task, by sketching circular graphs depicting the path of a rider on the Ferris wheel. Their justifications for circular graphs are exemplified by the following interview excerpt.

*Paula*: he's not going straight up or like going straight to the side, he's going in a circular motion so that is what I put it like that [a circular graph].

*Interviewer*: So, how would that change [*pointing to Paula's graph*] if the wheel were rotating the other way?

*Paula*: If it were rotating the other way, it would start here [*pointing to the right-most side of the wheel*] and then go around that way [*tracing around the wheel counterclockwise*]. So, it would go this way [*tracing the same path on her graph*].

Figure 2 shows these students' graphs.

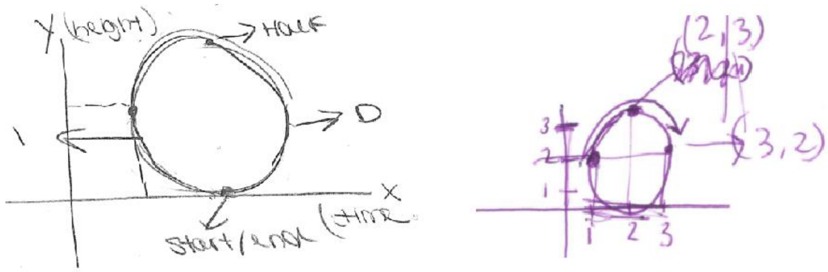

*Figure 2. Paula (left) and Sally's (right) graphs of circular paths.*

The remaining five students, Beverly, James, Suzy, Marianne, and Patricia exhibited emergent shape thinking while working the task. Beverly describes her graph as depicting the rider's position at a given time during the ride. She considers the horizontal axis to be "distance from the middle" or how she describes the rider's lateral displacement from a starting point. Her vertical axis is constructed similarly to reflect the rider's height above the ground. In this regard, she is coordinating simultaneous vertical and lateral displacements in a bounded space, both with respect to time, to produce her graph as the emergent path a rider travels around the ride. Her graph is shared in Figure 3.

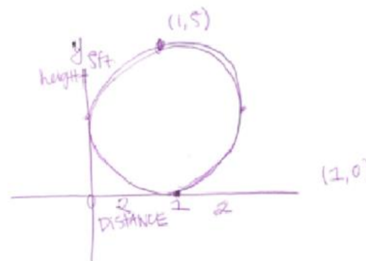

*Figure 3. Beverly's sketch of the path a rider travels as an emergent trace.*

Suzy and James both interpreted the prompt from the task to require two graphs: one for the relationship between a rider's distance traveled around the wheel over time, and a second for the rider's height over time. James' graph(s) in Figure 4 reflect how both students thought about this task. James sketches both relationships on the same plane, where the green graph depicts the rider's total distance traveled over time and the purple graph reflects the rider's height over time. James explains how he coordinates changes in time and height to construct his graph for that relationship, "at no time, you're at zero assuming it starts with the rider at the bottom…[then] halfway through that [height] would be halfway… so here's a graph." He continues, "for the total distance around it would be similar, but… it would extend forever."

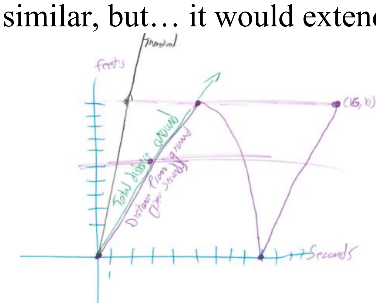

*Figure 4. James' graph(s).*

Marianne also interprets the prompt to be about a relationship between a rider's height and time, but she sketches a "sine or cosine curve" to represent the situation. Her emergent shape thinking is demonstrated in her explanation of how her graph changes for the second animation.

*Marianne*: So it stops about every like quarter of the way, so you would just have to like scrap your graph where it stops and draw a straight line. Um, but still have it like connect to the curve. So I guess it would stop like here [*sketching Figure 5*], so you would just straight line and it would resume. And then it would stop here, so straight line…

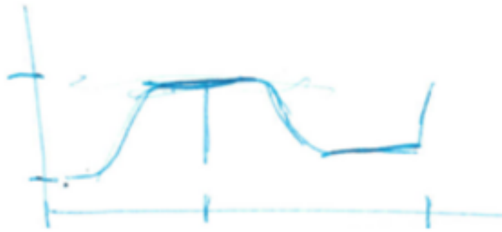

*Figure 5. Marianne's graph of the second animation.*

Lastly, Patricia coordinates changes in the rider's total distance traveled around the wheel with distance from the ground. In the following excerpt, Patricia demonstrates understanding her graph as an emergent trace created as the rider's distance traveled and distance from the ground covary by physically tracing her graph (Figure 6) as she explains its behavior associated with stopping in the second animation.

*Patricia*: …if we're traveling now [*tracing her graph with her pencil while watching the animation*] and I pause [*stops tracing*] I'm like, it doesn't affect [sic], like I'm not still going straight with my distance from the ground, and I'm not going down with my distance traveled because I am just standing there. Like I'm still, but then I keep going.

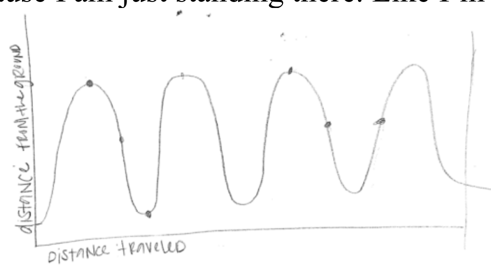

*Figure 6. Patricia's graph.*

The next section shares results from debriefings, to report on these students' engagement.

**Student Engagement**

**Concentration.** To begin, the average amount of time spent working the task was about 48 minutes, ranging from about 26.5 minutes (Patricia) to 76 minutes (Sally). This persistence with working and explaining their thinking evidences high levels of concentration in all students. Further, when asked about their concentration during debriefings, two themes emerged in responses regardless of shape thinking. First, students explained their focus on elements of the task they found confusing. For example, Patricia (emergent shape thinking) was "throw[n] off that time's not in there." Second, students discussed needing to concentrate on their explanations while working the task. Paula (static shape thinking) exemplifies this theme by reflecting on how evaluating her thoughts inhibited her work on the task, "just like the fact that maybe I was just wrong, so I would think about something and then I'd be like, no that is wrong, don't say that." Students concentrating on their own thinking is possibly due to the task-based interview setting, but does reflect high levels of concentration while working a mathematical task.

**Interest and Enjoyment.** All eight students did not describe similar feelings towards interest and enjoyment on the task. In fact, there appear to be differences in the self-reported levels of interest and enjoyment among groups of students whose shape thinking was categorized differently. Specifically, those who exhibited emergent shape thinking tended to enjoy the task because it was challenging, promoted problem-solving and thinking, and the context was relatable; these students also tended to find the task interesting because it was challenging, promoted problem-solving, and allowed for autonomy. For instance, Suzy discussed that she found the task interesting because "it makes a person think… this is very important to try to think logically and solve problems in real life."

Though, not all students demonstrating emergent shape think expressed high levels of enjoyment and interest. For example, Marianne indicated that she enjoyed the task because she "enjoyed thinking things out, like trying to make sense of the wheel and drawing it on paper." However, she mentioned that the open-ended nature of the task "put[ting] me back in that place where like I was unsure of myself." Further, Patricia found the task uninteresting and unenjoyable, both of which she attributed to the open-ended nature of the task prompt and not knowing what to do. Thus, Marianne and Patricia associated low confidence while working on the task to lower levels of enjoyment (and interest in Patricia's case).

On the other hand, students who demonstrated static shape thinking while working on this task did not enjoy the task but tended to find it interesting. They associated their lack of enjoyment with finding the task challenging, confusing, and allowing for too much autonomy. Paula and Sally also discussed low confidence being associated with their low level of enjoyment. For example, when asked about her enjoyment, Paula stated, "pretty bad… because I think it is just all wrong… Especially with this one [*referring to the first animation*] because I never saw this before, like the whole circle in just one little section." However, these students did report that working the task was interesting because it was challenging and open-ended. Sally explicitly states this apparently contradictory result "so interesting because difficult; not enjoyable because difficult."

Table 1 presents a matrix of themes associated with student engagement (i.e. concentration, enjoyment, and interest) discussed by students during debriefings based on shape thinking.

*Table 1. Themes associated with engagement by shape thinking*

| | Concentration | Low Enjoyment | Low Interest | Enjoyment | Interest |
|---|---|---|---|---|---|
| Static Shape Thinking | Persistence<br><br>Focus on confusing elements<br><br>Concentrate on explaining | Challenging<br><br>Confusing<br><br>Autonomy<br><br>Low confidence | | | Challenging<br><br>Open-ended |
| Emergent Shape Thinking | | Low confidence (Patrician & Marianne) | Autonomy (Patricia) | Challenging<br><br>Promotes problem solving<br><br>Context | Challenging<br><br>Promotes problem solving<br><br>Autonomy |

## Conclusion

There appears to be a relationship between community college precalculus students' engagement and shape thinking. Specifically, students exhibiting differences in shape thinking described differences in their interest and enjoyment, such that those exhibiting static shape thinking tended to be interested while working the task but experienced low enjoyment. On the other hand, students exhibiting emergent shape thinking tended to find the task both interesting and enjoyable, except for Patricia, who expressed struggling with confidence. Regardless of students' understanding of covariation and shape thinking, these students demonstrated and discussed high levels of concentration.

This study has shed light on factors community college precalculus students associate with their levels of engagement while working through a challenging mathematical task. Researchers have showed that student engagement is positively associated with academic achievement (e.g., Finn & Rock, 1997; Finn & Zimmer, 2012; Newmann et al., 1992; Reschly & Christenson, 2012; Skinner & Belmont, 1993) and success in mathematics (e.g., Barkatsas et al., 2009; Lan et al., 2009; Martin et al., 2015; Rimm-Kaufman et al., 2015; Robinson, 2013). Results presented in this study suggest that community college precalculus students can be highly engaged in mathematics tasks regardless of understanding and that students exhibiting different ways of thinking about graph construction tended to experience different forms of engagement. These results demonstrate the importance for establishing learning environments that foster student engagement.

# Observable Manifestations of A Teacher's Actions to Understand and Act on Student Thinking

Sinem Bas Ader
Istanbul Aydin University

Marilyn P. Carlson
Arizona State University

*This study produced a framework that describes different levels of teacher-student interactions during teaching. The framework characterizes observable teacher behaviors that are associated with each of the four levels of decentering that emerged from analyzing the teacher-student interactions of three teachers when teaching.*

*Keywords:* Decentering, teacher-student interaction, teacher education, radical constructivism

## Introduction

In recent decades, the importance of teachers' attending to and understanding their students' mathematical thinking, and building their instructional decisions on this understanding is highlighted in many research studies and publications in mathematics education (Ball & Cohen, 1999; Sowder, 2007). In *Principles and Standards for School Mathematics* (NCTM, 2000), one of the principles of effective teaching says "Effective teaching involves observing students, listening carefully to their ideas and explanations, having mathematical goals, and using the information to make instructional decisions" (p. 19). Therefore, it is crucial to characterize what is involved in attending to and understanding student thinking, and to illustrate how instructional decisions can be influenced by this understanding, especially in the context of teaching.

Studies have highlighted that understanding students' thinking and deciding how to act based on this understanding are not traits that are inherently possessed by teachers and they should be considered as types of expertise that need to be developed (Jacobs, Lamb, & Philipp, 2010). This position is supported by studies that have described teachers' difficulties in attending to, anticipating, and understanding students' mathematical thinking (Kazemi & Franke, 2004; Rodgers, 2002; Wallach & Even, 2005). In recent years, researchers have introduced and used theoretical constructs as a way to conceptualize the nature and development of this expertise. As one example, the construct of noticing has ben used to make inferences about teachers' ability to focus on students' mathematical thinking in a classroom environment (Sherin, Jacobs, & Philipp, 2011). Similarly, Jacobs et al. (2010) introduced the notion of professional noticing of children's mathematical thinking. They also recommend further research that "can connect teachers' professional noticing of children's mathematical thinking with the execution of their in-the-moment responses" (p. 197).

Piaget's (1955) construct of *decentering* has also been used as a theoretical lens to extend research on teachers' execution of in-the-moment responses based on student thinking (Carlson, Bowling, Moore, & Ortiz, 2007; Marfai, Moore, & Teuscher, 2011; Teuscher, Moore, & Carlson, 2016). In his work on child development, Piaget (1955) introduced the idea of decentering and described it as an action of adopting a perspective that is not one's own. More recently, Steffe and Thompson (2000) and Thompson (2000, 2013) extended Piaget's idea of decentering and conceptualized a meaningful human communication from the perspective of radical constructivism. Teuscher et al. (2016) state that, even though the construct of decentering has rarely been used to investigate interactions between a teacher and student(s), it has the potential to provide researchers with a framework for characterizing how a teacher's attention to (or lack of attention to) student thinking might impact the teacher's in-the-moment instructional decisions.

The purpose of this study was to characterize the degree to which a teacher attempts to make sense of and use student thinking when teaching. It was also our goal to describe the different levels of student-teacher interactions in terms of both the teacher's mental actions (i.e., decentering) and his or her observable behaviors. We have extended previous studies that described different levels of decentering (Carlson et al., 2007; Marfai et al., 2011) by presenting a framework of observable behaviors associated with teacher decentering. The framework has the potential to contribute to the research on effective teacher-student interactions by illustrating behaviors of a teacher that are associated with both non-decentered and decentered interactions between a teacher and her students.

## Theoretical Framework: A Conceptualization of Human Communication in Radical Constructivism

According to Thompson (2000), people interact with others reflectively or unreflectively. In the case of teacher-student interactions, if the teacher acts reflectively, she then can act as an observer and be aware of the student's contributions to the interaction. Otherwise, the teacher acts as an actor, which prevents her from attempting to adopt the student's perspective (i.e., decentering).

A reflective interaction between two people is described as "the process of mutual interpretation and accommodation" (Thompson, 2013, p. 64). In this process, each participant attempts to understand what the other has in mind by building second-order models of the other's mental structures. Second-order models are "the hypothetical models an observer may construct of the subject's knowledge in order to explain their observations (i.e., their experience) of the subject's states and activities" (Steffe, von Glasersfeld, Richards, & Cobb, 1983, p. xvi). During the reflective interaction, each participant continuously adjusts his or her second-order models of the other's knowledge by comparing the other's responses with the responses that he or she anticipates (Thompson, 2013). Besides attempting to understand the other, each participant also makes an effort to have the other understand what he or she has in mind. In the case of teacher-student interaction, for example, the teacher considers how the student could interpret his or her utterances when attempting to convey his or her ways of thinking to the student based on a second-order model of the student's thinking. By continuously updating second-order models of the student's thinking through decentering, the teacher makes better decisions about how to convey his or her intended meaning to the student (Teuscher et al., 2016; Thompson, 2013).

If a teacher interacts with the student unreflectively, he or she is an actor rather than an observer of the student's thinking in this interaction. Thus the teacher is constrained to use his or her first-order model when making decisions about how to act (Teuscher et al., 2016). First-order models are "the models an individual constructs to organize, comprehend, and control his or her own experience, i.e., their own mathematical knowledge" (Steffe, et al., p. xvi).

## Method

### Subjects of the Study

The subjects of the study were three graduate teaching assistants (GTA) at a large public university in the United States. Two of the subjects were PhD students in mathematics and one was a PhD student in mathematics education. They were using the research-based and conceptually oriented Pathways curriculum (Carlson, Oehrtman & Moore, 2016). Prior to the beginning of the semester the subjects attended a 2-day workshop and during the semester when teaching they attended a weekly 1.5-hour seminar, both which focused on supporting the course instructors in developing deep meanings for and critical connections among the key concepts of the course.

### Data Collection and Data Analysis

As the main sources of data, classroom observations were made during the spring semester 2017. Each subject's class was videotaped with a lapel microphone used to capture the teacher's explanations and conversations with students. Moreover, the first author of the study observed each lesson and took field notes.

We began our data analysis by identifying video excerpts in which the teacher was interacting with one of her students. We followed by transcribing these excerpts and began the process of studying the interactions carefully for the purpose of characterizing the degree to which the teacher exhibited decentering behaviors. We also took note of the mathematical meanings displayed by the teacher and the degree to which the teacher exhibited mathematical goals aligned with the mathematical goals of the Pathways curriculum. Our study of the videos led to our constructing codes to characterize the teacher's decentering actions, i.e., the degree to which they were constructing models of his/her students' thinking during interaction. In order to check the inter-coder reliability, two researchers independently coded randomly selected interactions (approximately 20% of the whole data set). We reached 85% agreement in our coding of these pieces of data. Discrepancies between the codes assigned by the two coders were discussed and a consensus on these codes was reached. The first researcher then coded the entire data set.

Following the coding process, we compared the collection of interactions and clustered interactions that were similar relative to the teacher's decentering actions. This analysis led to our identifying four types of student-teacher interactions. We then described observable behaviors and attempted to draw inferences about the mental actions (i.e., decentering) associated with each of the four levels of interactions. In the following paragraphs, we introduce the framework that emerged and then we illustrate how this framework can be used to characterize and describe teacher-student interactions.

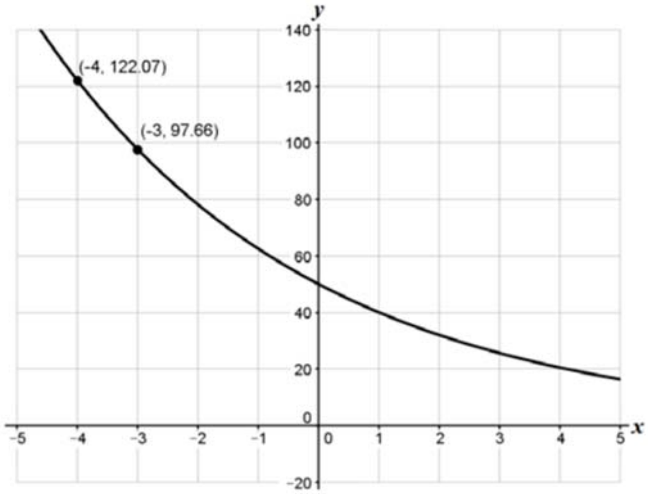
## A Framework for Analyzing Student-Teacher Interactions

The framework illustrates four different levels of student-teacher interactions. Level 1 and Level 2 are considered low-level interactions in terms of the teacher's decentering actions. We see that the teacher is acting from her/his mathematical meanings and is not considering how the student is thinking (Table 1). The primary difference between Level 1 and Level 2 interactions is that a teacher who is classified to be exhibiting Level 2 mental actions poses questions that probe students' thinking, while in a Level 1 interaction the teacher is only interested in students' answers and calculations, or getting students to echo the teacher's phrases. A Level 2 interaction is further characterized by the teacher posing questions and giving explanations aimed at moving students to his or her way of thinking.

Level 3 and Level 4 of the framework are considered to be higher-level interactions in terms of the teacher's decentering actions. In these levels, the teacher attempts to understand the student's perspective and makes general instructional moves based on the student's current thinking when interacting with the student around the course's key ideas. The primary distinction between Level 3 and Level 4 interactions is that during a Level 4 interaction, the teacher exhibits behaviors that suggest that she both respects students' idiosyncratic ways of thinking and makes moves to support students in making connections.

*Table 1. Framework for analyzing student-teacher interactions in terms of the teacher's mental actions and observable behaviors*

| Mental actions | Levels | Description of the behaviors |
|---|---|---|
| • Not reflecting on aspects of the interaction that are contributed by students (i.e., interacting unreflectively)<br>• Creating first-order models of the interaction to organize, comprehend and control his/her own experience<br>• Operating entirely from first-order models (i.e., his/her own mathematical knowledge) | *Level 1:* Shows no interest in students' thinking but shows interest in students' answers and takes actions to get students to say the correct the answer | • Asks questions to elicit students' answers<br>• Listens to students' answers<br>• Does not pose questions aimed at understanding students' thinking<br>○ May pose questions focusing on procedures or calculations<br>○ May evaluate how students' responses compare to his/her own way of thinking<br>○ May pose questions to get students to echo key phrases and/or complete steps to get an answer |
| • Assuming that students' thinking is identical with him/her. In the case of recognizing students' thinking is different then him/her, not attempting to discern the students' mental actions driving the student's behaviors | *Level 2:* Appears interested in students' thinking, does not pose questions focused on students' thinking and attempts to move students to his/her thinking or perspective without trying to understand or build on the expressed thinking and/or perspectives of students | • Poses questions to reveal student thinking but does not attempt to understand students' thinking (e.g., Why? What does that mean? What does that term represent?)<br>• Guides students toward his/her own way of thinking.<br>○ Poses questions for the purpose of getting students to adopt his/her way of thinking<br>○ Gives explanations aimed at getting students to adopt his/her way of thinking |
| • Reflecting on aspects of the interaction that are contributed by students (i.e., interacting reflectively)<br>• Creating second-order models of students' thinking to explain his/her experience of students' states and activities | *Level 3*: Appears to make sense of students' thinking and/or perspectives, and makes general moves based on the expressions of the students | • Asks questions to reveal and understand students' thinking<br>• Follows up on students' responses in order to perturb students in a way that extends their current ways of thinking<br>• Attempts to move students to his/her thinking or perspective<br>○ Poses questions and gives explanations informed by students' current thinking and his/her understanding of the mathematical ideas |
| • Operating from second-order models of student thinking<br>• Assuming that students have idiosyncratic thinking and attempting to discern the students' mental actions driving the students' behaviors | *Level 4:* Takes action to understand students' thinking, appears to understand the expressed thinking and/or perspective of students and takes actions that build on and respect the rationality of these expressions | • Prompts students to explain their idiosyncratic ways of thinking<br>○ Poses questions to gain insights into students' thinking<br>• Draws on students' idiosyncratic ways of thinking to advance students' understanding of key ideas in the lesson<br>○ Poses questions and/or gives explanations that are attentive to students' thinking and/or aimed at advancing students' understanding of an idea<br>○ Poses questions and/or gives explanations to support students in making connections between different viable ways of thinking of a mathematical idea |



1. Find the ratio of output values that correspond to increases of 1 in the input value in order to determine the growth or decay factor.
2. Determine the 1-unit percent change by comparing the change in the output values to the function value at the beginning of a 1-unit interval for x.
3. Identify or determine the value of the function when x=0.
4.Use the information from parts (a) through (c) to define a function formula for the relationship.

*Figure 1. The task used in the classes where the excerpts in the illustration1 and illustration 2 come from (Carlson et al., 2016)*

**Illustration 1:**

The task in Figure 1 requires that students understand that the growth factor in an exponential function represents the relative size of two output values in terms of both multiplicative and percent comparisons (Carlson et al., 2016).

Before the conversation in Excerpt 1 began, the teacher discussed the task by describing how he expected students to think when they see this type of question. He stated, "I know it is a decay factor because it looks like as I move my input up my outputs are going down. I want you to look at it and be thinking these kinds of thoughts". He followed by describing how he determines a 1-unit decay factor. The teacher appeared to be focused on getting the students to imitate how he approaches this type of question, in contrast to showing any interest in the students' thinking. He then turned his attention to finding the function's initial value (Excerpt 1, Line 1).

Excerpt 1

[Line1] *Teacher:* I need to find my initial value. How might I find it? However, I do know a way to find it because I know that every time to get my new output at -2, what do I multiply 97.66 by?

[Line2] *Student1:* .8

[Line3] *Teacher:* .8; the decay factor. So at -2, I have .8 times 97.66. Ok, to get my value at -1 what do I multiply this number by?

[Line4] *Student2:* .8

[Line5] *Teacher:* .8 again, right? So I'm just a kind of walking my way down the graph to figure out what my value is at 0. So I know that I'm gonna have to multiply by .8 once to get the -2, twice to get the -1, and three times to get the zero, right?

We classified this interaction between the teacher and students in Excerpt 1 at Level 1 since there is no evidence that the teacher was interested in the students' ways of thinking about exponential growth or the idea of growth factor. He posed questions and listened to students' responses. However, the teacher's questions were directed at getting students to express the computation to get the correct answer (Lines 1, 3). After one student suggested a factor for multiplying (Line 4), the teacher failed to acknowledge her response; instead he proceeded to explain how the decay factor could be used to find the initial value of the exponential function. This explanation was a presentation of the teacher's way of thinking with no regard for whether his explanations were relevant to the student (Line 5). During this exchange the teacher did not attempt to reveal and understand students' meaning of a 1-unit growth/decay factor, nor did he build a second-order model of his students' thinking. The teacher's questions and explanations were based on his first-order model (his understanding), instead of models he built of students' thinking/meanings.

**Illustration 2:**

Before the conversation in Excerpt 2 began, the teacher asked students to express their ways of thinking about how they could determine the initial value of the function. One of the students expressed that the initial value could be determined by finding the 1-unit growth factor first. The teacher followed by asking the student to express how she determined the 1-unit growth factor. This response suggests that the teacher was interested in understanding the student's meaning of a 1-unit growth factor. The student then explained that she determined the 1-unit growth factor by dividing 122.07 by 97.66. The teacher probed the student about the fraction ($\frac{122.07}{97.66} \cong 1.25$) by saying, "Take a second and looked at this fraction. Is there anything standing out about this fraction?" The teacher's decision to focus students' attention on the value of the growth factor appeared to be for the purpose of getting students to see that a growth factor of 1.25 is not reasonable. The teacher's question led the students to realize that the ratio ($\frac{97.66}{122.07} \cong 0.8$) would produce a reasonable growth for scaling. During this interchange the teacher's interest in supporting students' thinking resulted in him helping the student confront her weak meaning for growth factor. His questions appeared to be based on his understanding of the student's problematic way of thinking. Then the teacher prompted the student to consider how to approach finding the function's initial value (Excerpt 2).

Excerpt 2

[Line1] *Teacher*: How do we go from having a 1-year growth factor to confirming that our initial value is 50?
[Line2] *Student1*: What I did was I just divided .8 the 97.66 so then I kept going down three, three downs until my input is 0.
[Line3] *Teacher*: Ok. So you said you multiplied or divided by a 0.8?
[Line4] *Student1*: Divided
[Line5] *Teacher*: So you did like 97.66/0.8. What are you computing with that?
[Line6] *Student1*: The initial value when the input is -2.
[Line7] *Teacher*: So, to find $f$(-2) we take $f$(-3), which is 97.66 and divide by 0.8. What do you think?
[Line8] *Student2*: I don't know why this happened but you plug this in you get to 122.07
[Line9] *Teacher*: So you're saying that if you compute this value, you get 122.07?
[Line10] *Student2*: Yeah.

[Line11] *Teacher*: Ok. So, if we put that in your calculator we should all get this 122.07. Why is that happening? You should recognize that number, because it's $f$(-4), right? Why we're getting $f$(-4) back when we do this computation? Student3, what do you think?

[Line12] *Student3*: When you divide the output by the growth … bigger…so instead we need to multiply.

We classified this interaction between the teacher and students at Level 3. We observed that the teacher initially prompted students to explain how to find the initial value of the exponential function using the 1-unit growth factor (Line 1). The teacher prompted one student to explain his approach; he then asked the student to provide a rationale for his approach (Line 5), demonstrating that he was interested in understanding how the student was thinking. When the student replied by saying that he was finding the initial value when the input is -2, the teacher followed by re-expressing the student's explanation; his explanation (Line 7) suggests that he understood how the student was thinking. He continued by posing questions to reveal how the student was thinking (e.g., Why are we getting $f$(-4) back when we do this computation?, [Line 11]).

## Discussion and Conclusion

Prior research has characterized teachers' attempts to understand students' thinking, including how they respond when students express their thinking and whether they take student thinking into consideration during teaching. Researchers have used the idea of decentering as a theoretical lens to make inferences about a teacher's ability to make sense of student thinking (Teuscher et al., 2016). Piaget's construct of decentering has been considered as a powerful lens for researchers when focusing on how teachers build models of students' thinking and to what degree they use student thinking to make instructional decisions (Teuscher et al., 2016). Moreover, Thompson's (2013) conceptualization of a productive interaction between two people (i.e., the interaction where "each participant is oriented to understand what others have in mind and is oriented to have others understand what he or she intends" (p. 63)) extends the idea of decentering. There are also studies in which different levels of a teacher's decentering actions during his or her interaction with students are characterized based on this theoretical perspective (Carlson et al., 2007; Marfai et al., 2011; Teuscher et al., 2016). This study extends these research efforts by introducing a framework that provides a fine-grained characterization of teacher-student interactions. The framework describes two levels of a teacher's mental actions (i.e., non-decentered and decentered) and four levels of the teacher's observable behaviors that are associated with both non-decentered and decentered actions. The levels in the framework will be useful for both researchers and teacher professional developers by illuminating subtle and productive ways in which a teacher can leverage student thinking when interacting with students.

Studies also point out that all teaching actions are strongly related to the teachers' mathematical meanings for teaching (Thompson, 2013; Thompson, Carlson & Silverman, 2007). In Thompson's (2015) view, teachers' mathematical meanings for teaching are the main sources of their instructional decisions and actions. While this study does not examine how a teacher's meanings for a mathematical idea influence the quality of his or her decentering actions, we will investigate the relationship between teachers' mathematical meanings and their decentering actions in future research.

# Developing Strategic Competence With Representations for Growth Modeling in Calculus

Christopher Plyley
University of the Virgin Islands

Celil Ekici
Texas A&M University - Corpus Christi

*Using inquiry based modules centered around growth modeling, we study the development of strategic competence and representational fluency in undergraduate calculus. Building on student experiences and using multiple representations with discrete and continuous methods, we discuss the emerging substantial and problematic practices with representational fluency, communication, and strategic competence for modeling growth.*

*Key words:* Representational Fluency, Strategic Competence, Calculus, Differential Equations, Modeling

It has been suggested that mathematical modeling should be taught at every level of mathematics education (GAIMME, 2016), however successful modeling of realistic problems, like population dynamics, in STEM related fields requires students to achieve high levels of mathematical proficiency. The National Research Council defines mathematical proficiency as having five components, or interwoven strands: 1. conceptual understanding - comprehension of mathematical concepts, operations, and relations. 2. procedural fluency - skill in carrying out procedures flexibly, accurately, efficiently, and appropriately. 3. strategic competence - the ability to formulate, represent, and solve mathematical problems 4. adaptive reasoning - capacity for logical thought, reflection, explanation, and justification. 5. productive disposition - habitual inclination to see mathematics as sensible, useful, and worthwhile, coupled with a belief in diligence and one's own efficacy (NRC, 2001).

A crucial part of mathematical literacy, representational fluency refers to the ability to represent mathematical ideas with different representations, to translate these ideas across representations, to gain understanding about the underlying entities that are being represented, and to generalize across representations (Zbiek et al. 2007). It requires a metacognitive perspective requiring knowledge and synthesis beyond the representations themselves. This perspective was expressed by Sigel and Cocking as the ability to comprehend the equivalence of different modes of representation (Sigel and Cocking, 1977) after one can transfer information from one representation to another.

Despite the need for and benefits of representational fluency (e.g., Kaput, 1989), there is relatively little known about the calculus student's ability to solve problems when presented with different representations, or to translate ideas among different representations. Studies have reported that students have difficulties linking different representations and moving flexibly between representations (Even, 1998; Janvier, 1987). For example, researchers observed that calculus students were often comfortable with different results in different representations without realizing the inconsistency of the results (Ferrini-Mundy and Graham, 1993). Some researchers noted that students may link representations without an understanding of the deeper conceptual links between them (Greer & Harel, 1998). Beyond an equivalence perspective amongst representations, there is a need for a deeper look into how representational fluency translates to improved mathematical proficiency and strategic competence. More pointedly, little is known about how fluency among representations across discrete and continuous mathematics contribute to mathematical proficiency. Even (1998) highlighted that there is "not much known about the nature of the processes involved in working with different representations," despite agreement among mathematics educators about their importance in learning mathematics.

## Objectives and Research Questions

In this paper we discuss the collaborative action research of two mathematics faculty members with the goal of improving the practice of teaching calculus(Stinger, 2014). We infused collaboratively planned and purposefully designed inquiry based activities into a two semester freshman calculus sequence. Our activities were designed to provide opportunities for students to experience fluency with multiple representations from both a discrete and continuous perspective while investigating population growth modeling. Ultimately, we hope to further the development of both the strategic competence and the representational fluency in our students, and in doing so, to make the content of growth modeling more accessible for our student population. We both observed that this content is otherwise problematic with the traditional integration methods. Our main research questions are:

1. How do calculus students develop representational fluency when modeling population dynamics with an enriched instruction on discrete methods?
2. How do calculus students develop strategic competence when modeling population growth, specifically when they learn to connect complimentary discrete and continuous concepts, such as differential and difference equations?

## Conceptual Framework for Representational Fluency in Growth Modeling in Calculus

Multiple external representations traditionally associated with mathematics have been outlined by many authors (Lesh, Post, and Behr, 1987; Kaput 1998; Kendal 2003); in this paper, we will refer to five different modes: Graphical, Algebraic, Verbal, Manipulative Models, and Real Life Scenarios (see Figure 1). Aligning with Kaput and Lesh, we take special care to incorporate real life scenarios and manipulative models, extending beyond just the big three representations.

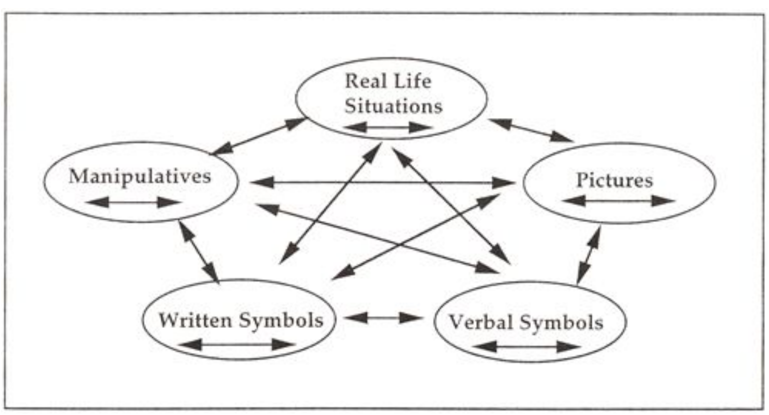

*Figure 1.* Lesh et al.'s model depicting five representational modes with Real Life Situations, Pictures/graphs, Written Symbols, Manipulatives/digital/concrete models, Verbal Symbols.

Each of the different representational modes affords the student different opportunities for mathematical insight. Advancements in technologies, the ease and availability of graphing calculators, and computer algebra systems now allow differentiation and integration to be easily calculated using numerical and graphical representations. Of course, these numerical and graphical solutions are primarily at a point or within an interval, rather than a global solution, as can be often found with the traditional analytical approach that relies on symbolic representations and algebraic manipulations.

In the context of calculus, and more specifically, growth modeling, students can demonstrate strategic competence by formulating modeling problems, by representing them with multiple representations, and by choosing flexibly among discrete or continuous methods to suit the demands of the mathematical content. Adaptive reasoning, on the other hand, refers to the capacity to think critically about the relationships among concepts and situations. Adaptive reasoning is the meta-cognitive leap to assess the fitness of the method and the adequacy of representations to provide the insight into problem in its realistic context.

We build on Rasmussen and Kwon's (2007) approach to inquiry based undergraduate mathematics by engaging our students in cognitively demanding tasks that prompt the exploration of important mathematical relationships and concepts, by orchestrating mathematical discussions in class and in small groups, by developing and testing conjectures, and by having students explain and justifying their thinking. Following an inquiry approach, we continually build upon, refine and expand our questions on population dynamics as we introduce new concepts in calculus. For example, we revisit population dynamics and present modeling opportunities at each step as we progress through major topics such as rates of change, anti-differentiation, and differential equations.

## Methods and Setting

In Calculus I and II, we integrated both differential and difference equations as major components with instructors devoting approximately four weeks in each semester to these topics. Realistic scenarios were built around population growth, which was used as a cross-cutting theme that permeates across courses for the same group of students. The inquiry based modules that we infused into the calculus sequence emphasized discrete approaches to problems traditionally approached from a continuous perspective. The researchers collaboratively designed the modules used for this study since 2013. Our students were tasked with solving difficult problems in small groups by utilizing visual, analytical and verbal representations. Activities were purposely designed with the main goals of i. creating a more balanced approach to calculus with discrete and continuous methods; ii. Enhancing representational fluency; iii. Developing strategic competence.

We used multiple data sources, including analyzing student work, student reflections, and student discussions in an attempt to observe the student's representational fluency and strategic competence during the activities. The researchers also noted their observations and reflections on student behaviour and practices in follow-up discussions. Data was collected from students during the Fall and Spring Semesters of 2016 and 2017; in total, there were 23 students in Calculus I and 19 students in Calculus II.

## An Integrated Calculus Instruction

As previously mentioned, the instructors spent approximately four weeks each semester engaging in inquiry based modeling activities focusing on discrete and continuous representations of population growth. For illustrative purposes, we offer a short description of two of the modeling activities we used, one from Calculus I and one from Calculus II. Aligning with recommendations from GAIMEE, we encourage our modeling problems to be approached in an open-ended manner to allow for the possibility of student conjecturing, exploration and investigation.

### A Growth Modeling Activity in Calculus I

Students are presented with a modelling scenario involving the growth a fruit fly population, which was inspired by a similar problem in Thomas' Calculus(2014) that builds the idea of derivative from the rates of change of a logistic model given visually and numerically.

> *Imagine that one day a rotting apple in your kitchen has attracted some fruit flies. Suppose that on that day you count two fruit flies. You (unwisely) leave you home for 50 days, leaving the apple on your counter. When you return, the fly population has grown by 350 flies.*

We introduce alternative growth models before discussing the rate of change behavior for a logistic curve, not only with continuous but also with discrete methods. Our goal is to have students explore the given real world scenario and develop various models that can represent the growth of the population over the 50 day period, based on the assumptions that they formulate. The instructor ensures that the students represent their idea using multiple representation modes. In this case, most students are initially drawn to familiar continuous representations of linear growth, such as the (continuous) algebraic representation: $y = 7x+2$, the (continuous) graphical representation: a linear graph, and the verbal description of "a growth of 7 flies each day." If they choose this continuous approach, they are required to demonstrate their model using graphing technology (Geogebra or similar). The instructor asks questions which require manipulation of their model under different conditions (different initial population or growth rate, etc.). In our case, all students began the activity using this continuous approach.

Once they have successfully modeled linear growth with continuous methods, they are challenged to represent the growth using discrete methods. The students must now transfer ideas laterally among the same representation modes; for example, the represent growth algebraically with a difference equation: $P_{n+1} = P_n +7$, graphically with a scatter plot, and they are asked to use a manipulative model such as Microsoft Excel to experiment with different parameters.

Students become aware of the limitations of the linear model and initiate investigations into other models, which we direct towards exponential and logistic growth. Once again, students must represent their ideas using algebraic equations, graphical images (see Table 1 below for more detail), and they must utilize manipulative models that can account for the changing of initial conditions. They are free to initiate either a discrete or continuous approach to their models, but through group collaboration, discussion, and reflection, all groups eventually see how these ideas can be modeled from both perspectives. Unifying questions relating the rates of change and the changes in the rates of change emphasize the complementary nature of the discrete and continuous approaches, and discussions involving the difficulties encountered by some approaches emphasize the importance of flexibility and strategic choice.

**Continuing Growth Modeling Activity in Calculus II**

In the second semester of Calculus, while studying first-order differential equations, students are presented with another modeling scenario involving a locally relevant invasive lionfish population:

> *Biologists have determined that a coral reef can safely sustain a population of 350 or fewer lionfish; however, once the population exceeds 350, irreversible damage will be done to the ecosystem.*

Once again aligning with GAIMEE recommendations, we allow students to formulate their own questions and ideas to investigate these scenarios. In this case, the instructors steered the students towards suggesting a harvesting strategy to keep the fish population below the threshold of 350. In previous modeling activities, students discovered a carrying capacity of 850 lionfish, and they proceed under that constraint. They make assumptions, such as an initial population, and the frequency of their harvesting expeditions, and proceed to answer questions like: *How many fish do we need to harvest if we send an expedition once every 6 months?* A continuous approach leads to representations like algebraic differential equations: $\frac{dy}{dx} =- 0.25y(1 - \frac{y}{850})$, continuous solution curves and slope fields, and manipulative models like slope field generators in GeoGebra. A discrete approach has students transfer between the difference equation: $P_{n+1} = 1.25P_n - \frac{0.25}{850} P_n^{\ 2}$, and the graphical scatter plots made using Microsoft Excel (or similar), with which they can experiment with different parameter values. Ideas are summarized and presented to the class, so that discussion can ensue on the pros and cons of the different approaches.

Without including the graphical representations, we provide descriptions of the basic growth models introduced in modeling the population dynamics.

*Table 1.*
Summary for the Models for Population Dynamics

| *Underlying Math Models for Growth* | *Contextual/ Verbal* | *Symbolic- Discrete* | *Symbolic Differential* |
|---|---|---|---|
| Linear | Constant Change | $\Delta P_n = P_n - P_{n-1} = k$ | $\frac{dP}{dt} = k$ |
| Exponential | Unbounded | $\Delta P_n = (a-1)P_{n-1}$ | $\frac{dP}{dt} = (a-1)P$ |
| Logistic | Limited Capacity | $\Delta P_n = mP_{n-1}(1 - \frac{P_{n-1}}{C})$ | $\frac{dP}{dt} = mP(1 - \frac{P}{C})$ |

## Observations and Results

Our observations suggest that the enhanced treatment of growth modeling with a balanced focus on discrete and continuous methods can improve the development of representational fluency and strategic competence in participants. On several occasions, we observed what we perceived as higher than usual student growth in the ability to transfer ideas across traditional representational paths, such as from continuous equations to continuous graphical representations. For instance, the majority of students (72%) that were unable to correctly connect a differential equation to its direction field prior to our modeling activities were able to successfully do so afterwards. The assessment question used in this case is seen in Figure 2.

*Which of the following equations is the differential equation whose slope field is shown below?*

- *a) y'=3-y-x*
- *b) y'=3+y-x*
- *c) y'=3-y+x*
- *d) y'=3+y+x*
- *e) y'=3-yx*

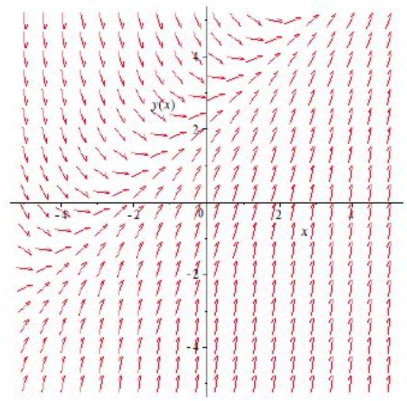

*Figure 2.* Slope field assessment task.

In addition, we also observed that upon the completion of our course, students were demonstrating an enhanced flexibly in choosing among discrete or continuous methods that best suited the problem at-hand. In our initial assessments, students would largely prefer continuous approaches, regardless of the comparative difficulty of discrete approaches. For example, in our unit on arc length, students were tasked with the well-known problem of finding the length of the Golden Gate Bridge, which is modeled with the equation $y = \frac{x^2}{8820} - \frac{10x}{21} + 500$, but only to within 10 feet of accuracy. We observed that 4 of 5 groups pursued an exact solution via the continuous integration formula, whereas the remaining group solved the problem using a line segment approximation. We note that students had practiced such approximations recently. In fact, all four groups were unable to solve to the continuous integral, and resigned the problem rather than switch approaches. After completing our modeling exercises, students attempted the following question:

> *The population of lionfish in a water column above a coral reef near Buck Island is given by* $\frac{dy}{dx} =- 0.15y(1 - 0.06375y + \frac{y^2}{12800})$ *where y is the population in lionfish and x is in years. Biologists determine that the reef can safely sustain a population of 350 or fewer lionfish, but once the population exceeds 350 irreversible damage will be done to the ecosystem. A diving survey team estimates a current population of 180 lionfish. After approximately how many months will the population equal 350?*

This time, the majority of the groups (4 out of 5) used a discrete approach (Euler's method) for their initial strategy; whereas the remaining group began with a continuous approach, but were able to switch the the discrete method after some initial failure. We further make note of our observation of what we perceived to be better than expected results in the student's ability to formulate and solve modeling problems. Groups engaged in the harvesting exercises demonstrated more mathematical autonomy and independence in completing their assigned tasks. It was clear that student's strategic competence became amply evident in growth modeling tasks when the instruction allows student experimentation with manipulatives, such as the dynamic spreadsheets that blend the numerical or graphical representations. Our students performance exceeded our expectations with their problem formulating skills, their critical thinking in the creation of their models, and their suggestions for harvesting schemes for population control. They also seemed to become more productive and reflective after strategic choices of visual representations, such as flow diagrams, substantially empowered them towards a dynamic sense of the global behavior of solution curves under different initial conditions.

By the culmination of the activity sequence, we observed students development in both the cognitive and content related skills in calculus, such as representational fluency and building connections between discrete and continuous methods in modeling growth. Our final remark is that the additional fluency involving the discrete representational forms emerged in a critical capacity as providing certain students access to deeper mathematical ideas that were inaccessible to them from a continuous standpoint. We observed that several students had difficulty solving growth problems analytically, in particular, when modeling logistic growth, however, they ultimately overcame their earlier problems producing solution curves algebraically when asked to use traditional integration techniques in calculus. Most of our students who struggle with difficult concepts in topics like differential equations were more able to experience success with this approach, as exemplified in the harvesting activity outlined above. Their exercised ability to use spreadsheets allowed even the weakest students to see the impacts of harvesting at set time periods clearly.

# Building on Covariation: Making Explicit Four Types of "Multivariation"

Steven R. Jones
Brigham Young University

*Covariation and covariational reasoning have become key themes in mathematics education research. In this theoretical paper, I build on the construct of covariation by considering cases where more than two variables relate to each other, in what can be called "multivariation." I share the results of a conceptual analysis that led to the identification of four distinct types of multivariation: independent, dependent, nested, and vector. I also describe a second conceptual analysis in which I took the mental actions of relationship, increase/decrease, and amount from the covariational reasoning framework, and imagined what analogous mental actions might be for each of these types of multivariation. These conceptual analyses are useful in order to scaffold future empirical work in creating a complete multivariational reasoning framework.*

*Key words:* covariation, multivariation, reasoning, mental actions

The construct of covariation and the cognitive activities involved in reasoning about it have become important themes within mathematics education research (e.g., Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Moore, Paoletti, & Musgrave, 2013; Moore, Stevens, Paoletti, & Hobson, 2016; Oehrtman, Carlson, & Thompson, 2008; Thompson, 1994). Yet, work on *co*-variational reasoning has essentially been limited to examining two variables changing in tandem with each other, perhaps with time as a mediator to that relationship (explicitly or implicitly). By contrast, as students continue to higher levels of science and mathematics courses, they encounter contexts in which there are more than two variables potentially changing in relation with one another. Note that I use the term "variable" in this paper to generally mean any potentially varying numeric value, including values of real-world quantities and mathematical function inputs and outputs. This theoretical paper is meant to build on the construct of covariation by explicitly considering cases where more than two variables (in addition to time) relate to and change with one another, in what can be termed "*multivariation*." In particular, I share the results of a conceptual analysis in which I identified four different types of multivariation, each with its own potential set of mental actions for reasoning about it. I also share the results of a second conceptual analysis examining what "*multivariational reasoning*" might possibly look like for each type, in terms of analogous mental actions corresponding to those already documented for two-variable covariational reasoning. The results of these conceptual analyses are meant to scaffold future empirical work, by helping to inform study design and data analysis, which can be used to establish a complete multivariational reasoning framework.

## Covariation and Multivariation

Over the past couple decades several researchers have been contributing to a carefully developed sense of what "covariation" means (Carlson et al., 2002; Castillo-Garsow, 2012; Confrey & Smith, 1995; Johnson, 2012; Saldanha & Thompson, 1998). The central theme to this work is that covariation consists of imagining "two quantities [i.e., variables] changing together" (Castillo-Garsow, 2012, p. 55) in which "they are changing simultaneously and interdependently" (Johnson, 2012, p. 315). The specific term "quantity" often has additional meaning beyond being only a numeric value, and usually implies a measurable quality of an object (Thompson, 1994). However, covariation has also been applied to purely mathematical functions that are not necessarily contextualized as relationships between physical quantities (Oehrtman et al., 2008; Thompson & Silverman, 2008). In this paper, I consider covariation of variables both in terms of physical quantities and mathematical functions.

An important part of covariation, regardless of the variables involved, is the concept of time (Castillo-Garsow, 2012; Oehrtman et al., 2008; Thompson, 2011). Sometimes time can be explicitly present in the covariation as one of the two real-world quantities, such as distance and time. However, even for two non-time variables, or for a mathematical function, $y = f(x)$, if one applies "smooth" covariational reasoning (see Castillo-Garsow, 2012), time must necessarily be involved in imagining the change in progress. The necessity of time resonates with the assertion in Oehrtman et al. (2008) that, "The idea of covariation is fundamentally that of parametric functions" (p. 38). Thus, for my purposes, if a variable "A" is said to be varying (or covarying with another variable), it can be thought of as changing in time, $\mathrm{A}(t)$. However, this change does not have to happen linearly in "real" time, but can be conceptualized to move forward quickly or slowly, or to move in reverse, or to pause at a given instant.

**Multivariation in the Current Literature and Conceptual Analyses**

I began thinking about the construct of "multivariation" during a study involving the limits of complicated expressions (Jones, 2015) and another study involving multiple, line, and vector integrals (Jones & Naranjo, 2017). These ideas were further stoked when I encountered the "partial derivative machine" at a RUME conference, in which it is not always possible to hold certain variables "constant" in order to use basic covariation (see Roundy et al., 2015). I also began to see in mathematics and science textbooks how many instances there were in which multivariation could be involved. I wish to make clear that I am in no way claiming to be the inventor of the notion of multivariation, and that ideas surrounding multivariation have, in fact, been present in the mathematics education research literature, including studies on the graphs of multivariate functions (e.g., Dorko & Weber, 2014; Martinez-Planell & Trigueros-Gaisman, 2012; Weber & Thompson, 2014), on partial and directional derivatives (Bucy, Thompson, & Mountcastle, 2007; Martinez-Planell, Trigueros-Gaisman, & McGee, 2014, 2015), and on multiple integrals (McGee & Martinez-Planell, 2014). However, the main reason I believe this paper is needed is that while ideas pertaining to multivariation are present in the literature, multivariation as a construct in and of itself has essentially been implicit. Thus, there is still a need to explicitly discuss what *multivariation* and *multivariational reasoning* might consist of.

This theoretical report consists of the products of two conceptual analyses (see Thompson, 2008) meant to form the basis of future empirical work. The first conceptual analysis, presented in this section, focuses on what possible types of multivariation might exist. (The second analysis is described in the next section). To perform it, I looked through a large set of mathematics, science, and engineering functions and formulas, found mostly inside textbooks (e.g., Hibbeler, 2012; Serway & Jewett, 2008; Stewart, 2015), and considered how the variables in them could be conceptualized as changing with respect to one another. This conceptual analysis led to the identification of four distinct types of multivariation: *independent, dependent, nested,* and *vector*.

**Four Types of Multivariation**

Here I describe the four ways I identified that more than two non-time variables might be "changing together" in a potentially "simultaneous and interdependent" way (Castillo-Garsow, 2012; Johnson, 2012). I have stipulated non-time variables precisely because time is inherent in all types of variation, as discussed previously, whether univariation, covariation, or multivariation. Thus, time-parametric equations are not considered a separate type of multivariation, since they are already inherent in all types.

**Independent multivariation**. The first type of multivariation I describe, *independent multivariation*, is probably the most commonly imagined type of multivariation in mathematics because of how we often work with multivariate functions, like $z = f(x,y)$. In this type, there are multiple “input” variables (e.g., $x$ and $y$) that each individually covary with an “output” variable (e.g., $z$), but where the “input” variables need not covary with each other. In other words, the covariations between each input variable with the output variable can be conceptualized as *independent* from each other. In contrast to covariation, a change in the output does not necessarily imply a change in one particular input, since the change in output could have happened as a result of covariation with a separate input variable. Next, I note that what counts as “input” and “output” does not necessarily need to be fixed (e.g., solving to get $x = f(y,z)$), so long as the covariations between each of the input variables and the output variable remain independent. I also note that this type of multivariation could be extended to include as many input variables as desired, such as for the function $z = f(x_1,x_2,\ldots,x_n)$.

Since each input variable covaries with the output variable, it might be tempting to think of this type of multivariation as simply basic covariation by holding all but one of the input variables constant at a time. While that can be true, what makes this distinct from two-variable covariation is that it is, in fact, possible to imagine *all* of the input variables changing at the same time, each having their own impact on the output variable. This is similar to the idea of directional derivatives (see Martinez-Planell et al., 2015), or to taking a surface defined by $z = f(x,y)$ and tracing out a curve on it by parameterizing $x(t)$ and $y(t)$ over the interval $a \leq t \leq b$.

This type of multivariation is present in many science contexts involving real-world quantities. The key is whether it is realistically and conceptually reasonable to hold certain variables constant while varying others. For example, force (an output variable) can be defined as the product of mass and acceleration (the input variables), as in $F = ma$. In this case, one can imagine holding $m$ constant and changing $a$ to produce changes in $F$, or holding $a$ constant and changing $m$. Yet, what makes this “multivariation” rather than “covariation” is that $m$ and $a$ could be imagined to be changing simultaneously, yet independently, each producing concurrent changes in $F$. Note that $m$ and $a$ do not have to be the input variables, since one could imagine holding $F$ constant and changing $m$ to produce changes in $a$.

**Dependent multivariation.** The second type of multivariation, *dependent multivariation*, more commonly arises in real-world contexts, since input variables for mathematical functions are typically conceptualized as, literally, “independent variables.” However, for certain scientific contexts it might not make sense to conceive of holding some variables constant while the others vary. In fact, some science educators have already brought up this idea, since “holding constant” is not always possible (e.g., see Bucy et al., 2007; Roundy et al., 2015). The main idea for this type of multivariation is that, rather than having several independent covariations between multiple “input” variables and a single “output” variable, a change in any variable produces simultaneous changes in *all* other variables. Further, as those other variables change, they also immediately induce changes in all other variables in the system.

For example, if a fixed amount of gas is contained in a flexible balloon, the ideal gas law models the relationship between the volume, $V$, pressure, $P$, and temperature, $T$, of the gas through the equation $PV= kT$. However, unless certain laboratory conditions are imposed, it might not be realistic to hold $P$ constant while $T$ and $V$ change with respect to each other. More realistically, if the temperature increases, the pressure and volume both increase simultaneously and their changes can feed back into the system immediately. Or, to pull from a rather different context, suppose an economist is examining how price, affected by demand and supply, is changing for a particular good in a market that is in flux. Again, it might not be realistic to imagine holding demand constant in order to manipulate supply and measure the corresponding changes in price. As the supply changes, both price and demand may change simultaneously as the market approaches a new equilibrium.

To be clear, in this type of multivariation, I am not saying that it is not *mathematically* possible to hold one of the variables constant in order to enact calculations. However, my point is that these types of contexts cannot conceptually be fully accounted for *only* through multiple independent two-variable covariations. Rather, one would have to use mental actions that involve multiple variables all having simultaneous impacts on each other in order to reason accurately about the real-world processes.

**Nested multivariation.** The third type of multivariation I describe, *nested multivariation*, comes from how one might conceptualize changes when the relationships between variables are based on the structure of function composition, such as $z(y(x))$ (for more on student understanding of function composition, see Ayers, Davis, Dubinsky, & Lewin, 1988; Breidenbach, Dubinsky, Hawks, & Nichols, 1992). For $z(y(x))$, if one imagines changes in $x$, then there are corresponding changes to $y$. Yet those changes in $y$ now correspond to changes in $z$. While it is true that one can, in fact, think of direct two-variable covariation between $x$ and $z$, nested multivariation conceptualizes the relationship as having intermediary variables. Thus, the difference between whether it is two-variable covariation or nested-variable multivariation is *not* inherently dependent on the structure of the formula or function. Rather, it is necessarily a product of how one *conceptualizes* the changes taking place. For example, for the equation $y = \sin^2(x)$, it is true that one can imagine $x$ and $y$ changing directly with each other. However, it is also possible to imagine that as $x$ increases, from say 0 to $\pi/2$, it produces corresponding increases in the value of "$\sin(x)$," and that as the value of $\sin(x)$ increases, it in turn generates increases to the "$\sin^2(x)$" values. In other words, as one variable changes it induces a change in a second, which induces a change in a third variable (and potentially so on to include as many variables as desired).

To describe an example from science, consider the formula from relativity relating velocity, $v$, with the relative mass of an object, $m$, given by $m = m_o \Big/ \sqrt{1-(v/c)^2}$ ($c$ is the speed of light and $m_o$ is the relative resting mass). When I have asked students to describe what happens to mass as $v$ approaches $c$, they tended to think through this formula piece by piece. They would first discuss how an increasing $v$ made the ratio between $v$ and $c$ approach one. They would then discuss how that corresponded to $\sqrt{1-(v/c)^2}$ shrinking to zero, which lastly made the value of the entire expression tend toward infinity. To represent their thinking in mathematical notation, they essentially thought of the mass equation broken down into a ratio function, $\beta(v) = v/c$, which became an input for the Lorenz factor, $\gamma(\beta) = 1\Big/\sqrt{1-\beta^2}$, which in turn became the input for the mass, $m(\gamma) = m_o\gamma$. As explained previously, it is true that one can think of direct covariation between $v$ and $m$. If one does so, then in that case they are employing covariational reasoning. However, if they imagine nested changes from $v$ to $\beta$ to $\gamma$ and finally to $m$, then I argue they are employing nested multivariation reasoning.

**Vector multivariation.** The last type of multivariation I describe, *vector multivariation*, may be the most cognitively complex and gets its name because it deals with multiple independent inputs each simultaneously associated with multiple independent outputs (i.e. a vector function).

Thus, vector multivariation is essentially a generalized version of independent multivariation in that it consists of several *independent multivariations* each happening *independently* of each other. For a vector function, $\vec{F}(x,y)=\langle u(x,y),\, v(x,y)\rangle$, like with independent multivariation, one can think of holding, say, $y$ constant and letting $x$ vary, but in this case that variation corresponds to changes in both $u$ and $v$ at the same time. Further, imagining both $x$ *and* $y$ varying simultaneously leads to four pairs of independent covariations that could potentially need to be cognitively managed all together. As with all other types of multivariation, vector multivariation could be extended to include as many variables as desired, including several input or several output variables.

For examples of vector multivariation, consider a vector field mapping $\mathbf{R}^2$ to $\mathbf{R}^2$. If one were to take a starting point $(x,y)$ and increase the $x$-coordinate, tracing a horizontal line through the vector field, both the horizontal and vertical components of the vector field could be changing simultaneously. Similarly, if one increased the $y$-coordinate and traced vertically through the vector field, both components of the vector field could change. Now, for full vector multivariation, if one traced out a curve, $C$, in the $x$-$y$ plane along which both $x$ and $y$ are changing simultaneously, one would have to coordinate how much $x$ and $y$ are each changing, and what the resulting changes in the horizontal and vertical components of the vectors are. This type of multivariation shows up in vector integrals, $\int_C \vec{V}\cdot d\vec{r}$, and also occurs for functions with complex inputs and outputs, $f: C \rightarrow C$. For complex functions, if the input complex variable changes along a curve in the complex plane, one would have to simultaneously attend to changes in the real and imaginary parts of the input variable, as well as the changes in the real and imaginary parts of the output variable. In science, this type of multivariation could be present in any context involving vector spaces, such as gravitational fields or electrical fields. One could imagine a particle tracing some path through those fields, with changes happening in each of the vector components as the path is traced out.

**Comparison of structures**. To summarize this first conceptual analysis, Figure 1 shows the distinct conceptual structures for the four different types of multivariation (and covariation). Of course, each type of multivariation could be extended to include as many variables as desired.

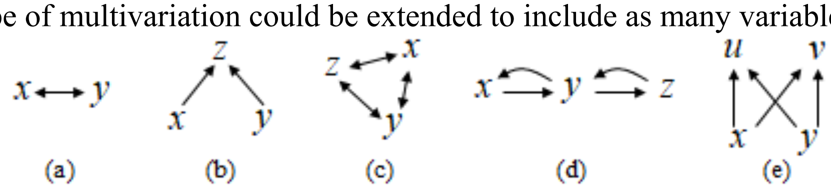

*Figure 1. Comparison of structures for (a) basic covariation, (b) independent multivariation, (c) dependent multivariation, (d) nested multivariation, and (e) vector multivariation, where (b)–(d) could each be extended to include as many variables as desired.*

## Covariational Reasoning and Multivariational Reasoning

To describe the second conceptual analysis, I briefly return to basic two-variable covariation. Carlson et al. (2002) described five mental actions that pertain to increasingly sophisticated levels of covariational reasoning. The first three mental action levels are given as (p. 357): (1) "Coordinating the value of one variable with changes in another," (2) "Coordinating the direction of change [i.e., increase or decrease] of one variable with changes in the other variable," and (3) "Coordinating the amount of change of one variable with changes in the other variable." For my purposes, I label these three mental actions as "relationship," "increase/decrease," and "amount." The fourth and fifth mental action levels then progress to changing rates of change, marking a shift from reasoning about the two variables directly to reasoning about how a rate of change itself varies. For my conceptual analysis, I focused on what mental actions for each type of multivariation might be analogous to the *relationship*, *increase/decrease*, and *amount* mental actions from covariation. I do not include changing rates of change in this conceptual analysis at this point because of the potential complexity of multiple simultaneous changing rates of change. Rather, my conceptual analysis focuses on providing an initial step into how one might imagine the variables themselves in the system and their direct relationships with each other.

**Analogous Multivariational Reasoning Mental Actions**

Here I describe the potential mental actions of multivariational reasoning that might be analogous to relationship, increase/decrease, and amount from covariation. This "thought experiment" is intended to scaffold possible empirical methods aimed at examining the nature of multivariational reasoning, by imagining beforehand what cognitive activities might specifically be targeted in empirical research.

First, what might be the mental actions in *independent multivariational reasoning* analogous to relationship, increase/decrease, and amount? The first mental action would likely consist of a realization that multiple input variables may impact a single output variable, and that each change may be happening in isolation or simultaneously. In thinking of the surface defined by the graph of $z = f(x,y)$, it would be the realization that one can trace a path along this surface in *any* direction, freely. The next mental action may consist of coordinating each individual change in the input variables to an overall net *directional change* for the *inputs*. In the case of $z = f(x,y)$, this would be congruent to imagining a "change vector," $\Delta V$, whose components are $<\Delta x,\Delta y>$, though I use the word "vector" for convenience and note that a student would likely not conceptualize it as an actual "vector." In contrast to the second level of covariational reasoning, where there is already attention to whether the output increases or decreases, I hypothesize that this is a required preliminary mental action for independent multivariational reasoning, not yet involving "increase/decrease." That is, it may be required to simply identify the direction of the change vector *before* determining whether the output increases or decreases along it. It would then be a separate mental action in which one would coordinate this *change vector* with whether the output variable increases or decreases. Thus, we can see additional sophistication in independent multivariation reasoning above what is required for two-variable covariational reasoning. Only after these three mental actions would a fourth mental action coordinate the *amount* of change in the output variable along the direction of this change vector.

Next, consider *dependent multivariational reasoning*. Here, the first mental action would likely consist of the coordination of a change in one variable with simultaneous and interdependent changes in all other variables in the system. That is, it would be the realization that some variables cannot be held constant in a realistic way and that a system may only be understood by imagining all variables changing interdependently. The second mental action might then consist of coordinating the change in one variable with whether each of the other variables increases and/or decreases. This mental action is quite sophisticated, since one must coordinate interdependent increases and decreases, meaning it may even consist of separate mental actions. For example, in the balloon context, increasing temperature would mean an increase in pressure, but the fact that the volume also increases means that the pressure would not increase by as much as would be predicted if volume were able to be held constant. The next mental action would consist of coordinating the change in one variable with the *amount* by which each of the variables in the system interdependently change as a result.

For *nested multivariational reasoning*, each mental action essentially deals with *chained* reasoning. The first mental action would involve coordinating a chain of changes from one variable to the next. It would be the realization that a change in one variable would have effects on a *sequence* of other variables. The second mental action may consist of coordinating the change in the first variable with whether the second variable increases or decreases, and coordinating whether increases or decreases in the second correspond with increases or decreases in the third, and so on. A possible metaphor is a sequence of gears where one attends to how a rotation in the first induces rotations on the others. Again, this may actually represent several separate mental actions. The next mental action would follow this same chain, but would coordinate *how much* each variable in the sequence increases or decreases.

For *vector multivariational reasoning*, the first mental action may consist of coordinating changes among several input variables with changes among several output variables. It would be the realization that multiple input variables can impact multiple output variables, in isolation or simultaneously. The second mental action, like with independent multivariation, would likely not deal with whether the output variables are increasing or decreasing, but would consist of a preliminary mental action of coordinating the changes in the input variables to form an overall "input change vector," $\Delta V_{in}$. This input change vector defines the direction along which the change is happening. I believe that it may then require several mental actions to achieve complete analogs to the increase/decrease and amount mental actions. The first of these would be to coordinate whether each output variable increases or decreases in the direction of the input change vector. The second would be to coordinate the amount of change in each of the output variables. The third would be to coordinate the changes in each of the output variables to create an overall "output change vector," $\Delta V_{out}$. These may then culminate into a fourth mental action that directly coordinates the *input* change vector, $\Delta V_{in}$, with the *output* change vector, $\Delta V_{out}$.

Lastly, I note that for independent and vector multivariation, it is possible to consider the direction of change first, such as imagining tracing along a curve, $C$ (like in line and vector integrals). In this case, some of the mental actions may reverse, and rather than construct the input change vector from changes in the inputs, the mental actions might consist of *decomposing* the change vector into changes in the inputs.

## Conclusion

In this paper I described conceptual analyses into different types of multivariation. I also described mental actions potentially associated with each type of multivariational reasoning and how they might be different from each other and from two-variable covariational reasoning. The usefulness of this report is in producing a conceptualization of multivariation that can provide the basis and framing for empirical studies into the nature of multivariational reasoning, such as ensuring that each hypothesized mental action is targeted during the study. I claim that the different types of multivariation described here are far more than theoretical curiosities. Students encounter, both in mathematics and in science, many contexts in which one of these types of multivariational reasoning might be needed. In fact, any context that involves more than two variables, which can even show up in pre-collegiate mathematics, may inherently require at least some of the more basic multivariational mental actions. As such, I believe this paper to be a useful step in understanding how reasoning about these contexts may be developed.

## E-IBL, Proof Scripts, and Identities: An Exploration of Theoretical Relationships[1]

Stacy Brown
California State Polytechnic University, Pomona

*The purpose of this theoretical report is to further current discussions of the relationships between Equity-Oriented Instruction (EOI) and Inquiry Based Learning (IBL) pedagogies. Specifically, it proposes a framing of Equity-Oriented Inquiry Based Learning (E-IBL) that foregrounds equitable practice, as opposed to viewing equitable practice as a gratuitous outcome of IBL pedagogies. Drawing on data from teaching experiments conducted in IBL-Introduction to Proof courses, the inter-relationships between knowledge, identity and practice (Boaler, 2002), Pickering's 'dance of agency,' Gutiérrez's dimensions of equity, and Bourdieu's notion of habitus, this paper explores why intentional attention towards the critical axis of equity – that which links identity and power – is necessary, if IBL pedagogies are to promote equity.*

*Key words*: Inquiry based learning, equity oriented instruction, identity, agency

### Introduction

The purpose of this theoretical report is to further current discussions about the relationships between *Equity-Oriented Instruction* (EOI) and *Inquiry Based Learning* (IBL) pedagogies. Specifically, this report proposes a framing of *Equity-Oriented Inquiry Based Learning* (E-IBL) pedagogies that foregrounds issues of equity, as oppose to viewing equity as a gratuitous outcome of IBL. To understand this position, current framings of EOI and IBL are considered and used to explore rationales for viewing IBL as a pedagogy that promotes equity. Then, drawing on excerpts from teaching experiments in IBL courses, I examine why IBL pedagogies may not gratuitously promote EOI. The paper concludes with a framing of E-IBL.

### A Framing of Equity-Oriented Instruction

Over the past two decades, researchers interested in student learning in school contexts have begun to reconceptualize equity in mathematics education. These researchers (Gutiérrez, 2008; Martin, 2009) have challenged our practice of "gap gazing" and argue for the *de-essentialization* of disparities in students' academic achievement; i.e., against "the framing of mathematics achievement …(as) a kind of individualistic accomplishment" (Gutiérrez, 2008, p. 361) Indeed, drawing on Bourdieu's notion of habitus[2] (Bourdieu, 1984), researchers are illustrating the ways in which practices of structural exclusion enacted in students' mathematics education function to marginalize working-class and culturally diverse students (Jorgensen, Gates, & Roper, 2014). This marginalization occurs through schooling practices that align with the habitus of some students but not others by requiring the linguistic capital and practices of particular classes. Working in ways that align with arguments both for de-essentialization and attention to habitus, Boaler (2002a) has sought to describe the situated nature of learning in schools and argued not only that students' knowledge, practices and identity are inter-related (Figure 1) but that these inter-relationships "constitute the learning experience." This model of the inter-relationship

[1] This paper came about, in part, from conversations with Aditya Adiredja, Luis Leyva, and William Zahner. I would like to thank them, as well as the members of the RUME 2016 Equity Working Group for their insightful comments and feedback during the early stages of this work.
[2] The term *habitus* refers to the informal knowledge and skills that are developed through one's socialization "within the family, home, and immediate environment" so that one learns how to "act in and interpret their worlds" (Jorgensen, Gates, & Roper, 2014, p. 223). It is best thought of as the dispositions that position the individual to operationalize class status.

between identity, practice and knowledge emerged during Boaler's studies of learning in diverse school settings. It posits that one's knowledge is interactively constituted with one's practices. In particular, Boaler found that, "practices such as working through textbook exercises, in one school, or discussing and using mathematical ideas, in the other, were not merely vehicles for the development of more or less knowledge, they shaped the forms of knowledge produced" (p. 43). Speaking to the different instructional practices employed in schools, Boaler notes that direct instruction places the student in a hierarchical relationship with the teacher, where the teacher is the authority and the students are "received knowers" (Boaler, 2002). In contrast, in discussion oriented classrooms students are called on to engage in acts of interpretation, expression, and agency. These practices do not promote students' passive acceptance but rather called on them to "contribute to the judgment of validity, and to generate questions and ideas." And is so doing they foster distinct relationships between students' identities and the "knowledge to be taught." Hence, as Boaler argues, the findings exemplify Wenger's (1998) claim "learning transforms who we are and what we can do, it is an experience of identity" (Wenger, 1998, p. 215).

Identity, however, is not influenced by practices alone. A key component of identity is one's sense of agency. Moreover, as argued by Pickering (1995), working in mathematics requires a *dance of agency*: an interplay of human and disciplinary agency. Disciplinary agency refers to the ways that established practices and artifacts (e.g., proving practices, linguistic conventions, syntax, etc.) interact with and affect the work of mathematics. While individuals express human agency – generating ideas, symbols, terms, and practices – and impact the discipline, the products of human agency must also "surrender to the 'agency of the discipline'" (Boaler, 2002, p. 49). In other words, human agency shapes and is shaped by one's discipline.

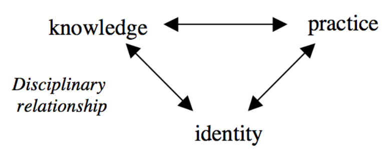

Figure 1. Adapted from Boaler (2002a).

Taken together the works of Gutierrez (2008), Jorgensen, Gates, & Roper (2014), Bourdieu (1984), Boaler (2002) and Wenger (1998) collectively point to the key characteristics of Equity-Oriented Instruction (EOI). EOI necessarily disrupts the reproduction of the structural inequities that are shored up and replicated through students' mathematics education. It intentionally attends to and broadens the forms of habitus that afford participation in schooling by valuing, among other things, the practices and "linguistic repertoires"– that is the capital (Bourdieu, 1984) – of those who are further marginalized by schooling (Jorgensen, Gates, & Roper, 2014). It affords the development of identities that enable rather than inhibit participation in the dance of agency and, therefore, students' engagement in authentic mathematical practices. As practices are enacted in discourses (Gee, 2001), EOI requires students be afforded opportunities to engage in collaborative work that forestalls the impact of one's social capital while also affording access to rich mathematics. It requires instructors avoid essentializing students while working to provide students with "opportunities to draw upon their cultural and linguistic resources (e.g., other languages and dialects, algorithms from other countries, different frames of reference) when doing mathematics, paying attention to the contexts of schooling and to whose perspectives and practices are 'socially valorized' (Abreu & Cline, 2007; Civil, 2006)" (Gutierrez, 2009, p. 5).

## A Framing of Inquiry Based Learning Pedagogies

Inquiry Based Learning (IBL) pedagogies have been defined in a variety of ways. Often IBL pedagogies are defined as any form of instruction in which students actively pursue knowledge through activities and discussions (Rasmussen & Kwon, 2007). According to the *Academy for inquiry based learning,* IBL is a "big tent" term for, "Teaching methods in mathematics courses … where students are (a) deeply engaged in rich mathematical tasks, and (b) have ample opportunities to collaborate with peers (where collaboration is defined broadly)."[3]

IBL pedagogies differ in (at least) two key ways from traditional, lecture-based mathematics instruction.[4] First, curricular activities are often inverted. By this I mean that rather than introducing institutionalized knowledge and having students practice using that knowledge, IBL curricular tasks elicit students' ways of understanding and then through task sequences provide opportunities for students to accommodate their understandings and develop disciplinary practices. The introduction of institutionalized knowledge is the final rather than first step in learning. Second, students are expected and encouraged to act with intellectual autonomy within collaborative settings. In other words, they are called on to demonstrate specific forms of human agency: (a) generating and proposing problem solving strategies; (b) comparing and contrasting approaches; and (c) engaging in acts of justification and validation.

## Why researchers have argued IBL promotes EOI

The association between active learning and equity has a long and well warranted history. The results of the Treisman (1992) studies demonstrated to many in the mathematics community that opportunities to collaborate around rich mathematical tasks could change the outcomes of students who are disadvantaged by structural inequities. More recently, Freeman et al. (2014) conducted a meta-analysis of 225 studies that compared active learning pedagogies to lecture-based instruction. They found that active learning pedagogies significantly decreased failure rates and that "active learning confers disproportionate benefits for STEM students from disadvantaged backgrounds and for female students in male-dominated fields." In a study that specifically focused on IBL pedagogies, Laursen et al. (2014) found not only did enrollment in IBL classes positively impact student success in subsequent courses but also that the IBL courses reduced the gender gap, with female students not only showing equal or greater learning gains but also higher levels of intention to persist than those in non-IBL courses.

Beyond these empirical studies, supports for IBL's potential to promote equitable outcomes can be found in recent theoretical analyses. Tang, Savic, El Turkey, Karakok, Cilli-Turner, and Plaxco (2017) provided an analysis of IBL and its relationship to the dimensions of equity proposed by Gutierrez (2009). Specifically, Tang et al. argue that in collaborative learning environments, *all* students are invited to engage in the "doing, discussing, and presenting" of mathematics. The implication here is that IBL pedagogies increase access to rich mathematics, while also promoting achievement (Freeman et al., 2014; Laursen et al., 2014). Building on the findings of Hassi's (2015) qualitative study, Tang et al. also discuss how collaborative learning environments in which students assert agency, foster growth in self-esteem and self-confidence and, therefore, students' sense of power. Thus, according to Tang et al., IBL pedagogies act not only along the dominant axis of equity but also the critical axis.

---

[3] Retrieved from http://www.inquirybasedlearning.org on July 29, 2017.
[4] Kuster and Johnson (2016) proposed a four-component model of IBL that aligns with that proposed here. Cook, Murphy and Fukawa-Connelly (2016) have proposed a six-component model. Due to space limitations, these models are not discussed in this theoretical report.

### Why IBL might not gratuitously promote EOI.

*identity has as much to do with others as it does with self … A large part of who we are is learned from how others interact and engage with us. (Pierson Bishop, 2012, p. 38)*

It is not the purpose of this section to argue that IBL pedagogies do not promote more equitable learning *outcomes* than traditional lecture-oriented pedagogies. Certainly, it would be a fool's errand to do so given recent research (e.g. Freeman et al., 2014). Instead the purpose is to argue that IBL pedagogies are not necessarily EOI pedagogies and, consequently, do not produce equitable learning *environments* "for free." Instead, intentional attention to equity is required.

To explore the ways in which IBL might fail to function as a form of EOI, I will discuss two data excerpts drawn from field notes and proof scripts collected during a series teaching experiments. These experiments occurred in IBL-*Introduction to Proof* courses taught at a designated Hispanic-serving university, where the majority are first generation college students eligible for need-based financial assistance. The classes were majority-minority classrooms: on average 67% were ethnic minorities and approximately one-third were students who identify as female. Students classified as Hispanic by institutional categories were the dominant minority group, with many preferring the terms Latino/Latina or Chicano/Chicana rather than Hispanic.[5]

**The first example.** The first data excerpt is drawn from field notes. It concerns an event of *othering*: viewing or treating an individual as distinct from or alien to oneself or one's group (possibly without intent).

**The Vignette.** The class begins with a whole class discussion about the theorems the class will focus on proving that day and a target time for discussing their proofs. Students are asked to move into their small groups, which have been assigned by students counting off the numbers 1 through 7. Mariella[6], a Latina, begins to move her desk towards her group. She stops a few feet short of her group because the other members of her group (three male students) have already moved their desks together and left no space for her desk. (The pre- and post-grouping of the desks is shown in Figure 2, with Mariella's desk shown as a circle.) She quietly works on her own, occasionally looking at the male students who do not appear to notice her exclusion.

The instructor observes Mariella's situation for approximately 20 minutes in an effort to provide adequate time for the male group members (or Mariella) to rectify the exclusionary situation. The instructor speaks with Mariella to confirm that the group of three male students is, in fact, her assigned group. Mariella requests of the instructor that she be allowed to work alone. The instructor respects her request, observing that she is uncomfortable. The classroom learning assistant (an advanced undergraduate) is asked by the instructor to check in with Mariella periodically. Several extended mathematical conversations are observed between them. After the class, the instructor asks two other female students from the class to speak with her individually outside of class. The instructor asks each student how she would prefer instructors respond in similar situations. Unprompted, both women share similar experiences where they were either physically excluded or "invisible" during group work. Both suggest moving Mariella to a group with another female. The next day Mariella is asked to change her group and, shortly thereafter,

---

[5] Following Gutierrez (2013), I use the terms Chicano and Chicana to refer to people with indigenous ancestry in the western United States. I recognize its use by students (and researchers) as intentional and political. Hence forth, I will use the gender neutral terms, Chican@ and Latin@.

[6] All names are pseudonyms.

observed assisting the other female student. Instances of Mariella actively engaging with her new group while engaging in proving efforts are observed in several subsequent classes.

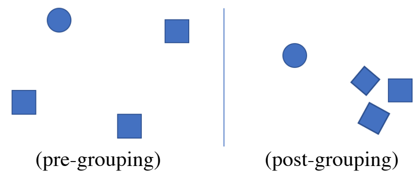

Figure 2. Pre- and post-grouping desk arrangements

**Vignette Discussion.** Why is this an instance of IBL not gratuitously promoting EOI? To be certain, some might argue that the students described in the vignette were not engaging in IBL because a central tenet of IBL is collaboration and the students weren't collaborating. There are two issues with this response. First, the male students were collaborating. Second, Mariella had tried to join the group to collaborate but had been excluded. Another critique might center on the fact that the instructor could have remedied the situation by reminding the male students of the participation norms which were discussed extensively at the beginning of the course or that Mariella should have acted to end her exclusion, since participation is an expectation of *all* IBL students. Such responses, however, assume that the tenets of IBL should be privileged to such an extent that they are enacted in lieu of EOI practices. They ignore the costs marginalized students pay to participate when they are called on to enforce IBL practices and (potentially) act against their own identities, dispositions, or cultural practices. Moreover, privileging collaboration while ignoring these costs does little to mitigate marginalized students' sense of exclusion or the potential for such practices to create the *illusion of participation*. And it is here that the problem lies. Even if *all* IBL students are expected to advocate for their own participation it is not the case that *all* students are called on to do so. More importantly, it is not the case that *all* will have identities, dispositions, or a cultural habitus that are at odds with such actions. Indeed, a post-class discussion with Mariella confirmed that she felt extremely uncomfortable "forcing" herself into the group, preferring instead to work alone after having been publicly *othered*.

**The Second Example**

*Mom, how do you say quesadilla in Spanish?*
*-Sebastian, Age 7*

As noted earlier in the paper, EOI requires students be afforded opportunities to engage in collaborative work that forestalls the impact of one's social capital while simultaneously supporting and empowering students' identities. The position taken in this paper is that one's linguistic practices are not secondary to one's identity but rather are an integral component (Bishop, 2012). The extent to which one's language, culture and practices are valued in an environment determines the extent to which one's identity is valued. Since 1998, Latin@ and Chican@ students have had to deal with the educational fallout of California Proposition 227. This proposition codified a stance towards bilingualism that views students' use of non-English languages as a deficit rather than an asset to the students and their communities. It is one of the reasons Californian dialects that heavily integrate Spanish words are often practiced without users recognizing their use of another language – a point exemplified by Sebastian's remarks.

Gee (2001, 2005) and Sfard and Prusak (2005) argue that identities are constructed through discourse. Others, such as Bishop (2012), argue that discourses “play a critical role in enacting identities” (p. 44). Most who have taught university mathematics courses in environments where the majority of students are first generation urban students can readily attest to the varied and at times colorful slangs currently used. These languages stand in stark contrast to that employed with great continuity for thousands of years among the practitioners of the discipline of mathematics, especially when writing proofs. To illustrate this continuity, I ask the reader to consider the resemblance between the two proofs in Figure 3, the first from *Euclid’s Elements* (c. 350 BC, T.L. Heath’s 1909 translation) and the second from *Mathematical Proofs: A Transition to Advanced Mathematics* by Chartrand, Polimni and Zhang (2008) (see pp. 145-6).

| | |
|---|---|
| ***I.6 If in a triangle two angles be equal to one another, the sides which subtend the equal angles will also be equal to one another.***<br><br>***Proof:*** Let ABC be a triangle having the angle ABC equal to the angle ACB; I say that the side AB is also equal to the side AC. For if AB is unequal to AC, one of them is greater. Let AB be greater; and from AB the greater let DB be cut off equal to AC the less; let DC be joined. Then since DB is equal to AC, and BC is common, the two sides DB, BC are equal to the two sides AC, CB respectively; and the angle DBC is equal to the angle ACB; therefore, the base DC is equal to the base AB, and the triangle DBC is will be equal to the triangle ACB, the less to the greater: which is absurd. Therefore, AB is not unequal to AC; it is therefore equal to it. | ***6.17 For every nonnegative integer n, $3 \mid (2^{2n}-1)$.***<br><br>***Proof***: Assume, to the contrary, that there are nonnegative integers $n$ for which $3 \nmid (2^{2n}-1)$. By Theorem 6.7, there is a smallest nonnegative integer $n$ such that $3 \nmid (2^{2n}-1)$. Denote this integer by $m$. Thus $3 \nmid (2^{2m}-1)$ and $3 \mid (2^{2n}-1)$ for all integers $n$ for which $0 \leq n < m$. Since $3 \mid (2^{2n}-1)$ when $n = 0$ it follows that $m \geq 1$. Hence, $m = k+1$, where $0 \leq k < m$. Thus $3 \mid (2^{2k}-1)$ which implies that $2^{2k} - 1 = 3x$ for some integer $x$. Consequently, $2^{2k} = 3x + 1$. Observe that $2^{2m}-1 = 2^{2(k+1)}-1 = 2^{2k+2}-1 = 2^2 \cdot 2^{2k}-1 = 4(3x+1) - 1 = 12x + 3 = 3(4x + 1)$ Since $4x+1$ is an integer $3 \mid (2^{2m}-1)$, which produces a contradiction.<br>■ |

Figure 3. Proofs from Euclid (c. 350 BCE; 1909 translation) and Chartrand et al (2008).

Now consider the following thought experiment: Imagine that humans had not invented mathematical proof well over 2000 years ago and that despite not having invented proofs, enough mathematics developed for some modern technologies (e.g., cell phones, twitter, and texting). What would our proving practices look like if they were invented by our culturally-diverse, economically-disadvantaged, urban youth? Would answers like that shown in Figure 4 be considered normative rather than examples of norm breaching (Herbst & Chazen, 2011)?

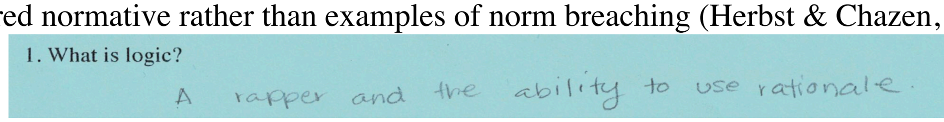

Figure 4. Student Survey Response

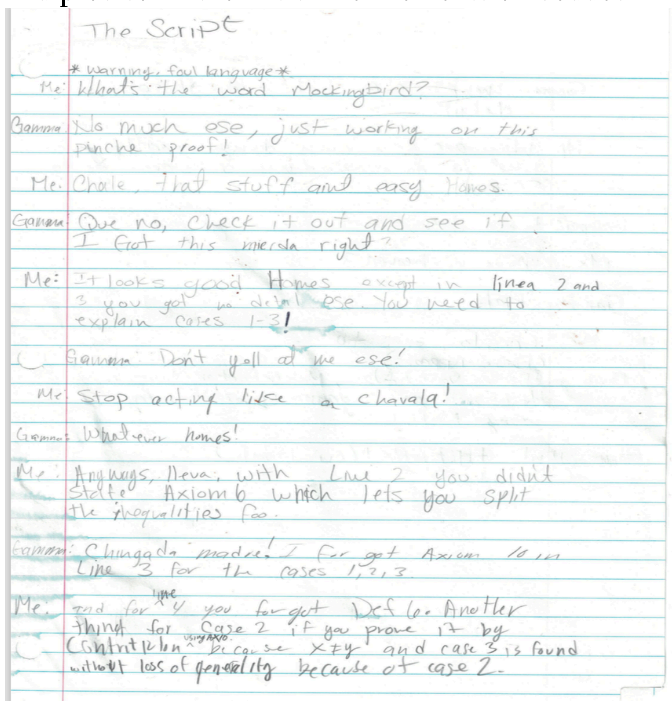
Moreover, would students’ proof scripts, like that shown in Figure 5, be viewed as an instance of authentic mathematical discourse rather than as something written in another dialect? Would the pervasive code-switching that occurs in the dialog be seen as exemplifying a student’s masterful blending of two dialects – the urban and the mathematical – rather than as indicative of a lack of participation in unspoken, yet implicitly demanded, disciplinary dialectic practices?

The student’s script was drawn from a set of 43 *proof scripts*: written dialogs in which a student and a fictional peer discuss a proof so as to promote the peer’s understanding of any gaps or key points in the proof. It was chosen as an example of one of many instances of students describing deep mathematical issues using their normative discursive practices. Indeed, field notes indicate that throughout the IBL *Introduction to Proof* course, students had grown increasingly accustom to intensely discussing proofs in their everyday vernacular. It is included in the paper to demonstrate a tension between IBL and EOI. A key tenet of IBL is that students’ move towards institutionalized knowledge (and therefore, normative disciplinary discursive practices) through their collaborative activities. It privileges rather than challenges normative practice by calling on instructors to enact discourse hierarchies in lieu of attending to the critical role discourses play in identity formation and student agency. Consequently, enacting IBL pedagogies means working to curtail rather than recognize (or value) students' discourses. In contrast, practitioners who privilege EOI practices over those central to IBL must attempt to navigate the tension between students' means of expressing identity and disciplinary discursive practices. They must recognize that privileging EOI means rejecting discourse hierarchies while simultaneously providing opportunities for students to become knowledgeable of disciplinary discourses. In other words, drawing on Gutierrez (2009), this paper argues that privileging EOI when enacting IBL, means valuing instances in which students "change the game" (e.g., by seeing value in the student's bridging of his own and disciplinary vernaculars) while also valuing the student's success "playing the game" (e.g., by valuing the mathematical sophistication which underlies the detailed and precise mathematical refinements embedded in the student's remarks).



The Script

*warning, foul language*

Me: What's the word Mockingbird?

Gamma: No much ese, just working on this pinche proof!

Me: Chale, that stuff ain't easy Homes.

Gamma: Que no, Check it out and see if I Got this mierda right?

Me: It looks good Homes except in linea 2 and 3 you got no detail ese. You need to explain cases 1-3!

Gamma: Don't yell at me ese!

Me: Stop acting like a chavala!

Gamma: Whatever homes!

Me: Anyways, lleva, with Line 2 you didn't State Axiom 6 which lets you split the inequalities too.

Gamma: Chingada madre! I forgot Axiom 10 in Line 3 for the cases 1,2,3.

Me: And for line 4 you forgot Def 6. Another thing for Case 2 if you prove it by Contradiction using Ax10 because x≠y and case 3 is found without loss of generality because of case 2.

Figure 5. Joseph's Proof Script Excerpt

## A framing of E-IBL

In this paper, I call into question the assumption that IBL pedagogies gratuitously promote EOI and argue E-IBL requires intentional attention to equity. I posit that intentional attention to equity calls on practitioners to employ EOI as a lens when viewing IBL learning environments. Applying such a lens necessarily entails foregrounding issues of structural exclusion and acting to disrupt the social mechanisms that result in their reproduction in institutional spaces (Jorgensen, Gates, & Roper, 2014; Battey & Leyva, 2016). It means privileging students' identities and habitus when IBL practices call on students to act against either; e.g., by valuing varied forms of social capital (e.g., linguistic resources (Zahner & Moschkovich, 2011)) or addressing instances of *othering* by first attending to students' identities and habitus; i.e., the costs some pay to participate. At its core, this framing posits E-IBL instructors must be willing to recognize that, as argued by Wenger (1998), learning is "an experience of identity" and that identity and power are negotiated in institutional contexts (Adiredja & Andrews-Larsen, 2017). Thus, privileging the demands of EOI over the tenets of IBL, requires instructors navigate the tensions present in spaces that support students not only "playing the game" but also "changing the game" (Gutierrez, 2009) as they develop expertise in mathematics.

# Generalisation, Assimilation, and Accommodation

Allison Dorko
Oklahoma State University

*This paper builds theory by connecting Piaget's assimilation and accommodation constructs to Harel and Tall's (1991) framework for generalisation in advanced mathematics. Based on what they imagined to be the cognitive processes underlying generalisation, Harel and Tall proposed that generalisation might be* expansive *(occurring when a student expands the applicability range of an existing schema without reconstructing it),* reconstructive *(occurring when a student reconstructs a schema to widen its range of applicability), or* disjunctive *(occurring when a student constructs a new, disjoint schema to deal with a new context). I contend that expansive and reconstructive generalisation align with assimilation and accommodation, respectively. I provide 'proof of concept' using data from a study of students' generalisation of graphing from $R^2$ to $R^3$. Further, I show how linking Piagetian constructs to Harel and Tall's work provides a theoretical explanation for other empirical findings about generalisation.*

*Key words:* generalisation, multivariable function, graphing, assimilation, accommodation

## Introduction

Generalisation is a key component of mathematics. Mathematicians seek general formulae; kindergarteners generalise when they seek the next shape in a pattern; and multivariable calculus students generalise their notion of function to include functions of more than one variable. Because generalisation is so critical to mathematical thought, research that investigates how people generalise supports student learning. Moreover, students often struggle to form correct generalisations (e.g. Dorko & Weber, 2014; Jones & Dorko, 2015; Kabael, 2011; Martínez-Planell & Gaisman, 2013, 2012; Martínez-Planell & Trigueros, 2012). Generalising is important to many science, technology, engineering, and mathematics (STEM) courses. For example, students must be able to generalise their mathematics knowledge to chemistry, physics, and upper division mathematics. Difficulty generalising may contribute to students switching out of STEM studies. Efforts to better understand how students generalise and how instructors can support their generalisations could help solve the problem of retaining STEM majors (c.f. Bressoud, Carlson, Mesa, & Rasmussen, 2013; Rasmussen & Ellis, 2013; Uysal, Ellis, & Rasmussen, 2013).

Descriptions of how people generalise often come in the form of frameworks. Frameworks provide language to describe and account for qualitative differences in students' thinking and activity. Knowing what students attend to when generalising can inform instruction and the development of mathematical activities to support productive generalisation. In this paper, I connect Harel and Tall's (1991) framework for describing the "different qualities of generalisation in advanced mathematics" (p. 1) to Piaget's assimilation and accommodation constructs. This came about from my use of Harel and Tall's (1991) framework to classify empirical data, during which I often struggled to distinguish between the expansive and reconstructive generalisation categories. While the definitions of the categories seem clear, I struggled to operationalize them so they could be applied to my data. Because the descriptions of these categories seemed similar to the definitions of assimilation and accommodation (respectively), I wondered if there existed connections between the framework and the Piagetian constructs.

There are two reasons it felt worthwhile to tease apart any possible connections. The first is that such an investigation could provide insight into the cognitive processes involved in generalisation. Harel and Tall (1991) propose three ways students might generalise, but do not explain why a student might engage in one type of generalisation instead of another. Thinking about generalisation in terms of assimilation and accommodation could provide a tenable explanation. A second reason is to situate the framework in widely-understood language. This is useful because while many researchers cite Harel and Tall's (1991) definition of generalisation (e.g. Ellis, 2007; Mitchelmore, 2002) or offer hypothetical examples of Harel and Tall's three categories (e.g. Greer & Harel, 1998; Mitchelmore, 2002), the framework has been used in only three empirical studies (Fisher, 2008; Jones & Dorko, 2015; Zazkis & Liljedahl, 2002). My experience is that Harel and Tall's framework provides a powerful way to think about generalisation, but that it can be difficult to distinguish between the expansive and reconstructive categories. This difficulty may explain the lack of empirical use. I thought that if the expansive and reconstructive categories could be linked to assimilation and accommodation (respectively), it might be easier to use the framework for classifying empirical data. Moreover, the ability to talk about generalisation in terms of assimilation and accommodation affords communication about theory and results in terms of a widely-understood learning theory. This has been the case for research that has connected assimilation and accommodation to transfer (Wagner, 2010) and backward transfer (Hohensee, 2014).

This paper is structured as follows. First, I present Harel and Tall's (1991) framework and connect it to Piaget's assimilation and accommodation constructs. Then, I describe the data set and methods I used to tease apart possible connections. I follow this with an example of the utility of these connections in the context of a student generalising her thinking about graphing from $R^2$ to $R^3$. Then, I discuss how assimilation and accommodation explain other researchers' empirical findings about students generalising graphing and their notion of function from the single- to multivariable case. Finally, I offer suggestions for further research and for instruction.

## Harel and Tall's (1991) Framework, Assimilation, and Accommodation

Harel and Tall (1991) proposed that generalisation in advanced mathematics fell into three categories, termed expansive, reconstructive, and disjunctive generalisation. Table 1 (next page) provides definitions of these categories and an example in the context of vector addition.

I argue that when students engage in expansive and reconstructive generalisation, they do so via assimilation and accommodation (respectively). Piaget proposed assimilation and accommodation as the mechanisms by which people learn. He discussed them in the context of schemes, or "organi[s]ation[s] of mental and affective activity" (Thompson, 2016, p. 436). *Assimilation* is defined as "the integration of new objects or new situations and events into previous schemes" (Piaget, 1980, p. 164 as cited in Steffe, 1991, p. 192). Assimilation "comes about when a cogni[s]ing organism fits an experience into a conceptual structure it already has" (von Glasersfeld, 1995, p. 62). In contrast, *accommodation* is a modification of a scheme. Accommodation occurs when a person's attempt to assimilate a situation to a scheme has an unexpected result, causing a perturbation and disequilibrium. To re-attain equilibrium, the person modifies the scheme (accommodation). In the next section, I describe the data set I used to explore the framework and Piagetian constructs.

## Data Set and Methods

The data excerpts in this paper come from a longitudinal study of calculus students' generalisation of function from single- to multivariable settings (AUTHOR, 2017). I conducted

Table 1. Harel and Tall's (1991) Framework

| Category | Example[1] |
|---|---|
| **Expansive generalisation** "occurs when the subject expands the applicability range of an existing schema without reconstructing it" (Harel & Tall, 1991, p.1). The original schema is "included directly as [a] special case in the final schema" (ibid, p.1). | A student understands vector addition <a,b> + <c,d> as performing addition twice. The student generalises her understanding of addition in R by "repeating it across more terms" (Jones & Dorko, 2015, p.156). |
| **Reconstructive generalisation** "occurs when the subject reconstructs an existing schema to widen its applicability range" (Harel & Tall, 1991, p.1). The original schema "is changed and enriched before being encompassed in the more general schema" (ibid, p.1). | A student understands vector addition <a,b> + <c,d> as performing addition twice. The student generalises her understanding of addition in R by repeating it across more terms. The student learns the geometric interpretation of vector addition as placing vectors head to tail and finding the resultant vector. The idea of vector addition "may not exist for the student in basic addition in R, and consequently the underlying idea of "addition" itself is reconstructed for the new $R^2$ context" (Jones & Dorko, 2015, p. 156). |
| **Disjunctive generalisation** "occurs when, on moving from a familiar context to a new one, the subject constructs a new, disjoint schema to deal with the new context and adds it to the array of schemas available" (Harel & Tall, 1991, p.1). | A student understands vector addition <a,b> + <c,d> as completely separate from addition in R. Jones and Dorko (2015) describe this hypothetical student thinking as "we might still use the same word 'addition,' but it is not the same thing as 'regular' number addition" (p. 156). |

four task-based clinical interviews (Hunting, 1997) with each of five students over the span of their differential, integral, and multivariable calculus courses. The total interview time ranged from 4.25 to 5.67 hours per student. Students answered questions about single- and multivariable topics while they were enrolled in differential and (later) multivariable calculus. This design provided insight into both students' initial sense-making of how ideas from $R^2$ might generalise to $R^3$, and the sense students made of those ideas after instruction. Space constraints prohibit listing all the tasks students answered; this paper focuses on a student's response to the tasks (1) Graph $y = x$ in $R^3$; (2) Graph $y = 2x + 1$ in $R^3$; and (3) Graph $z = 4$ in $R^3$. Students answered these questions at the beginning of their multivariable calculus course before instruction about graphing in $R^3$. This timing provided insight regarding students' initial generalisations of how to graph equations. Prior to their answering the tasks, I provided students with a blank copy of $R^3$ axes and explained the axes' positions.

The first step in my data analysis was to review the data and identify instances of generalisation. I followed Harel and Tall's (1991) definition of generalisation as "the process of applying a given argument in a broader context" (p. 1). I then attempted to code these instances

[1] Harel and Tall (1991) offer two hypothetical examples of their categories, a detailed example of generalising how to solve systems of equations and a brief example of generalising addition in R to vector addition. Jones and Dorko (2015) offer a more detailed description of the vector addition generalisation.

as expansive generalisation, reconstructive generalisation, or disjunctive generalisation based on the definitions from Harel and Tall's (1991) framework (Table 1). I did not find any instances of disjunctive generalisation, and as such, any connections between Piagetian constructs and disjunctive generalisation are not discussed here; this is an area for future work. Finally, I took each instance and sought to code it as assimilation or accommodation based on the definitions provided above.

I gave the data presented in this paper to another researcher, who at the time was studying generalisation in real analysis from a Piagetian perspective and hence was knowledgeable about and experienced with identifying assimilation and accommodation in practise. This person coded the data separately and their codes were the same as my own. In the next section, I provide an example that illustrates the connections between assimilation and expansive generalisation and accommodation and reconstructive generalisation.

## An Example: Line or Plane?

Based on my analysis, I concluded that students may engage in expansive generalisation when they assimilate a new context to an existing scheme, and they may engage in reconstructive generalisation when a new context triggers a perturbation that causes them to modify a scheme. In the following example, Wendy (pseudonym) first draws $y = x$ and $y = 2x + 1$ in $R^3$ as lines and $z = 4$ in $R^3$ as a plane. I argue that these were expansive generalisations, occurring as a result of assimilating $y = x$ and $y = 2x + 1$ in $R^3$ to a scheme for graphing linear functions in $R^2$ with $m \neq 0$ and assimilating $z = 4$ to a scheme for graphing linear function in $R^2$ with $m = 0$ (that is, a scheme for $y = b$). After drawing the three graphs, Wendy said she found it "interesting" that she had drawn both lines and planes. She compared the graphs and equations and reasoned that all three should be planes. That is, she engaged in reconstructive generalisation. I contend that Wendy's initial observation that she had drawn lines and a plane served as perturbation, which caused her to accommodate her scheme for graphing $y = \mathrm{m}x + \mathrm{b}$ equations ($m \neq 0$) in $R^3$.

### Assimilation and Expansive Generalisation

Excerpts 1 and 2 below provide what I take as evidence of Wendy's assimilating $y = x$ and $y = 2x + 1$ in $R^3$ to a scheme for $y = mx + b$ ($m \neq 0$) in $R^2$. "Int." is short for "interviewer."

Excerpt 1. Assimilating $y = x$ in $R^3$ to a scheme for graphing linear functions ($m \neq 0$) in $R^2$

*Wendy:* So if you just plug in values for $x$ and then pull out values for $y$, you're gonna get like 0, 0, 1, 1, 2, 2 [plots these on the $xy$ plane as she says them] and then it's just going to continue being a straight line like this… you could choose any $x$ value, really. I chose like 1. So if $x$ is 1, then $y$ is equal to $x$, so that's also 1.

*Interviewer:* Can you label some of the coordinates that you plotted?

*Wendy:* Okay, so this is going to be like 1, 1, 0 and then 2, 2, 0.

*Interviewer:* Why do we get a line here?

*Wendy:* The way I think of it is it's just like having a 2D graph and plotting $y = x$ and that'll give you a line, you're just taking it and adding and then ignoring the $z$ component… if $y = x,$ you can just always assume that $z$ is 0.Excerpt 2. Assimilating $y = 2x + 1$ in $R^3$ to a scheme for graphing linear functions ($m \neq 0$) in $R^2$

*Wendy:* I'm thinking that it will be like the same kind of concept where we're just ignoring $z$ so you can say like $+0z$ here and that will give you the same equation [writes $y = 2x + 1 + 0z$]. So if you went $2x + 1$ that would be 0, 1 and then 1, 3… basically you would just take the same line that you would have with your $x$ and $y$.

*Interviewer:* And do we get a line there?

*Wendy:* Yeah, that's a line… like I said we're ignoring the $z$ component, but you can think of it as there, you're just, have it, 0 set to it.

I argue that Wendy assimilated these equations to a scheme for graphing in $R^2$. Wendy talked about the coordinate points as $(x, y)$ tuples (e.g., "0, 0, 1, 1, 2, 2") as she was plotting the points (Excerpt 1). Though she described the points as $(x, y, z)$ tuples when asked to identify points, I posit that her thinking of the points as $(x, y)$ tuples during the act of graphing indicates that she had assimilated the question about creating a graph in $R^3$ to a schema for graphing in $R^2$. My inference is supported by Wendy's explicit statement that she saw $y = x$ in $R^3$ as "just like having a 2D graph and plotting $y = x$".

I contend Wendy's treatment of $z$ facilitated her assimilation. We know that Wendy considered $z$ because she said in both graph tasks that she was "ignoring $z$" (Excerpts 1 and 2) or setting it to 0 (Excerpt 3)[2]. Further, when asked what points she had plotted on her $y = x$ graph, Wendy gave $(x, y, z)$ tuples. However, Wendy's statements about $z$ provide evidence that she (a) explicitly considered $z$ and (b) treated it in a way that allowed her to assimilate the $y = x$ and $y = 2x + 1$ in $R^3$ tasks to a scheme from $R^2$. This is in accordance with assimilation as "reduc[ing] new experiences to already existing sensorimotor or conceptual structures" (von Glasersfeld, 1995, p. 63). The result of Wendy's assimilation and expansive generalisation was that she drew these graphs as lines.

I argue that Wendy assimilated $z = 4$ to a different scheme. Specifically, Wendy appeared to have a scheme for $y = b$ in $R^2$. She drew $z = 4$ as a plane (Excerpt 3).

Excerpt 3. Assimilating $z = 4$ in $R^3$ to a scheme for graphing $y = b$ in $R^2$

*Wendy:* I'm thinking that whenever, no matter what $x$ and $y$ equal, $z$ is always going to equal 4. So you get a plane here at 4. That's a really bad drawing of it, but, no matter what these [gestures to $x$ axis] equal, you're always just going to get 4.

*Interviewer:* Can you tell me a little bit more about the 'no matter what these equal'?

*Wendy:* So if you're graphing, so $z = 4$, it's like saying $y = 4$ on a normal graph you get a line at $y$, or 4. You just get that [sketches $y = 4$ in $R^2$]. Because it doesn't matter what $x$ equals. So here I'm kind of thinking that it's the same concept, that no matter what $y$ or $x$ equals, $z$ is always going to equal 4.

*Interviewer:* Do you, as you graphed that $z = 4$, so you pretty immediately said oh, this is a plane. Did you think about this $y$ and $x$ graph? [points to Wendy's graph of $y = 4$ in $R^2$].

*Wendy:* I basically, I took the concept of it and applied it.

*Interviewer:* And what's the concept of it?

*Wendy:* Yeah, the concept of it is like I said even though there's no $x$ in this equation, like we always know that $y$ is going to be equal to 4 so it really doesn't matter what $x$ is, so that's why there's no $x$ in the equation.

*Interviewer:* How come $z = 4$ isn't just a line?

*Wendy:* Because you're in 3D, so if say like $x$ was 1 and $y$ was 2, you're always, $z$ is going to equal 4.

I take Wendy's comment "it's the same concept" as evidence that she assimilated $z = 4$ to an already-existing scheme. What Wendy appeared to see as the "same concept" was that $y$ equaled 4 in $R^2$ "[no] matter what $x$ equals", so $z$ would equal 4 in $R^3$ "no matter what $y$ or $x$ equals." Wendy argued that $z = 4$ was a plane using the example of (1, 2, 4) as a point on the graph.

[2] It is important to note that for Wendy, writing $+0z$ meant that she was setting $z$ to 0 (Excerpt 3). This contrasts a normative interpretation of $y = 2x + 1 + 0z$, in which one sees $z$ as varying.

I contend Wendy assimilated $z = 4$ to a different scheme than the scheme to which she assimilated $y = x$ and $y = 2x + 1$. That is, Wendy appeared to have a scheme for constant functions in $R^2$, and an element of which was $x$ as free. She expanded this to the $R^3$ case by viewing $x$ and $y$ as free. In contrast, she appeared to have a scheme for non-constant linear functions, an element of which was that such functions' graphs are lines. Wendy expansively generalised this scheme to the $R^3$ case by choosing to "ignore $z$" or, equivalent in her mind, 'set it to 0'.

**Accommodation and Reconstructive Generalisation**

The result of Wendy's assimilations to two different schemes resulted in two different graphs, triggering a perturbation that subsequently caused Wendy to reconstruct her scheme for non-constant linear equations in $R^3$ (Excerpt 4).

Excerpt 4. Perturbation

*Wendy:* It's interesting to me… That I think of that [$z = 4$] like that, and then the other ones [$y = x$ and $y = 2x + 1$] I don't think of like that. So if I, if I applied what I did in [$z = 4$] to [$y = x$ and $y = 2x + 1$] I would get planes again, which would look like this… because $y$ is going to equal $x$. I feel like I'm confusing myself.

Wendy then compared her work on the three graphs, which led her to reconstruct her notion of a free variable (Excerpt 5).

Excerpt 5. Accommodation

*Interviewer:* Okay, so do you want to look at these again? [puts $y = x$ and $y = 2x + 1$ graphs in front of Wendy]

*Wendy:* So if I think about it like this [points to $z = 4$ graph], so if I thought of this [$z = 4$] like I think of this [points to $y = 2x + 1$], then this [$z = 4$] would just be a point.

*Interviewer:* Can you say that sentence [again]… the word 'this' gets hard when I do the audio, when I transcribe it.

*Wendy:* Okay so on the previous ones I was thinking of, I was thinking of this [$y = x$] as – this – the $y = x$ as just like $y = x$ and then I was thinking of it as $+0z$. And so out of that you get a line. But instead of thinking of this $+0y + 0x$, I thought of it as more of the $y = 4$. That no matter what the, no matter what the $y$ and $x$ values are here, the $z$ is always going to equal 4… so if I, if I applied what I did in [$z = 4$] to [$y = x$ and $y = 2x + 1$] I would get planes again, which would look like this… because $y$ is going to equal $x$. I feel like I'm confusing myself.

*Interviewer:* So, so do you think $y = x$ in $R^3$ is a plane or a line?

*Wendy:* My initial thought was that it was a line, but now I'm unsure… my initial thought process of it's a line is because I was thinking that you didn't change this $x$ and $y$ coordinate, you just laid it flat, and that is the only thing you did to make it 3D here. And so you could just graph it in 2D and then just lay it flat and put a $z$ axis in it and that wouldn't change the $y = x$. But that was if I was thinking $+0z$ which there isn't a $+0z$. So I think that no matter what $z$ is, $y$ is always going to equal $x$. So whatever $x$ and $y$ are, you're going to have that plane.

I interpret the change in Wendy's graph from a line to a plane as occurring as a result of the following cognitive acts. Wendy's statement that she found it "interesting" that she had drawn a line for two of the graphs and a plane for the third suggests that she expected the graphs to look similar. The unexpected results (the graphs did not look similar) caused a perturbation. Wendy sought to re-equilibrate by comparing how she approached the $y = ...$ equations and the $z = 4$ equation. In doing so, she noticed that in the $y = …$ equations she had assumed $z = 0$, while in the $z$ = 4 equation she had assumed $x$ and $y$ could take on any value. Wendy accommodated her scheme for $y = x$ in $R^3$ as meaning $z$ equaled 0 meaning $z \in R$. Her initial (expansive) generalisation had been that these were lines. When she realised they were similar to $z$ = 4 in that they had a free variable, she engaged in reconstructive generalisation because she widened the applicability range of her notion of free variables. That is, she applied her argument about free variables to the $y = x$ and $y = 2x + 1$ context. This allowed Wendy to "change and enrich" (Harel & Tall, 1991, p.1) her graphing schema for $R^3$.

## Discussion

It appears that assimilation and accommodation explain a variety of empirical findings about what students generalise from $R^2$ to $R^3$. For example, researchers have observed student difficulties with graphing in $R^3$ (Dorko & Lockwood, 2016; Martínez-Planell & Trigueros, 2012; Trigueros & Martínez-Planell, 2010). One finding is that students may draw $f(x, y) = x^2 + y^2$ as a cylinder or a sphere because they are accustomed to $x^2 + y^2$ representing a circle in $R^2$ (Martínez-Planell & Gaisman, 2013). I posit students assimilate the $f(x, y) = x^2 + y^2$ to a scheme for circles in $R^2$, causing them to draw "circle-like" shapes in $R^3$. In support of this, Moore, Liss, Silverman, Paoletti, LaForest, and Musgrave (2013) have documented that students often create graphs based on *shape thinking*, or "conceiving of graphs as pictoral objects" (p. 441). That is, a possible explanation for students' graphing difficulties in $R^3$ is that they assimilate $f(x, y)$ equations to their schemes for the shapes of graphs in $R^2$, which allows them to expansively generalise by creating similar shapes on $R^3$ axes. As an example in a different context, researchers have found the function machine model to support students correctly generalising their notion of function from the single- to multivariable case (Dorko & Weber, 2014; Kabael, 2011). I contend that such a model allows students to assimilate multivariable functions to their function machine scheme for single-variable functions, and as such, expansively generalise their notion of function.

These examples illustrate the explanatory power of thinking about generalisation in terms of assimilation and accommodation. More broadly, they demonstrate how identifying connections between frameworks can help researchers better understand phenomena of interest. There are many generalisation frameworks, and one area for future research is to tease out relationships among them and their links to underlying theory.

Finally, Harel and Tall's stated aim in developing their framework was to "suggest pedagogical principles designed to assist students' comprehension of advanced mathematical concepts" (p. 1). One pedagogical suggestion stemming from linking the framework to Piagetian constructs is related to students' tendency to overgeneralize, such as Wendy's initial thought that the $y = \ldots$ equations would be lines in $R^3$ as they are in $R^2$. When instructors notice students overgeneralising, they might consider if students are assimilating when they should be accommodating. Instructors can then help students discern features of the new context that will result in the student becoming perturbed, leading to accommodation.

# Conceptualizing Students' Struggle with Familiar Concepts in a New Mathematical Domain

Igor' Kontorovich
The University of Auckland

*This article is concerned with cognitive aspects of students' struggles in situations in which familiar concepts are reconsidered in a new mathematical domain. Examples of such cross-curricular concepts are divisibility in the domain of integers and in the domain of polynomials, multiplication in the domain of numbers and in the domain of vectors. The article introduces a polysemous approach for structuring students' concept images in these situations. Post-exchanges from an online forum were analyzed for illustrating the potential of the approach for indicating possible sources of students' misconceptions and meta-ways of thinking that might make students aware of their mistakes.*

*Keywords:* concept image, conceptual change, cross-curricular concepts, epistemological obstacles, polysemy

## Introduction

The multidimensional nature of mathematical concepts has been addressed in a number of frameworks. For example, Sfard (1991) and Gray and Tall (1994) distinguished between approaching a concept as a process and as an object. In the former approach, $\sqrt{9}$ is an operation of extracting the square root from the number 9; in the latter approach, it is a number – an object with particular properties. Research suggests that students' fluency with concepts' dimensions and flexibility with switching among them are necessary for developing a deep understanding and for successful problem solving (e.g., Gray & Tall, 1994; Sfard, 1991). Consequently, considerable effort has been invested in supporting students' linkage among concepts' dimensions through stressing their similarities and compatibility (e.g., Moreno & Waldegg, 1991; Sandoval & Possani, 2016). In these studies, the researchers often focused on a particular concept (e.g., infinity, line and vector) and considered them in a singular mathematical domain (e.g., sets, 3-D).

However, in the landscape of students' mathematical education some concepts are reconsidered in different domains. The domains can be rooted in different axiomatic systems and contain different or new objects. Accordingly, a domanial shift of these *cross-curricular* concepts is often accompanied by a substantial change in familiar dimensions (i.e. definitions, properties, procedures, connections with other concepts, etc.). For instance, when extracted in the field of real numbers, $\sqrt{9}$ equals 3; an application of the De Moivre theorem in the field of complex numbers yields 3 and -3 (Kontorovich, 2016a)

The domanial shift and the substantial change in concept dimensions are potential sources for students' difficulties and mistakes (e.g., Kontorovich & Zazkis, 2016). Accordingly, the study reported in this article is concerned with students' struggles with cross-curricular concepts in a new domain. Specifically, my focus is on cognitive aspects of situations in which students, who are relatively fluent with some dimensions of a concept in one domain, encounter its incompatible dimensions in another domain. The aim of the article is to introduce a polysemous approach for analyzing this phenomenon and to illustrate its usage for indicating possible sources of students' mistakes and affordances that might make students aware of them.

## Theoretical Foundations

This section presents the structures of concept image and polysemy, which are then used for presenting the developed approach.

### Concept Image, Terminology and Symbols

The notion of *concept image*, introduced by Tall and Vinner (1981), remains one of the most utilized constructs in mathematics education literature until today (e.g., Panaoura, Michael-Chrysanthou, Gagatsis, & Elia, 2016). The notion refers to the accumulative cognitive structure that a learner associates with the concept, which includes all the mental pictures, properties and processes. Tall and Vinner suggested that it is unlikely that a learner operates with the whole concept image at once and they assumed that various stimuli evoke partial concept images. Accordingly, mathematics education research has been often concerned with exploring tensions among the evoked concept images (e.g., Bingolbali & Monaghan, 2008; Tall & Vinner, 1981).

The terminology and symbols that one associates with a concept can also be considered as a part of her concept image. Extensive research on the tight connections between language and thinking show that discourse shapes our understanding of mathematical concepts (see Austin & Howson, 1979, for an elaborated review). In our case, it seems reasonable to assume that students can identify cross-curricular concepts based on the same terminology and symbols which are used in different domains. This assumption brings up the constructs of homonymy and polysemy.

### Polysemy of Mathematical Concepts

Durkin and Shire (1991) use the notions of *homonymy* and *polysemy* for referring to words with multiple meanings. The meanings of a homonymous word are different and not related, for example "volume" in the sense of a measure of a 3-dimensional object as opposed to intensity of sound. A word is called polysemous if its meanings are related. In terms of this article, it can be proposed that a concept is homonymous if its dimensions in different domains are barely related, for examples a graph of a function in calculus and a graph in graph theory. A polysemous concept, in its turn, can be characterized with dimensions that are valid in different domains and dimensions that hold in particular domains only. Let us take the square root, for instance: The statement "if $b$ is a square root of $a$ then $b^2=a$" is valid for real and complex numbers; however, thinking of $b$ as a non-negative number is appropriate in the former domain only.

A considerable amount of research has been invested in exploring students' understanding of polysemous words with daily and mathematical meanings (e.g., Shire & Durkin, 1989). The polysemy of meanings within the mathematical register is less acknowledged. Zazkis (1998) exemplified the ambiguity of "divisor" with the exercise $12 \div 5 = 2.4$ where in the domain of rational numbers, the number 5 can be addressed as a divisor, since it is defined as the denominator of a fraction. However, if the exercise is considered in the domain of integers, 5 is not a divisor of 12 because there exist no integer that when multiplied by 5 equals 12. Mamolo (2010) focused on the polysemy of symbols '+' and '1'. Her analysis accounted for the changes in the definitions and, consequently, in symbols' meanings in the contexts of modular arithmetic, transfinite mathematics, et cetera. Based on their analyses, Mamolo (2010) and Zazkis (1998) argued that polysemy in mathematics is a potential source of struggle for learners. This study can be considered as an examination of their argument.

## The Study

In terms of IES and NSF (2013) this is an early-stage exploratory research that aims to contribute to core knowledge in education by refining and developing theories for teaching and learning. Thus, the research was approached with the *abduction* methodology (Peirce, 1955). The methodology requires identification of a phenomenon of interest (see Introduction) and gives rise to an initial theory. Then the theory is supported and refined through a purposeful corpus of evidence (Svennevig, 2001). Svennevig (2001) argues that while being a less than certain mode of inference, abduction compensates with a vengeance by providing new ideas and developments. Moreover, the methodology relies on contextual judgements, which are necessary for analysing conceptual development.

Ideas and evidence emerged from a project that involved 25 high-achieving ninth-graders who participated in a linear algebra course (see Kontorovich, 2016b for more details). The course was aimed at preparing for and engaging school students in undergraduate education in parallel with their regular school studies. The course instruction could be described with an often criticized "definition-theorem-proof" structure, which was applied in the topics of polynomials, matrices and vector spaces. When introduced, polynomials and matrices were approached as not being connected to each other, but were later reconsidered as instances of a vector space.

After each lesson the students were provided with a list of problems to solve at home. The solutions were not intended for submission, but variations of some of the problems appeared in a quiz in the following lesson. This led the students to active engagement with course materials and with each other. The students were encouraged to collaborate in a special closed-for-public asynchronous web-forum. Forum post-exchanges were reviewed in a search for evidence of students' identification and struggle with cross-curricular concepts. The two illustrations presented in the article were chosen to highlight various aspects of the developed account.

## Polysemous Concept Images

This section introduces the theoretical account of *polysemous concept image* that was developed in the study. I start with an illustration that stimulated the appearance of the account and continue with another illustration of its various aspects. The illustrations comprise abbreviated post-exchanges between students.

### Divisibility in the domains of polynomials and integers

*Johnny*: [1] Hi guys, I think there is a mistake in question 1d: it asks to show that $q(x)|p(x)$ when $p(x) = 3x^3 - 19x^2 + 38x - 24$ and $q(x) = 6x - 8$. I did the division and got $0.5x^2 - 2.5x + 3$, which has fractions so $q(x)$ can't be a divisor.

*Student 1*: I'm not sure that I got you. Why isn't $6x - 8$ a divisor?

*Johnny*: [2] Think about $3|7$, you divide and get $2\frac{1}{3}$, a fraction right? So 3 is not a divisor of 7. Same here.

*Student 2*: What about the question 1c?

*Johnny*: [3] It's ok. You divide $0.5x^2 - 3x - 4$ by $1 - 0.5x$, get $-x + 4$ and everyone is happy.

In Tall and Vinner's (1981) perspective, the illustration sheds light on Johnny's concept image of divisibility (or divisor). His image is an ontologically distinct category containing (at least) two types of conceptions: the ones that regard divisibility in the domain of polynomials and the ones that regard divisibility in the domain of integers. For instance, Johnny's utterances [1] and [3] show that he was aware that the two domains contain different elements (i.e. polynomials and integers) and different division procedures. Accordingly, I propose that Johnny's concept image was compartmentalized into *domain-valid conceptions* – ways of thinking that he perceived as valid in one domain but not in another. Furthermore, Johnny was successful with choosing conceptions from the domain that was intended in problem situations in [1-3].

The connections that Johnny drew between the divisibility in each domain allow proposing that both of them were regulated for him by some common set of conceptions. For example, in both domains Johnny used the '|' symbol for denoting divisibility. The element on the left of '|' was the one by which the element on the right was divided. I use *overarching conceptions* to refer to ways of thinking that can be assigned to one's concept image as a whole. Overarching conceptions make one's concept image *polysemous*: consisting of distinct domains that are connected through conceptions which are valid in each of them (see Figure 1 for a schematic representation of Johnny's concept image).

Johnny's reasoning in the domain of polynomials (see [1] and [3]) can be rephrased as "*r(x)* is a result of dividing *p(x)* by *q(x)*. If *r(x)* contains non-integer coefficients, then *q(x)* is not a divisor of *p(x)*". This reasoning resonates with a variation of conventional definitions of a divisor in the domain of integers: "*r* is a result of dividing *p* by *q*. If *r* is not an integer then *q* is not a divisor of *p*". Accordingly, Johnny's mistake in [1] can be explained with a misclassification of a conception, which is valid in the domain of integers, to the set of overarching conceptions regulating the whole image of the divisibility concept.

Johnny's doubt in [1] in the correctness of the assigned problem suggests that he was convinced in the validity of his misclassified conception. What way of thinking might have helped Johnny to question his solution or maybe even to avoid the mistake? A formal definition of divisibility of real polynomials did not seem to help although he was exposed to it in the classroom[1]. Allow me to address the question with a speculative proposal: in the course of his mathematics learning, Johnny engaged with a variety of concepts and domains. In many cases, if a concept was used to manipulate with elements from the domain, the result was also an element belonging to the same domain (e.g., union, intersection and exclusion of sets is a set; calculations with numbers result in a number; operations with functions create a function). It is very likely that Johnny was not aware that he engaged with instances of closure under operation. We can only wonder whether thinking in terms of "operation with elements from the domain often results in an element belonging to the same domain" would have made a difference for Johnny in the problem situation under discussion. Potentially, this way of thinking might have led him to an observation that his reasoning [1-3] was not consistent: in [3], he operated with polynomials having coefficients of a half and negative half, which indicates that he accepted polynomials with non-integer coefficients as elements of the domain of polynomials. However, in [1] he did not accept such a polynomial as a legitimate result of the division operation between two polynomials, which deviates from the presented way of thinking in terms of closure.

I consider a closure as an instance of a *meta-premise* – a generalized way of thinking, which is conceptualized as valid for various mathematical concepts and domains. Additional examples of meta-premises could be formulated as "a contradiction often indicates a flaw in preceding reasoning", "the same symbol usually denotes the same concept", "if a concept has different

[1] The standard definition that was provided in the classroom stated: Let $p(x)$ and $q(x)$ be polynomials in $\mathbb{R}[x]$. If there is a polynomial $r(x)$ such that $p(x) = r(x) \cdot q(x)$ then $p(x)$ is said to be divisible by $q(x)$ and we denote $q(x)|p(x)$.

definitions then they are likely to be equivalent". Note that while these meta-premises are valid in many cases, they are not always valid. Accordingly, Johnny could only notice that his reasoning in [1-3] deviates from the meta-premise but there would be no reason for him to interpret the deviation as a univocal indicator of a mistake. Indeed, there are concepts for which the described closure-under-operation premise does not hold, for example, a scalar product of vectors is not a vector but a number.

The presented post-exchange does not contain evidence of Johnny's engagement with a meta-premise. Next illustration demonstrates how a student can attend and interpret a deviation of their domain-valid and overarching conceptions from meta-premises.

**Multiplication in the domains of vectors and numbers**

In the following post-exchange, students discussed the problem:

In an isosceles triangle *ABC* (*AB*=*AC*) the medians to the legs are perpendicular (*BB'*⊥*CC'*). Find the value of cos *A* (see Figure 2).

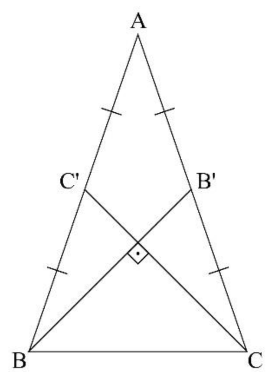

*Figure 2. A triangle from Molly's problem.*

*Molly*: [1] Please find my mistake: I say that $\overrightarrow{AB} = \vec{u}$ and $\overrightarrow{AC} = \vec{v}$.

[2] So I know that $\overrightarrow{BB'} = \overrightarrow{BA} + \overrightarrow{AB'} = -\vec{u} + 0.5\vec{v}$. In the same way I know that $\overrightarrow{CC'} = -\vec{v} + 0.5\vec{u}$.

[3] Now they are perpendicular so: $\overrightarrow{BB'} \times \overrightarrow{CC'} = 0$.

[4] $(-\vec{u} + 0.5\vec{v})(-\vec{v} + 0.5\vec{u}) = 0$

[5] $\vec{u}\vec{v} - 0.5\vec{u}^2 - 0.5\vec{v}^2 + 0.25\vec{u}\vec{v} = 0$ (actually ignore this part)

[6] $-\vec{u} + 0.5\vec{v} = \vec{0}$ or $-\vec{v} + 0.5\vec{u} = \vec{0}$

[7] and I get $\vec{u} = 0.5\vec{v}$ or $\vec{v} = 0.5\vec{u}$.

[8] But when I come to plug it in the formula I get $\cos A = \frac{\vec{u}\cdot\vec{v}}{\|\vec{u}\|\|\vec{v}\|} = \frac{0.5\|\vec{v}\|^2}{0.5\|\vec{v}\|^2} = 1$. So it means that it is a right-angle triangle, which can't be.

*Student*: What's the problem with a right-angle triangle? Then you get cos*A*=*1* and we are done.

*Molly*: [9] I wish… Then we have two different perpendiculars from C to BB' :(

[10] I probably messed up with vectors.

In terms of the introduced approach, the excerpt shows that Molly holds a polysemous image of the multiplication concept, which she considered in the domains of vectors and numbers. While the former domain was new to her, she demonstrated a high fluency with it: she introduced vectors into a problem (see [1]), added and subtracted them (see [2] and [7]), and manipulated with an inner product for determining angles between vectors (see [3] and [8] where Molly erroneously extracted a right angle from $\cos A = 1$). However, her set of overarching conceptions is a mixture of mathematically correct and invalid concept dimensions: distributivity of multiplication is valid to vectors and numbers indeed (see [4-5]) but the symbols of '$\times$', '$\cdot$' and an empty space are not tantamount in the vectors domain (see [3-5]). Also, in [6] she presumed that if a multiplication of two vectors equal zero, then one of them is the zero vector. This is another example of a conception that was misclassified from the domain of numbers, in which it is valid, to the set of conceptions overarching the whole image of the multiplication concept.

In contrast to Johnny, Molly was convinced that her solution contained a mistake [8-9]: after determining the measure of angle $A$ in the domain of vectors, she reconsidered the obtained triangle with geometry and spotted a contradiction. Accordingly, Molly shifted the assigned problem situation between two domains and interpreted a contradiction in one of them as an indicator of a flawed reasoning employed in another. As a result of engaging with a contradiction, which I consider as an instance of a *meta-premise*, Molly pointed out correctly that she "messed up with vectors" (see [10]). The forum contained no additional data to suggest how Molly continued her work, if at all. However, engaging with a meta-premise helped Molly to become aware of a flaw in her reasoning, which I consider to be a milestone towards restructuring the concept image that she developed.

It is worth mentioning that similarly to the case of Johnny, Molly's engagement with a meta-premise cannot be considered as a dogmatic strategy for verification of developed conceptions and solutions. Molly seemed to take for granted that the concepts of angles, triangles and perpendicularity preserve their dimensions after being shifted from the domain of vectors to the domain of geometry. Clearly this was correct in the particular case. However, spotting an incompatibility of concept's dimensions in axiomatically different domains (e.g., Euclidean and Hyperbolic geometries) requires further work for identifying its source: polysemy of a concept or a flaw in one's concept image and reasoning.

## Summary and Discussion

This article is concerned with cognitive aspects of students' engagement with cross-curricular concepts, and particularly with struggles that can emerge when familiar concept dimensions become invalid in a new mathematical domain. A polysemous approach was introduced for systematizing some sources of students' misconceptions including the affordances that might make students aware of their mistakes. The approach is a theoretical development consisting of overarching conceptions governing one's concept image as a whole and conceptions that are valid in one domain but not in another. A concept image of such a structure was referred in this article as polysemous – fragmentized into compartments which are distinct but related.

The approach was introduced for capturing students' ways of thinking in situations that require a conceptual change. Then, it is not surprising that some aspects of the findings that emerged from data analysis with the approach can be reviewed from the theoretical perspectives of Chi (1992), Vosniadou (2014) and others. For instance, the struggles of Johnny and Molly with separating between domain-valid and overarching conceptions bear resemblance to what Vosniadou (2014) calls "fragmented and synthetic conceptions". These conceptions reflect students' attempts to incorporate new and incompatible knowledge into familiar ways of thinking.

The article contributes to the literature on cognitive change by documenting cases in which students employ meta-premises for indicating the existence of mistakes in their ways of thinking, mistakes that follow from domain-valid and overarching conceptions. Notably, Molly indicated an existence of flaws in her ways of thinking without assigning the flaws to a particular conception. These indications can be associated with an intermediate stage in the process towards a conceptual change, at which learners acknowledge the need for it. Analogously, reviewing a solution or an approach to a problem from the perspective of meta-premises can be interpreted as a metacognitive mechanism that is necessary for carrying out a cognitive change.

An important feature discerning the introduced approach from the literature on a cognitive change is that it acknowledges the existence of epistemological obstacles in mathematics teaching and learning – obstacles that are ingrained in mathematics as a discipline (cf. Brousseau, 1997), polysemy for example. In this way, a polysemous perspective on students' concept images does not only account for the gaps between one's concept image and formal definitions but it also distils the domains in which the developed conceptions are valid. The importance of gaps has been addressed with extensive research conducted with the constructs of concept image and concept definition. Domains of validity are instrumental for recognizing the reasonableness in ways of thinking that students bring to the classroom. Analysis of one's ways of thinking in terms of the approach is aimed at explicating their domains of validity rather than at abandoning them.

Students' struggle with epistemological obstacles of mathematics is unavoidable by definition. In the case of polysemy two features should be considered: First, while progression through mathematical topics can yield opportunities for engaging with cross-curricular concepts, it is still up to the students to identify concepts appearing in different domains as *the same*. Second, fluency with polysemy requires acknowledgment of its existence, experience in making connections between ideas studied in different domains, as well as proficiency in axiomatics and formalism. It is not easy to find educational settings in which a combination of these forms of knowledge is systematically promoted.

Key Memorable Events During Undergraduate Classroom Learning

Ofer Marmur
Simon Fraser University

*This paper presents a theoretical construct termed Key Memorable Events (KMEs): classroom events that are perceived by students as memorable and meaningful in support of their learning, and are typically accompanied by strong emotions, either positive or negative. As such, the proposed concept implies a hierarchy between different events and their contribution to the learning by focusing on those moments perceived by students as most significant. The concept is exemplified in context of large-group undergraduate-calculus tutorials. Theoretical and pedagogical implications are discussed in terms of lesson design, data analysis, and conceptualization of learning in the undergraduate classroom.*

*Keywords:* Memorability, Classroom Learning, Instruction, Affect

## Introduction

Undergraduate mathematics courses are typically taught in a frontal teaching style (henceforth referred to as FTS), and are often attended by large amounts of students (≥ 100), especially in first-year courses (e.g., Cooper & Robinson, 2000; Pritchard, 2010). The common practice of the traditional FTS at university has been criticized repeatedly, specifically regarding the one-directional non-responsive mode of communication this teaching style promotes. In this regard, it has been argued that FTS is focused on transmitting information (Biggs & Tang, 2011), and does not promote independent student thought (Bligh, 1972). Considering that emotions have been recognized to take an integral part in mathematical problem-solving behavior (e.g., Op't Eynde, De Corte, & Verschaffel, 2006), it has additionally been claimed that FTS does not reveal the human struggle for reaching mathematical discovery, and treats students as "non-emotional audience" who are granted no room for individual difficulties (Alsina, 2002).

While alternative teaching styles have been explored and their benefits acknowledged (e.g., Larsen, Glover, & Melhuish, 2015), FTS remains to be widespread, not prone to change, and will most likely not disappear in the near future (Cooper & Robinson, 2000; Koichu, Atrash, & Marmur, 2017; Nardi, Jaworski, & Hegedus, 2005). Therefore, it is important that research efforts will additionally be put into improving the system from "within", theoretically and practically. This includes gaining a better understanding of the following: how students learn during frontal undergraduate lessons, whilst additionally examining how the learning is shaped by student affect and the teaching that took place; how frontal undergraduate lessons can be designed to create and support a positive and meaningful learning-experience for the students; and how to identify the learning opportunities in class that enable students to be actively engaged learners during the lesson itself and in support of their subsequent independent learning at home. These goals are in line with Lester's (2013) call for attention to be given to the teacher's role in problem-solving instruction and how *large groups* of students learn problem solving in real classroom situations.

The current paper addresses these goals by suggesting a theoretical construct termed *Key Memorable Events* (KMEs): classroom events that are perceived by *many* students as memorable and meaningful in support of their learning, and are typically accompanied by strong emotions, either positive or negative. It should be noted that the *key* aspect here refers to the significance of the event to the *many* at classroom level. While the construct originated out of empirical evidence (see Marmur, 2017, for further detail), the focus of this paper is theoretical, discussing the potential contributions of the notion of KMEs for lesson design, data analysis, and understanding of classroom student-learning. Nevertheless, some data are presented to illustrate the construct.

## Theoretical Background

In the literature there is a variety of concepts that employ different frameworks and terminologies for addressing what we may globally refer to as *key events* during the process of student learning. Such events are situated in the affective and/or cognitive domain, and may have a substantial impact on both the short- and long-term learning. Though the separation between cognition and affect is not always clear-cut, addressing the literature according to these two perspectives can shed light on the nature of these events.

From an affective perspective, Goldin (2014) refers to *key affective events* as events "where strong emotion or change in emotion is expressed or inferred" (p. 404). Rodd (2003) claims that "undergraduate learning is frequently triggered by those unique events which contribute to an individual's agency or self-motivation" (p. 20). In line with this claim, Weber (2008) demonstrated how a single and strong positive experience of success may have a considerable effect on a student's success in a high-level calculus course, by altering the student's attitude and type of engagement with the material for the continuation of the course. This "direct path" to attitudes and beliefs through a single powerful experience has also been reinforced by Liljedahl's (2005) discussion of "Aha!" experiences during problem-solving activities.

From a cognitive perspective, different researchers have focused on crucial moments in student thought-processes during problem-solving activities. Nilsson and Ryve (2010) focus on what they refer to as *focal events*, i.e. those parts of student reasoning that are noticeably salient. They explain that such events steer our educational attention towards "the problems that stand out as central in the students' thinking in a certain phase of a learning activity" (pp. 245-246). In an analysis of a collaborative-learning situation, Damsa and Ludvigsen (2016) identify *key moments* in the group interaction, i.e. "an action or sequence of actions at the epistemic level that triggered subsequent actions and leading to a particular relevant development regarding the shared object" (p. 5). Their analysis of such moments was based on the more general theoretical approach provided by Webster and Mertova (2007) of considering *critical events* as an analysis tool in research on teaching and learning.

## Conceptualizing KMEs

In continuation of the theoretical approaches presented above, this paper wishes to put emphasis on the aspect of the *memorability* of a classroom event, as the memorability of an event may shed "unified" light on both dimensions of cognition and affect related to student learning. The New Oxford American Dictionary (Stevenson & Lindberg, 2010) defines the adjective *memorable* as "worth remembering or easily remembered, especially because of being special or unusual". It additionally suggests the following as possible synonyms: unforgettable, significant, notable, noteworthy, important, special. These definition and synonyms suggest that *memorable events* are not merely events that can be recalled from memory upon request, but that these are events that additionally hold significance and meaning for a person who experienced them. For example, one can imagine the moment when "the penny dropped" (i.e., the moment when some important aspect of the material became understood and things fell into place) to be a memorable event for a student, and that for him/her this event was also filled with emotions, such as the excitement of success in understanding a complex concept, followed by a raise of self-confidence.

The suggested focus on memorability of events finds further support in the neuroscientific domain, which informs us that the brain does not store all information it encounters. As articulated by Wolfe (2006), the brain is in fact "designed to forget" (p. 36). Focusing on memorable events may supply insight into student short- and long-term learning processes, since, as claimed by Wolfe, memorability means that information is stored in permanent and rich networks, thus enabling its future retrieval. In this regard, "emotional events often attain a privileged status in memory" (LaBar & Cabeza, 2006, p. 54), taking a crucial physical part in filtering which information from the environment will be "saved" for future use (McEwen & Sapolsky, 1995). For example, neuroscientific experiments reveal that the triggering of negative emotions may jeopardize the functioning of the working memory during mathematics problem-solving (e.g., Ashcraft & Krause, 2007), or even induce physical reactions that can alter the memory altogether (e.g., McEwen & Sapolsky, 1995). On the other hand, lessons designed to evoke student emotion may lead to stronger memories, and can consequently serve as a hook for learning (Wolfe, 2006). In summary, this demonstrates neuroscientific reinforcement for the link between memory, emotions, and learning, and its relevance to education research (see also Hinton, Miyamoto, & Della-Chiesa, 2008).

When considering student learning-experiences in the undergraduate classroom, I propose to imagine a two-dimensional representation, where on one axis there is a detailed list of consecutive classroom events, and on the other axis a list of the different students attending the lesson. Accordingly, we may treat the location (X, Y) in the resulting table as the meaning and importance given to event X by student Y in terms of his or her learning experience at that moment in time. However, as supported by the theoretical background presented above, if we conceptualize the flow of a lesson as a sequence of classroom events, these events will not all be at the same level of importance to students, and some events may be more significant than others. These will be referred to as *memorable events* (see Figure 1: Key Memorable Events).

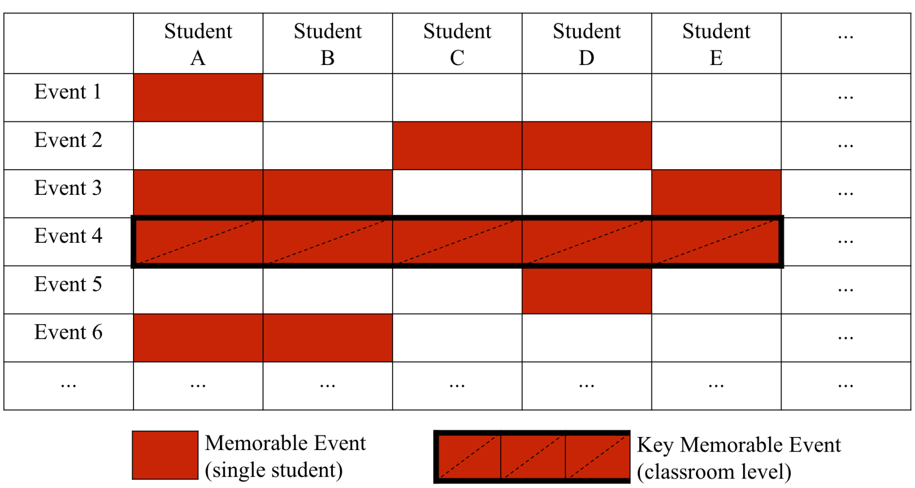

*Figure 1: Key Memorable Events*

Continuing this representation, I suggest two complimentary approaches that may be used for addressing and analyzing the nature of the learning in class. We may consider the learning of a *single student* through the progression of classroom events, leading us to a conceptualization of a single student's learning trajectory, in Simon's (1995) framework, or the student's affective pathway, in Goldin's (2000) framework. On the other hand, and what is here emphasized, is the focus on a *single event* and how this event affects the different students in class in similar ways. This approach may supply insight into how a specific pedagogical act impacts the students as a *group* by recognizing repetitive themes students report on regarding this event. Repeating this approach with different events during a lesson may result in an overall categorization of how various instructional acts relate to the students' learning as a whole. Accordingly, this approach emphasizes the immediate relation between the teaching and the overall classroom learning.

Focusing on the memorability of events on the group level, it should be acknowledged that what may be memorable to one student, may not be memorable nor significant to another. The term *key memorable events* is thus used to refer to those events in the lesson that are perceived by *many* students in class as memorable and meaningful in support of their learning (see Figure 1: Key Memorable Events). Whereas an operational definition should additionally quantify the phrase "many students", this conceptual definition could nonetheless be easily implemented methodologically by means of stimulated-recall interviews (see Marmur, 2017) in order to identify classroom events that are memorable and key.

## Two Examples

The two examples presented here are taken from a wider research project examining student learning in undergraduate large-group calculus tutorials. The first exemplifies the utility of KMEs as a guide for lesson design, whilst the second example demonstrates its utility as a methodological tool in explaining classroom phenomena.

### Example 1: A "Designed" Setting

Marmur and Koichu (2016) presented an iterative process of lesson design aimed at creating an aesthetic experience for students in a "traditional-instruction" calculus tutorial. In the final successful iterations of the lesson, the incorporation of two surprising events of reaching a dead-end in the solution, prior to the surprising presentation of a non-routine solution, managed to serve as a teaching method leading to an aesthetic experience for many students.

Revisiting the data with the suggested terminology of KMEs, the students' strong and emotional responses to these "surprising events" revealed that these events indeed served as KMEs of affective nature for the students (as expressed in stimulated-recall interviews, as well as observed in class). The data suggest that this combination of KMEs not only supported the creation of an aesthetic experience, but was also most influential on the students' learning process in both cognitive and affective terms (see also Koichu et al., 2017). In affective terms, the students reported heightened involvement and enjoyment during the lesson, as well as a rise in self-confidence by being encouraged not to give up when initial attempts at solving a challenging problem are unsuccessful while working independently. In cognitive terms, the KMEs raised the students' focus, attention, and interest during the lesson; they exposed the students to an expert's thought process of how to reach a solution; and they enhanced the memorability of the material taught. Moreover, students reported to be actively engaged learners by attempting to accomplish a range of self-imposed tasks. These included independently testing alternative ideas to the solution; attempting to predict the next step in the solution; identifying difficult places in the proof to come back to; looking for connections between the problem taught in class and the corresponding homework assignment; and formulating problem-solving strategies from their current experience that they could use in the future. It should be noted however, that the students reported that this was not part of their routine behavior in class. Additionally, some students reported that this lesson impacted their after-class learning activity in a non-standard way. This included deciding to independently re-solve the problem, as well as go through all material from the beginning of the semester. The latter was encouraged by the students' newly recognized need for what Schoenfeld (1985) refers to as *resources* – knowledge in support of solutions for non-routine types of problems.

**Example 2: A "Regular" Instructional Setting**

Marmur and Koichu (in press) juxtaposed two similar large-group undergraduate-calculus tutorial-lessons as a contrastive basis to examine how students' emotional states relate to the type of mathematical discourse conducted in class. Though both lessons contained a similar challenging problem the students did not understand, the students evaluated the lessons in opposite manners. While the lack of understanding in one of these lessons (Lesson-N) was (unsurprisingly) accompanied by negative student emotion of anger and frustration, the second lesson (Lesson-P) was (surprisingly) perceived by the students as special and good, even though they admitted key parts of the proof to be incomprehensible, and showed disbelief in their ability to solve such problems on their own.

In KME terminology, the difference was analyzed by the identification of a single KME of affective nature per lesson, that shaped the students' overall learning experience. The difference was related to the type of discourse initiated by the instructor during the identified KME. In the KME of Lesson-P, the instructor initiated a type of meta-level discourse on how to approach a challenging problem (termed *heuristic-didactic discourse*). According to the data, this KME demonstrated expert problem-solving heuristic-behavior in an approachable way to students, shaped the learning experience during the rest of the lesson, and additionally served as a neutralizing factor for possible negative emotions as a result of not understanding the solution. However, in the KME of Lesson-N, the instructor made a promise for heuristic-didactic discourse, yet did not fulfill this promise in the remainder of the lesson.

## Discussion

The proposed concept of KMEs may supply insight into student learning at group-level, and could be utilized both as pedagogical tool for the improvement of undergraduate teaching (as in Example 1) and as methodological tool for analyzing real classroom situations (as in Example 2). As the second use requires a presentation of additional data outside the scope of this paper (see Marmur, 2017), I expand the discussion focusing on the first proposed use for teaching improvement, as well as a theoretical reflection on classroom student learning.

**KMEs as a Guide for Lesson Design**

Being that KMEs are conceptually regarded as events that are perceived as memorable and meaningful by *many*, I suggest that they may be utilized by instructors as indicators for events in the lesson that will most likely remain "invariant" in future "same" lessons taught to other students. Building on variation theory (Marton & Booth, 1997; Runesson, 2005) for lesson design, Watson and Mason (2009) claim that variation in lessons should be "foregrounded against relative invariance of other features" (p. 98). As suggested by their argumentation, the significance of understanding the invariant aspects of lessons is to be able to utilize them as "anchors" on top of which variation is created. Accordingly, KMEs may indicate a likely *invariance* in a lesson design, which provides crucial information for its further development and refinement. In practice, utilizing the notion of KMEs as such "anchors", may additionally allow lecturers and instructors to each time "fill" them with varying mathematical content.

In this regard, it should be noted that the creation of hierarchy between different classroom events in regard to student learning, as suggested by the KME concept, is not foreign to the way some researchers address the mathematics itself. For example, according to Leron (1983), the common practice of presenting proofs linearly in undergraduate lessons is unsuccessful in its support of student learning, as it lacks the dimension of communicating how such proofs are generated and thought of. Rather, Leron's notion of a "structural proof" suggests to first supply students with the general structure of a proof, and only then start filling in the missing details.

Continuing the analogy, while this paper focuses on *key events* as experienced by many students, in the literature we may find research focusing on *key mathematical ideas* (e.g., Gowers, 2007; Hanna & Mason, 2014; Raman, 2003). Raman (2003) states that: "For mathematicians, proof is essentially about *key ideas*; for many students it is not" (p. 324). Gowers (2007) emphasizes the relevance of key ideas to mathematical activity, by claiming that a focus on the key ideas of a proof may increase its memorability and promote its mathematical understanding. This naturally comes with the pedagogical implications of how to reveal to students what these key ideas are, and how these may serve their learning. In relation to lesson design, I suggest that the notion of KMEs may be considered in combination with key mathematical ideas that could be learned in context of the problem (as in Example 1, a KME around a non-routine solution method for a challenging mathematical problem).

An additional use of KMEs for lesson design relates to the affective domain, and more specifically to negative student emotions. As we know, negative emotions are a natural part of mathematical learning, and as Goldin (2014) suggests, may even lead to greater satisfaction and pleasure when "overcoming" challenging problems. However, it is our responsibility as educators and researchers to support students' meta-affect in relation to such experienced emotions. As claimed by Goldin (2000, p. 218):

> "The challenge to the educator is to interrupt the incessant negative feelings, a first and necessary step in the needed cognitive and affective reconstruction. The challenge to the researcher is to find ways to do this."

I suggest that the concept of KMEs may be utilized in lesson design as a tool to "steer" student emotions towards specific segments of a lesson, and thus be able to reduce the overall experienced negative emotions. This is illustrated in Lesson-P (see Example 2), in which the creation of a very positive event at the beginning of the lesson (on how to approach the problem), managed to neutralize possible negative student emotions stemming from not understanding the subsequent solution. Such a case demonstrates that, even though we may not be able to stop students feeling frustrated when dealing with challenging mathematics, we may utilize the idea of KMEs in order to design lessons that could shape what would ultimately be perceived as a more positive memorable learning-experience.

## KMEs and Theoretical Considerations on Learning

> "The line, even in science, between serious theory and metaphor, is a thin one—if it can be drawn at all. [...] There is no obvious point at which we may say, 'Here the metaphors stop and the theories begin.' " (Scheffler, 1991, p. 35)

In regard to existing literature and theory, I suggest that the KME concept may provide a theoretical contribution to our views on learning, as well as on the evolvement of student affect during the process of learning. Sfard (2015) argues that we conceptualize and examine human learning by utilizing metaphors, and that "what often appears as but an innocent figure of speech may in fact inform how we think about the topic, what we are able to notice, and what pedagogical decisions we are likely to make" (p. 635). Furthermore, Sfard (1998) emphasizes that in order to produce a critical theory on learning, we must be willing to lean on more than one "metaphorical leg" (p. 11), even if the different metaphors induce some level of contradiction.

Though learning is not a linear process, I argue that some of the very useful learning metaphors we find in the literature at least hint towards some level of linearity. Conceptualizing student learning over the course of a lesson in metaphors such as "paths", "pathways", "trajectories", or "tracks", indeed has great pedagogical value in terms of lesson design. As suggested by Simon's (1995) notion of *learning trajectories*, a teacher may hypothesize on learning paths of students, whilst aiming to "match" these with preconceived teaching goals. However, at least on a theoretical level, this metaphor may imply an unrealistic linearity in the process of learning, where students have to go through a series of consecutive steps, each one supporting the following. It is interesting to note that even when discussing emotions, which are clearly nonlinear, in context of learning, we find it convenient to conceptualize these into *affective pathways* (Goldin, 2000) that progress from one emotional state to the next.

I suggest that the concept of KMEs may supply a "horizontal" approach to learning (see also Figure 1: Key Memorable Events), enriching the more dominant "vertical" view on learning as pathways. The KME notion suggests a hierarchy between different events and their contribution to learning, whilst putting emphasis on what we may regard as "*snapshots*" or *highlight moments* in a lesson as identified by many. I do not wish to imply that other moments in a lesson are insignificant for the learning, or even that they do not play a contributing role in the creation of a KME. However, I suggest such a hierarchal approach is not only a useful tool for lesson design, but also examines learning in closer relation to what we may refer to as our "human experience". If for example we imagine a musical piece, it is reasonable to assume we will not remember all individual notes. Rather, our overall experience is shaped by certain highlight moments during its course (Huron, 2006). Bringing the analogy back to KMEs, the findings presented in Example 1 and 2 suggest that a student's overall learning-experience in a lesson is shaped by several key moments during its course.

Lastly, I suggest that the KME concept may supply an added layer to Goldin's (2000, 2014) theory on local and global affect. While the KME construct addresses emotion experienced during a lesson, the dimension of strong memorability points towards a possible affective phase situated in an "intermediate zone" between local emotional states and longer-term attitudes and beliefs. Though there seems to be a consensus in the literature, that the more stable attitudes and beliefs are a result of a lengthy and slow process of experiencing repeated emotional states (e.g., Goldin, 2000; Zan, Brown, Evans, & Hannula, 2006), not all these experienced states are of equal importance. Focusing on those experienced emotions during what is here referred to as KMEs, may supply us with a more accurate indication of how this transitional process possibly takes place.

# Toward a Functional Grammar of Physics Equations

Kirk M. Williams, David T. Brookes
Department of Physics; California State University, Chico; Chico CA 95929

*An area of student difficulty in introductory physics courses is how they use and reason with equations. We propose that part of this difficulty is due to meaning that is embedded in the structure of equations. As equations are manipulated, their structure and concomitant meanings change. As mathematics is considered the "language of physics," our starting point will be to propose that it has a grammar. As equations change form and meaning, they are doing so within a certain grammatical system. We will show how physics equations can be categorized and mapped to ideational clause types as devised by Halliday (1994). This mapping could be useful in relating the mathematical "language" used in physics to "natural language," benefitting physics instructors who are trying to understand the struggles of their students, and helping students to understand the rich meanings embedded in physics equations.*

*Keywords:* physics, mathematics, linguistics, ontology, grammar

It is often stated, to the point of cliché, that "math is the language of physics." This is intuitive, and readily accepted by most. The concepts of physics can be explained without any mathematics whatsoever, but this approach results "...in an understanding of physics that is fundamentally different from physics as understood by physicists" (Sherin, 2001, p. 524). Certainly, for most who are looking for any kind of practical aptitude in these concepts, it is essential to be able to work with equations.

If, indeed, mathematics is the language of physics, what kind of a language is it? What is its system of grammar? Knowing this could be useful, especially for educators whose competence in this language has surpassed the need to think of its underlying structure. At such a high level of expertise, it can be difficult to truly understand what is causing students difficulties as they learn how to communicate and do physics with mathematics. If instructors could see how conceptually complex it really is to know what equations *mean*, perhaps they could better understand the struggles of their students and be better equipped to help. Research has been conducted into the lexical meaning of symbols in physics and how those diverse meanings pose both interpretative and epistemic difficulties for students (Torigoe & Gladding, 2011; Redish & Kuo, 2015). Others have examined the structure of equations themselves and how that structure facilitates or constrains physical reasoning (Sherin, 2001; Landy, Brookes, & Smout, 2014). Weinberg, Dresen and Slater (2016) have examined mathematics as a semiotic system used productively by students for meaning-making. But to the best of our knowledge, no real attempt has been made to develop a grammar of physics equations. Our goal in this paper is to lay the groundwork for this process. We are going to suggest that equations have fundamental spatial structure, ordering, and function that encodes underlying meaning and it is in this area that additional challenge arises for students. It should be noted that our focus is on physics equations, in particular those seen by students in lower-division undergraduate physics courses. The broader discussion about the grammar of mathematics as a whole is beyond the scope of our work.

This project began with the observation that common physics equations can be separated into different categories based on their meanings. As equations are rearranged or manipulated, these meanings change. For instance, $a=F/m$ (Newton's second law) is what we would call a *causal* equation; it has an effect - acceleration - on the left side, and a cause - force - on the right. Mass is an inhibitive contribution to the cause, as it is inversely proportional to the effect. Research has already empirically shown that equation users are sensitive to the ordering of causal equations (result left of the equals sign, cause on the right), and reversing the order is confusing or changes the meaning of the equation (Mochon & Sloman 2004). We claim this is prima facie evidence of equations having a grammatical structure.

## Is Mathematics a Language?

Before proceeding, we must ask a simple question that - it appears to us - has no simple answer: Is mathematics legitimately a *language*? To address this, we will start in the broader realm of semiotics. Mathematics is most certainly a kind of semiotic system; it is vehicle for making meaning and communicating. Semiotics, to put it simply, is the study of signs. There are two predominant models of signs: the dyadic and the triadic. A dyadic sign would consist of a "signifier" and a "signified." The signifier could also be called the "sign vehicle" and the signified the "referent" (Noth, 1990). Essentially, there is a thing being represented and a way of representing it. The chief limitation of the dyadic model is that it lacks context. There are semantics and syntax, but no pragmatics (Ongstad, 2006). A triadic model, as devised by C.S. Peirce, would add what he called the *interpretant* to the previously described schema. A more commonly used term for this is *sense*, meaning there is someone or something "receiving" the sign and interpreting it. The triad is thus *sign vehicle*, *sense*, and *referent* (Noth, 1990).

Both of these models have played out in existing analysis of the semiotics of mathematics. A kind of dyadic model is proposed by Rotman (1988), in which the mathematical sign has the components *thought* and *scribble*. The two cannot be separated and be considered a true mathematical sign. In Rotman's mathematical semiosis, a person in essence *creates* a Mathematician, who then creates an Agent. Each of these take on the firstness, secondness, and thirdness, as devised by Peirce, as they proceed through the creation of a proof (Rotman, 1988). Ongstad advocates for a triadic model in which a sender and receiver are involved in the interpretation of content. The sign itself in this case is made up of the elements Symptom, Symbol, and Signal. These correspond to senders, "objects or states of affairs," and receivers, respectively (Ongstad, 2006).

The semiotics of mathematics is a rich topic. It is clear that in doing mathematics, we are engaging in some form of communication. But what of our treatment of mathematics as a language? Leibniz attempted to develop a universal language involving a "...*calculus ratiocinator*, a system of rules for the combination of semantic primitives" (Noth, 1990, p. 274). Frege's mathematical symbolism "embodies fundamental principles of reasoning based on an analysis of language" (Bouissac, 1998, p. 249). Rotman describes mathematical texts as being a "...mixture of natural and artificial signs...conventionally punctuated and divided up into what appear to be complete grammatical sentences…" (Rotman, 1988, p. 7). Ongstad gets more specific in proposing that mathematics could be "...a set of interrelated, semiotically different languages or sign systems" (Ongstad, 2006, p. 248). If one takes this perspective, it is reasonable to suggest that physics equations might be a language in their own right, semiotically different than the languages of pure mathematics or statistics (Redish & Kuo, 2015).

What is it that makes physics equations unique? At least part of it is that they do not consist of pure, abstract mathematical objects; rather, they use these objects to describe patterns in nature. This distinction is what shall characterize the ontology - and, as we shall see, the grammar - of physics equations.

## Systemic Functional Grammar

If we are to devise a grammatical system of physics equations, it must - if it is to be useful - be analogous to one that is familiar to us. We will use our native language of English, but we will attempt to minimize applications of grammatical concepts that are not also applicable to other languages. For this kind of universality, we look to Functional Grammar, as devised by Halliday. It is a systemic theory, a "...theory of meaning as choice, by which language, or any other semiotic system, is interpreted as networks of interlocking options…" and it is "...functional in the sense that it is designed to account for how the language is **used**" (Halliday, 1994, p. xiii). Our focus has been primarily on the experiential aspects of the grammar, which look mostly at the clause. The clause in this framework has three different metafunctions (sometimes called components); ideational ("clause as representation"), interpersonal ("clause as exchange"), and textual ("clause as message") (Halliday, 1994). The ideational metafunction is the most appropriate for application to our mathematical "clauses" of interest. Physics equations do, after all, *represent* - or model - objects, interactions, systems, and states (Etkina, Warren, & Gentile, 2006).

The ideational metafunction models the clause as a process, within which there is an internal process (typically a verb), a participant (typically a noun), and, optionally, a circumstance (Halliday, 1994). For instance, in the sentence, "The girl caught a fish from a lake," "The girl" and "a fish" are participants, "caught" is a process, and "from a lake" is a circumstance. These classifications are quite broad, so different process types are used depending on the function of the clause. This type of categorization is called a *transitivity system*. Structure is "explained in terms of meaning." The three primary process types within the ideational component are material, mental, and relational processes. These are processes of doing, sensing, and being, respectively (Halliday, 1994).

For example, a material process might be our previous example (omitting the circumstance for brevity), "The girl caught a fish." In this case, we call "the girl" the Actor and "a fish" the Goal. These describe processes of *doing*.

In the case of a mental process, it is necessary to have a personified participant - something that can "sense" something else. In the sentence, "He likes it," "he" is classified as a Senser and "it" is a Phenomenon. "Likes" is the process. We sometimes use this language in physics to personify things like electrons, which we might say "want to be in the ground state" (Brookes & Etkina, 2007).

Relational processes are the most varied and complex, as they describe relationships in which things are identified, symbolized, or otherwise related to other things. The two main types of relational processes are attributive and identifying. The participant types associated with these are Carrier/Attribute and Identified/Identifier (sometimes called Token/Value), respectively. The former treats a participant as a member of a category, while the latter *identifies* the participants as each other, and is thus reversible ("Alice is wise" vs. "Alice is the wise one") (Halliday, 1994). In addition, the relational process has three subcategories: Intensive ('$x$ is $a$'), circumstantial ('$x$ is at $a$'), and possessive ('$x$ has $a$'). These can each be combined with either "attributive" or "identifying" to form such combinations as "circumstantial identifying" or "possessive attributive." Distinctions like this will be quite useful in formulating a kind of transitivity system for physics equations.

Finally, our brief summary of some important aspects of functional grammar must include a discussion of what goes on "below the clause." At this level, the ideational component splits into two categories: Experiential and logical. These turn out to be two different ways to examine phrases and groups within a clause, and the ordering of functional elements within a group. For instance, let's look at the experiential structure of the nominative group "those two old diesel trucks." It exhibits the typical ordering of elements: Deictic, Numerative, Epithet, Classifier, and Thing. To arrange the sentence in any other way would not make sense. If we look at the same group's logical structure, we would call "trucks" the Head and everything else the Modifier. Each word is then assigned a Greek letter, starting on the right with "trucks" and moving to the left. We would thus *read* this group's logical structure from left to right: Modifier (ε, δ, γ, β), Head (α). Conceptually, this ordering is characterized as moving "...from the kind of element that has the greatest specifying potential to that which has the least…" (Halliday, 1994, p. 187) This type of analysis could be effective in characterizing the order of elements in mathematical "groups" as well. There are clearly certain consistent tendencies, like putting numerals before constants, which are then put before variables. Our focus here is less on the group and more on the clause, as we aim to set up a transitivity structure for our equations. However, the ways in which mathematics is at least "like" a language continue to unfold; it does not appear to be a superficial connection.

## Ontology, Grammar, and Interpretations of Equations

An important concept in this discussion is that of ontological "trees," as devised by Chi, Slotta, & de Leeuw (1994) and later modified by Brookes and Etkina (2007). Chi et al. proposed that people separate the world into three primary ontological categories (trees), each having its own subcategories (branches). These are Matter, Processes, and Mental States. When an idea or entity is initially conceived to belong to one of these categories, and then must be moved to another, this is called *conceptual change*. Topics that require this kind of shifting exhibit a kind of "incompatibility" of conception and tend to be more difficult to learn. This is part of what is called the Incompatibility Hypothesis. Many science concepts require the learner to continually alternate between categories, which creates exceptional difficulty (Chi et al., 1994).

The version of this model adapted specifically for the language of physics by Brookes and Etkina changes the category of Mental States to the more general States (Brookes & Etkina, 2007). Etkina, Warren, & Gentile devised a taxonomy of physical models, which comprised of models of objects, interactions, systems and processes (split into causal and state equations) (Etkina et al., 2006). These were mapped to the ontological categories of matter processes and physical states, in part to understand the prominent use of metaphorical language in how physicists talk about physical ideas (Brookes & Etkina, 2007). For example a physicist might say "Energy flowed into the system by heating." In this sentence "energy" is the *matter*, "flowed" is the *process*, and "by heating" is a circumstance that elaborates the nature of the *process*. On the other hand, a physicist could say "Heat flowed into the system." In this case, "heat" has shifted in its grammatical function (from circumstance to participant) and likewise has shifted its ontological category from elaborating the *process* to being categorized as *matter*.

Another important precedent for our work is the concept of *symbolic forms*. Symbolic forms are what Sherin (2001) describes as "knowledge elements" with two components: A symbol template and a conceptual schema. The symbol template component is primarily how Sherin distinguishes the forms. This is an abstraction of a mathematical expression in which symbols are replaced primarily with shapes ($\square$), generalized variables ($x$) and ellipses (...), so that the focus is on the structure of the expression, rather than its specific content. For example, the symbolic form "balancing" is represented with the symbol template $\square = \square$. "*Identity*" is represented with $x = […]$. Sherin presents a "semi-exhaustive list" of these forms, and suggests that its organization into "clusters" is "...primarily for rhetorical purposes - not to reflect any psychological grouping of the elements. However, within a given cluster, the various schemata tend to have entities of the same or similar ontological type" (Sherin, 2001, pp. 505-506). We suggest that the reason these clusters are not clearly defined is because of the level of abstraction used in the model of symbolic forms. The meanings of the mathematical structures cannot be adequately understood when their "participants" have been generalized and removed from their processes. Sherin seems to be primarily analyzing the constituent structure (Halliday, 1994) of the equations' *orthography*, not their grammar. That is, we see how this "language" is typically written down, but not how it is used. For example: $\vec{p} = m\vec{v}$ fits into the *identity* template and is recognized as such in physics, but so does $N = mg$, an equation that does not represent *identity*.

Among Sherin's references is Anna Sfard, who has written at length about the meaning of the equals sign. She has suggested that although "*...there is a deep ontological gap between operational and structural conceptions…* they are in fact *complementary*" (Sfard, 1991, p. 4). This duality of object vs. process is found in many forms in the mathematics education literature, but Sfard's comparison of this distinction to the "complementarity" of waves and particles in quantum mechanics is unique. This illustrates the subtlety and ambiguity of the equals sign, our grammatical "process."

## Mapping Grammar to Equation Types

Taking into consideration all of the literature reviewed above, the most potent for analyzing the meanings of physics equations has been Halliday's functional grammar. It works surprisingly well to simply map ideational process types to equation categories. This mapping is certainly not one-to-one, but it offers useful distinctions and is remarkably consistent with the way these equations are used in (for example) Knight's popular undergraduate physics textbook (Knight, 2004).

We started the mapping by dividing equations in physics into three broad categories based on three distinct meanings of the equals sign. Building on prior work (Keiran, 1981; Sherin, 2001; Redish and Kuo 2015) we recognized that an equals sign in physics can mean "is," "is equal to," or "is a result/consequence of." The second key to mapping equations to grammar is to examine how the equation functions in relation to the words that surround it. In other words: equations in physics *cannot* be separated from the surrounding (English) sentence if we want to understand their full meaning. We will present our analysis based on a commonly used University-level, introductory physics textbook (Knight, 2004).

In our framework, equations in which the equals sign means "is" belong to a category we called "Operational Definition," similar to Sherin's *identity* template. For example, acceleration $\vec{a} = \frac{d\vec{v}}{dt}$, or momentum $\vec{p} = m\vec{v}$ operationally define useful physical quantities in terms of how they are measured. These correspond to grammatical relational intensive processes. We take this to generally also mean these processes are identifying rather than attributive, because mathematics does not have quite the same issues with reversibility and active vs. passive voice that we have in English. For example, when dealing with momentum, Knight writes, "The product of a particle's mass and velocity is called the momentum of the particle: momentum = $\vec{p} = m\vec{v}$" (Knight, 2004, p. 262). This is an intensive identifying clause; it is reversible, and it serves to assign an identity to the signs $p$ and $mv$. The equation itself does essentially the same thing. The two signs are interchangeable - the equation serves to identify.

Next, we identified a category of equations where the equals sign reads "is equal to". Equations in the "Is Equal To" category map to relational circumstantial processes. Each of these is true only within certain specific circumstances. One example from Knight: "If the angle $\theta$ is such that $\Delta r = d\sin\theta = m\lambda$, where $m$ is an integer, then the light wave arriving at the screen from one slit will be *exactly in phase* with the light waves arriving from the two slits next to it" (Knight, 2004, p. 938). In this sentence $d\sin\theta = m\lambda$ functions as a grammatical circumstance. On the other hand, that equation, presented on its own on (for example) an equation sheet, lacks any indication of its circumstantial nature. We hypothesize that an expert seeing this equation implicitly sees the surrounding context as well, even when it is absent. The sentence quoted doesn't come out to be a single circumstantial clause, but it doesn't need to. As we have noted, this mapping from the grammar of language to the grammar of physics equations is not one-to-one. The distinguishing characteristic of these equation types is their being tied to circumstance, sometimes in a subtle way. For example, $N = mg$ (another equation that falls into the "is equal to" category) is only applicable when an object of mass $m$ is resting on a level/horizontal surface, close to the earth's surface and ignoring the fact that our rotating (Earth's) reference frame is slightly non-inertial. Halliday writes of circumstantial identifying processes in which the participants act as the circumstantial element: "The relation between the participants is simply one of sameness; these clauses are in that respect like intensives, the only difference being that here the two halves of the equation - the two 'participants' - are, so to speak, circumstantial elements in disguise" (Halliday, 1994, p. 131). This true of an equation like $\lambda = v/f$. In order for this to be true, there has to *be* a frequency $f$ to create a wave with a wavelength $\lambda$ constrained to be traveling at a velocity $v$ through a medium.

The third meaning of the equals sign ("is a result/consequence of") defines a category of equations we have called "Causal." These equations represent material processes - processes of *doing*. Much as we have an Actor and a Goal in such grammatical processes, causal equations have what we shall call a Result (or Change) on one side of the equals sign, with an Agent and, optionally, an Inhibitor on the other. In the ubiquitous equation that represents Newton's second law, $\vec{a} = \frac{\sum \vec{F}}{m}$, "$a$" is our Result (*defined* to be $\frac{d\vec{v}}{dt}$: a rate of change in velocity with respect to time), while "$\sum \vec{F}$" is the Agent and "$m$" is the Inhibitor. These kinds of relationships are some of the clearest, as we can see in Knight's words: "A force applied to an object causes the object to accelerate" (Knight, 2004, p. 120). It is interesting to note that some controversy about the causal form of Newton's second law exists. Although many textbook authors readily acknowledge forces exerted on an object cause the object to accelerate, Newton's second law is frequently written in a form that contradicts that causality: $\sum \vec{F} = m\vec{a}$. Future work needs to examine whether there is indeed a student difficulty that arises from the apparently inconsistent ways in which Newton's second law is presented and understood by experts. Another example of a causal equation with the Inhibitor absent would be the first law of thermodynamics: $\Delta U = Q + W$. Here $Q$ and $W$ represent the two possible agents (heating and work) that result in the change in internal energy $\Delta U$ of the thermodynamic system.

## Implications and Future Work

Students in beginning physics courses face many challenges, but perhaps the most daunting for them is the use of equations. A substantial contributing factor to this area of student difficulty is a sense of what equations *mean*. This problem is both lexical *and* ontological in nature, and if we are to understand the ontological challenges that students face, we need to understand the grammar of physics equations. We suggest that in order to understand equations in action we need to understand how their meaning shifts as they are rewritten and manipulated. For example, a student might start out with a causal form of Newton's second law: $\vec{a} = \frac{\sum \vec{F}}{m}$ and at some later point rewrite the same equation as $F = ma$ to find the value of a particular force in order to solve a specific physics problem. In manipulating the equation this way, force has shifted grammatically (and consequently, ontologically) from being an Agent to an entity that can be determined from other physical quantities. Grammatically the equation has shifted from the material process category to being a circumstantial clause. We hypothesize that, in a way that is analogous to spoken or written language, the meaning and function of entities in an equation are constantly shifting as the equation is re-organized, and manipulated. A key part of reasoning with mathematics (Redish and Kuo, 2015), is being comfortable with these shifts, just as a native speaker of a language is comfortable turning verbs into nouns and noun into verbs in a way that is communally understood by other native speakers of that language. In short, the mark of native speakers of a language is their ability to play "fast and loose" with the lexico-grammatical interaction of that language and still engage in meaningful communication. A detailed exposition of this should be followed up upon in future work.

Educators often take the reasons for students' difficulty with equations for granted because of their experience and expertise. If educators could see how complex the meanings of common physics equations are, they could perhaps be more equipped to help students make sense of them. If we are willing to look at these equations as a part of the "language of physics," as most already do, we can treat them as clauses in this language. Halliday's Functional Grammar is a useful tool in making meaningful comparisons between different types of equations and types of clauses in English. Mapping between our proposed categories of physics equations and Halliday's transitivity system for ideational clauses works exceptionally well as a theoretical framework to understand meaning-making with equations

The theory as presented is a sketch. It has the potential to be fine-tuned with more analysis of physics textbooks, as well as deeper research in linguistics and perhaps other fields. Involving experts in other fields, such as linguists, educators, psychologists, mathematicians, and more, could be of immense benefit to the theoretical framework.

Finally, it will be necessary to devise experiments from which we can extract data to help determine the useful applications of this idea. Pedagogical strategies involving the theory must be developed and then tested, perhaps by surveying large groups of students and/or examining smaller groups working and reasoning with equations. The implementation of this theory into curriculum could be subtle, where the instructor could simply repeatedly emphasize the meanings of equations, or more overt, where the students are explicitly made aware of the equations' grammatical structure and the implicit meaning associated with that structure.

# Conceptual Analysis in Cognitive Research: Purpose, Uses, and the Need for Clarity

Alan E. O'Bryan
Arizona State University

*This theoretical paper discusses conceptual analysis of mathematical ideas relative to its place within cognitive learning theories and research studies. In particular, I highlight specific ways mathematics education research uses conceptual analysis and discuss the implications of these uses for interpreting and leveraging results to produce empirically tested learning trajectories.*

*Keywords:* Conceptual Analysis, Cognitive Research, Hypothetical Learning Trajectories

Cobb (2007) argued that mathematics education "can be productively viewed as a design science, the collective mission of which involves developing, testing, and revising conjectured designs for supporting envisioned learning processes" (p. 7). This requires that researchers' work leverages scientific methods to inform design (at the instructional, curricular, or institutional level) that positively impacts student learning.

Thus, a useful way to characterize cognitively-oriented research goals is the production of empirically tested learning trajectories that provide opportunities for students to construct ideal ways of reasoning about mathematical ideas within a coherent trajectory spanning their entire mathematical careers.[1] *Conceptual analysis* (Thompson, 2008a) plays an important role in this work, yet researchers are not always explicit about how they use conceptual analysis, nor are they clear about how conceptual analysis of an idea contributes to both the design and refinement of interventions that contribute to the broader goal of advancing knowledge in the field.

In this paper I will discuss conceptual analysis of mathematical ideas relative to its place within cognitive learning theories, highlight different ways that conceptual analysis is used in specific research studies, and explore how these uses contribute in different ways to achieving the overall goals of cognitively-oriented mathematics education research.

## The Importance of Theory in Mathematics Education Research

Conceptual analysis focuses on defining mental activity characterizing both real and epistemic individuals' meanings, and as such derives from general constructivist principles. diSessa and Cobb (2004) and Thompson (2002) both describe theoretical perspective hierarchies starting from broader background theories like Piaget's (1971) genetic epistemology to more narrow domain-specific theories that "entail the conceptual analysis of a significant disciplinary idea…with the specification of both successive patterns of reasoning and the means of supporting their emergence" (diSessa & Cobb, 2004, p. 83). Background theories serve "to constrain the types of explanations we give, to frame our conceptions of what needs explaining, and to filter what may be taken as a legitimate problem" (Thompson, 2002, p. 192). Domain-specific theories address "ways of thinking, believing, imagining, and interacting that might be propitious for students' and teachers' mathematical development" (p. 194).

That conceptual analysis originated from radical constructivism has implications for its character and purpose. A description of what it means to understand a mathematical idea should be phrased in terms that reflect a researcher's epistemology, and not in a faint or elusive way. This is why conceptual analysis, as defined by Glasersfeld (1995), Steffe & Thompson (2000),

[1] The use of "ideal" here is framed as a goal even if consensus is never reached. Refinements to improve the effectiveness and coherence of students' mathematical experiences is the manifestation of this goal in practice.

and Thompson (2008a), is a description of cognitive states and processes. Grounding conceptual analysis in descriptions of mental actions and schemes attunes us to focusing on important ways of understanding foundational ideas that influence students' abilities to construct and leverage productive images of sophisticated ideas articulated by a researcher's learning goals and *hypothetical learning trajectory* (Simon, 1995).

**Conceptual Analysis, Hypothetical Learning Trajectories, and Teaching Experiments**

Thompson (2008a) defined conceptual analysis as a description of "what students must understand when they know a particular idea in various ways" (p. 42) and outlined four uses: 1) to build models of students' thinking by analyzing observable behaviors, 2) to outline ways of knowing potentially beneficial for students' mathematical development, 3) to outline potentially problematic ways of knowing particular ideas, and 4) to analyze coherence in meanings among some set of ways of knowing. From a Piagetian-constructivist perspective, understandings are organizations of mental actions, images, and conceptual operations. Describing an understanding—either actual or intended—therefore involves specifying the mental actions, images, and operations that constitute it. Conceptual analysis provides clarity on the mental actions that characterize particular understandings, their potential origins, and their implications for subsequent mathematical learning. Conceptual analysis does not produce a list of mathematical facts or particular learning objectives. Conceptual analysis is about articulating the cognitive processes that characterize particular understandings, which serves as a basis for task design and shapes researchers' identification of students' mathematical thinking and learning. Thus, conceptual analysis is a form of theory itself—an operationalization of what diSessa and Cobb (2004) call an *orienting framework* in the context of mathematics education research.

Ellis, Ozgur, Kulow, Dogan, & Amidon (2016) joined others (e.g., Clements & Samara, 2004; Sztajn, Confrey, Wilson, & Eddington, 2012) in stressing the importance of learning trajectory research. There is no consensus definition for hypothetical learning trajectory yet. Most descriptions are refinements of Simon's (1995) original definition as "[t]he consideration of the learning goal, the learning activities, and the thinking and learning in which students might engage" (p. 133). Hypothetical learning trajectories, as indicated by their name, should be framed as hypotheses to be tested in empirical studies, which often employ the teaching experiment methodology (Steffe & Thompson, 2000). As such, each of the three components of a hypothetical learning trajectory must be clearly articulated in enough detail so that during a teaching experiment, and in retrospect, it is possible for the researcher to provide empirical support for accepting or rejecting any part of the hypothesis. A teaching experiment, as described by Steffe and Thompson (2000), is the means by which to assess and refine hypothetical learning trajectories informed by a conceptual analysis. Teaching experiments have three parts, and different uses of conceptual analysis contribute to each part in different ways (see Figure 1).

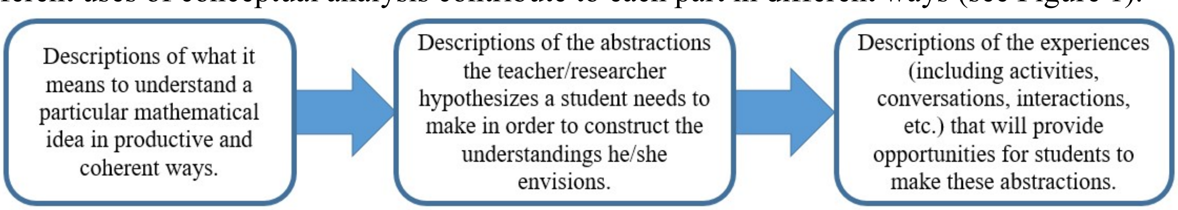

*Figure 1. Parts of a teaching experiment.*

Thinking in these terms, we can clarify how the results from different research studies contribute to the goal of creating empirically tested ideal mathematical learning trajectories.

## Examples of Different Uses of Conceptual Analyses

Since researchers' contributions to learn trajectory research depend on how they used conceptual analysis, their conceptual analyses constitute an interpretive lens to make sense of their data and indicate the specific ways that others should leverage and interpret their work. The following three examples will help to illustrate this point. Each are drawn from compelling, influential research related to the teaching and learning of exponential growth.

### Confrey and Smith's Retrospective Conceptual Analysis: Modeling Student Reasoning

Confrey (1994) and Confrey and Smith (1994, 1995) developed robust descriptions for students' images of multiplication, ratio, covariation, function, and rate based on retrospective conceptual analysis of teaching interviews. Student working through tasks like paper folding and predicting future values for an item retaining 90% of its value each year leveraged meanings for multiplication, rate of change, and function that often differed from conventional meanings. By carefully modeling students' schemes, Confrey and her colleagues described productive images that they claimed could be a powerful foundation for understanding exponential growth.

**Images of multiplication, covariation, function, rate of change, and exponential growth.** Confrey (1994) described thinking about multiplication via *splitting*. A *split* is the action of creating equal copies of an original amount or breaking an original amount into equal-sized parts. She then defined multiplication as the result of some $n$-split on an original whole and division as examining one of the equal parts of the split relative to the whole. Ratios rather than differences are then the natural means of comparison when conceptualizing splitting. Confrey and Smith (1994, 1995) described students engaging in *covariational reasoning* when coordinating splits and defined *covariation* discretely as a process of synchronizing successive values of two variables. A function relationship is then "the juxtaposition of two sequences, each of which is generated independently through a pattern of data values" (1995, p. 67) with specific function characteristics emerging from repeated actions during this coordination.

Confrey and Smith argued that students reasoning covariationally developed notions of *rate* that differed from conventional definitions. Some students coordinating arithmetic and geometric sequences to reason about exponential growth described the relationship as having a constant rate of change, meaning that thinking about rates as a ratio of additive differences is not an inevitable choice for students. They proposed defining *rate* in a way that respects students' intuitions. A *rate* is a unit per unit comparison where *unit* refers to what remains constant in a repeated action (Confrey, 1994). Thus, changes (and rates) can be conceived of additively or multiplicatively. Confrey and Smith argued that coordinating repeated addition to move through an arithmetic sequence with repeated multiplication to move through the geometric sequence and interpolating values by coordinating arithmetic means with geometric means is productive foundation for understanding exponential growth.

**Commentary.** Confrey and Smith's work modeled students' constructed schemes from empirical data and theorized about the utility of specific meanings for multiplication, covariation, function, and rate of change for understanding exponential growth. This kind of retrospective conceptual analysis is very useful for characterizing the way that some students productively reasoned about specific tasks spontaneously, including novel ways of thinking not typically emphasized in curricula. Confrey and Smith were not focused on generating detailed learning trajectories,[2] nor did they consider the implications for their specific meanings on understanding

[2] Weber (2002a, 2002b) and Ström (2008) both studied the implications of Confrey and Smith's conceptual analysis, as did Amy Ellis and her colleagues. I will say much more about Ellis et al.'s work later in this paper.

sophisticated mathematical ideas students will encounter in the future such as the Fundamental Theorem of Calculus (FTC). Their work was limited to modeling students' meanings for mathematical ideas within a fairly narrow scope of mathematical tasks and considering implications of these meanings for what they conceived as related ideas.

There are some limitations in studies using conceptual analysis in this manner, and understanding these limitations is critical to putting their results in perspective. In teaching interviews and experiments, results are always impacted by a researcher's choice of tasks and initial assumptions. For example, Confrey and Smith assumed that repeated multiplication is a useful foundation for defining exponential growth, and all of the tasks could be solved by (and perhaps encouraged) images of repeated multiplication. Since they were attuned to looking for productive ways of reasoning in these tasks, their conclusions depended on this initial assumption. Since results are influenced by the researchers' initial assumptions and task selection, their work does not compare the relative strengths of various potential meanings and learning trajectories. That requires a different use of conceptual analysis that looks more broadly at issues of coherence in mathematical ideas at all levels, which is not what Confrey and Smith sought to achieve. Scientific and mathematical progress throughout history is almost entirely a story about breakthroughs in understanding that defy human expectations and intuition. Thus, we should expect that classifying students' productive schemes for an idea will give us powerful insights into how individuals construct internally coherent schemes but not necessarily uncover ideal meanings we may want students to construct.

**Thompson's Conceptual Analysis: Coherence of Mathematical Ideas Leading to Calculus**

Thompson's (1994a) unpacking of the key ideas in calculus, particularly the FTC, motivated and informed his conceptual analysis for exponential growth (Thompson, 2008a). Thompson imagined a broadly coherent trajectory for students' mathematical experiences focused on quantitative reasoning, covariational reasoning, and representational equivalence that could unite most topics from grade school mathematics through calculus (Thompson, 2008b). Thus, his conceptual analysis considers exponential functions as just one of many opportunities for students to develop and apply particular ways of thinking.

**Quantitative and covariational reasoning, rate of change, accumulation, and the FTC.** Thompson's meanings for covariation, function, and rate of change are different from Confrey and Smith's because his goals are different. His work is grounded in *quantitative reasoning*, which describes conceptualizing a situation to form a quantitative structure that organizes relevant *quantities* (measureable attributes) and *quantitative operations* (new quantities representing a relationship between other quantities) (Thompson, 1988, 1990, 1993, 1994b, 2011, 2012). If someone sees a situation as composed of quantities that change together and attempts to coordinate their variation, then she is engaging in *covariational reasoning* (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Saldanha & Thompson, 1998; Thompson & Carlson, 2017). Sophisticated covariational reasoning involves linking two continuously varying quantities to create a *multiplicative object*, a unification that combines the attributes of both quantities simultaneously (Saldanha & Thompson, 1998; Thompson, 2011; Thompson & Carlson, 2017).

Thompson (1994a, 1994b) and Thompson and Thompson (1992) outline an image of constant rate as a proportional correspondence of two smoothly covarying quantities. When one quantity's magnitude changes by *any* amount, the other quantity's magnitude changes proportionally. This was Newton's image of rate that allowed him to conceptualize the relationship between accumulation and rate of change expressed formally in the FTC (Thompson, 1994a, 2008a). Over small intervals, he imagined that any two covarying quantities change together in a proportional correspondence. This can be modeled by a piecewise constant rate of change function and its corresponding piecewise linear accumulation function. The FTC describes how these two functions are related as the interval sizes tend to zero. See Figure 2.

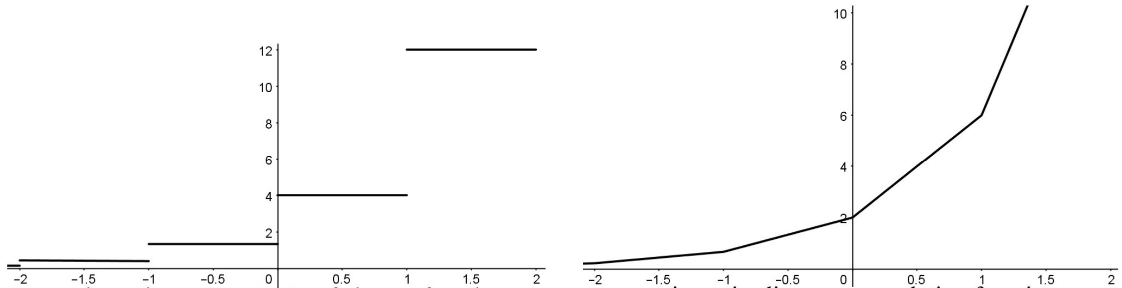

*Figure 2. Piecewise linear accumulation function and piecewise constant rate of change function.*

**Exponential functions.** Building from his images of constant rate of change and the FTC, Thompson's (2008a) conceptual analysis involved thinking about classifying functions based on similarities in their rate of change functions and imagining a function as emerging through accumulation. Specific to exponential functions, he conceptualized a relationship with a rate of change on some interval that is always proportional to the function value at the beginning of the interval. As the interval size decreases, the piecewise linear accumulation function converges to an exponential function. Thompson (1994a, 2008a) argued that this way of understanding allows a person to conceptualize both change and accumulation as happening simultaneously, makes it natural to imagine the function value growing continuously and producing outputs for all real number inputs, is consistent with a coherent way of reasoning about all function relationships, and leads to a productive operational understanding of the FTC.

**Commentary.** Much like Confrey and Smith, Thompson's work is not a detailed hypothetical learning trajectory.[3] Thompson's conceptual analysis is part of a broader, idealized web of ideas stretching from students' first mathematical experiences through calculus. It does not consider students' actual mathematical background experiences in modern classrooms, the cognitive load it places on students, or whether the ideas reasonably coincide with common ways students may attempt to spontaneously reason about tasks. It also depends on a different meaning for function relationships, how functions are categorized, and the foundational criterion for a relationship to be exponential. In Thompson's conceptual analysis, exponential growth is related to repeated multiplication almost by coincidence and is not the foundational meaning.

### Ellis and Colleagues: From Exploratory to Hypothetical Learning Trajectory

Ellis and her colleagues (Ellis, Ozgur, Kulow, Williams, & Amidon, 2012, 2015; Ellis et al., 2016) mostly leveraged Confrey and Smith's images of covariation, rate, and exponential growth to construct a rough exploratory learning trajectory surrounding a single context. Ellis et al. extended and clarified how Confrey and Smith's ideas might productively support students' understanding of exponential relationships and chose a situation where they conjectured students could easily justify that the function's domain and range were not restricted to a set of discrete values. They built a Geogebra applet showing the image of a plant (the Jactus) with a height that varied exponentially with elapsed time. The applet's user can vary the elapsed time by sliding the plant along the horizontal axis and its height would update in real time. The applet also displays the time elapsed and the plant's height as an ordered pair as the user slides the plant horizontally.

[3] Castillo-Garsow (2010) did produce a learning trajectory and empirical study based on this conceptual analysis.

In designing their study, Ellis et al. anticipated, and later confirmed, that students' initial models for exponentiation involved an informal image of repeated multiplication. Ellis et al. wanted students to leverage covariational reasoning to build a more robust image of exponential growth focused on coordinating multiplicative changes in one quantity with additive changes in another quantity. With this understanding, students might understand $b^x$ as both the possible height of a plant at some moment in time and as representation of a (multiplicative) change in height. Students working through the activities exhibited key shifts in their thinking reflecting increased attention to how the two quantities changed together over intervals of varying size. "[These] results…offer a proof of concept that even with their relative lack of algebraic sophistication, middle school students can engage in an impressive degree of coordination of co-varying quantities when exploring exponential growth" (Ellis et al., 2012, p. 110).

**Commentary.** Ellis et al. used conceptual analysis in three ways. First, they further unpacked Confrey and Smith's conceptual analysis of exponential growth as students might construct it from images of coordinating additive and multiplicative changes. Second, they continuously modified and updated their exploratory learning trajectory and tasks throughout the study based on models of students' schemes. These analyses, coupled with retrospective analysis on the empirical data, allowed them to craft highly detailed descriptions of students' meanings at various points in time and how those meanings developed through interactions with tasks and teaching interventions (Ellis et al., 2016). The result is the foundation for a powerful hypothetical learning trajectory. Ellis et al. now have empirical grounding for theories on how students may come to construct specific meanings related to exponential growth and related ideas. The refinements from the exploratory research and their model for how students construct specific meanings in specific contexts is now a fully realized hypothesis for systematic testing.

Ellis et al.'s work is an impressive example of critical work in developing empirically tested learning trajectories and demonstrates how initial exploratory work in developing an understanding of students' scheme construction, like the work of Confrey and Smith, can be refined and expanded to contribute to important work on learning trajectories. However, as they note, "Our learning trajectory is an attempt to characterize the nature of the evolution of students' thinking in a particular instructional setting" (2016, p. 153) and is thus only one of many possible learning trajectories. Like Confrey and Smith, their work assumes that repeated multiplication is the starting point from which to develop an understanding of exponential growth. In fact, the initial activities in their exploratory learning trajectory encouraged and then attempted to modify this reasoning. Their work does not extend to considering the long-term implications for students who develop their intended meanings compared to students with other potential meanings for exponential growth, nor does it (as of yet) seek to explain persistent challenges students encountered. This was not the role of the described study but does describe critical future research.

## Summary and Theoretical Implications

A teaching experiment is a method of testing a research hypothesis (a carefully detailed hypothetical learning trajectory) informed by conceptual analysis that analyzes the degree to which (and aspects of) tasks and interactions that promoted specific abstractions. None of the research studies described in this paper satisfy these criteria of a formal teaching experiment because the empirical work, when present, was more exploratory in nature. However, each of them contribute to the goals of cognitively-oriented mathematics education research in powerful ways. Confrey and Smith described students' schemes related to repeated multiplication based on spontaneous reasoning about particular mathematical tasks. Ellis et al. further unpacked these schemes and, based on retrospective analysis of empirical data, produced a well-defined hypothetical learning trajectory for specific meanings using specific tasks that now has the clarity and specificity necessary to be a scientific hypothesis. Thompson's work takes a broader view and suggests ways of understanding exponential growth situated within a coherent body of mathematical ideas extending beyond a single topic.

Currently there is no consensus on the exact meaning of a hypothetical learning trajectory. Ellis et al. (2016) have an excellent literature review detailing the different interpretations. In addition, reflecting on their work suggests that the field may benefit from greater clarity in defining different types of learning trajectories with the definitions influenced by the role of conceptual analysis. A potential starting point is given below.

- *Exploratory learning trajectory* – Conceptual analysis (either based on a researcher's analysis of mathematical ideas or based on empirical data) can suggest potentially useful ways of understanding particular ideas. A researcher then creates tasks and a rough exploratory trajectory for gathering empirical data on how students reason about specific contexts in specific settings. Since the enacted learning trajectory is continually modified based on modeling students' emerging meanings, this is not yet a scientific hypothesis.
- *Enacted learning trajectory* – An actual learning trajectory unfolded based on the exploratory learning trajectory. Conceptual analysis is used retrospectively to describe how students' schemes changed as a result of their mathematical activity.
- *Hypothetical learning trajectory* – This describes a specifically stated research hypothesis outlining specific targeted mental actions and schemes, specific tasks and a task sequence, and descriptions of how those tasks will contribute to students accommodating their schemes. The teaching experiment that tests this hypothetical learning trajectory seeks to accept or reject particular aspects of the hypothesis, and will ultimately result in refinement. Conceptual analysis is critical to the design of the learning trajectory and retrospectively in analyzing outcomes in the more formal teaching experiment.
- *Empirically supported learning trajectory* – After potentially several rounds of refinement and testing with hypothetical learning trajectories, a researcher can articulate an empirically supported learning trajectory. In comparing the results and implications of competing empirically supported learning trajectories, researchers can move closer to a learning trajectory that supports the development of ideal ways of understanding.

Any of these learning trajectories could be narrow in scope (focused on a particular mathematical idea) or grand in scope (focused on students' learning as an arc from grade school through graduate level mathematics). Researchers' questions of interest and how they use conceptual analysis dictate the type of learning trajectory they are developing and studying, and the scope of their work dictates their contribution to the field from models of students' schemes relative to particular ideas to coherent mathematical experiences across many topics and grade levels.

As researchers, we are obligated to not only produce scientifically-valid findings but also to communicate our work in ways that allow others to leverage our results to advance the collective mission of our design science. Being more explicit about the role of conceptual analysis in our work and having greater clarity on how our learning trajectory research contributes to design research can help us achieve this. I hope that my articulation of how different uses of conceptual analysis are relevant to developing different kinds of learning trajectories facilitates relevant and productive communication among cognitively-oriented, qualitative mathematics education researchers.

*In recent years "Computational thinking" has become a trending topic among teachers who have seen their curricula include the term, and researchers who seek to pinpoint both what it means and how it can be implemented in a meaningful way in classrooms. We see a crucial need in mathematics education to understand how students could be empowered to participate in the computational thinking that is now becoming an integral part of the mathematics and broader community. In our research, we are interested in examining how university mathematics students may come to appropriate programming and engage in computational thinking for mathematics, as mathematicians would do. In this paper, we present the theoretical framework that grounds our research.*

*Keywords:* computational thinking, instrumental genesis, programming, third pillar of scientific inquiry, undergraduate mathematics

## Introduction

Before the advent of the personal computer, Papert (1971) envisioned a world in which children fluently program computers, using them as a tool to act as young mathematicians. Nearly half a century later, we've witnessed a widespread resurgence of interest in that vision, manifested in educational reforms (e.g., in Europe: Bocconi, Chioccariello, Dettori, Ferrari, & Engelhardt, 2016) and research regimes (e.g., Computational Thinking in Mathematics Education, n.d.) in the name of computational thinking, which now is deemed a 21st century skill. We see a crucial need to understand how students can be empowered to participate in such computational thinking that has become an integral part of the mathematics and broader community.

This paper focuses on the theoretical framework that grounds our recently launched 5-year study, funded by the Canadian Social Sciences and Humanities Research Council (SSHRC), that seeks to examine how postsecondary mathematics students learn to use programming as a computational thinking instrument for mathematics. It is a naturalistic study that takes place in a sequence of three programming-based mathematics courses implemented in the mathematics department at Brock University (Canada) since 2001, where undergraduate mathematics majors and future mathematics teachers learn to design, program, and use interactive computer environments to investigate mathematics conjectures, concepts, theorems, or real-world applications (Buteau, Muller, & Ralph, 2015; Muller, Buteau, Ralph, & Mgombelo, 2009). The objectives of our research include: (a) describing students' instrumental geneses of using programming as a computational thinking instrument for mathematics; (b) exploring whether or not students appropriated it and, if so, have sustained it beyond course requirements; and (c) identifying how instructors create a learning environment to support students' instrumental geneses. This study builds on our past and ongoing research (e.g., Buteau & Muller, 2014; Buteau, Muller, & Marshall, 2015; Buteau, Muller, Marshall, Sacristán, & Mgombelo, 2016).

## Proposed Theoretical Framework

We start by discussing computational thinking and programming from a broad perspective based on the work of Wing (2008) and others. We then turn our attention to computational thinking in mathematics portrayed by mathematicians' research practices—for example, as stated by the European Mathematical Society (2011). This leads to a discussion of computational thinking in mathematics education, which in turn is informed by the work of Weintrop et al. (2016) and the constructionist paradigm (Papert and Harel, 1991). Next, we elaborate on our view of learning mathematics by engaging in computational thinking drawing on some ideas from the work of Lave and Wenger (1991). Finally, we discuss Guin and Trouche's (1999) instrumental approach framework to inform our understanding of technology integration in mathematics teaching and learning.

**Computational Thinking**

Wing (2014) describes computational thinking as "the thought processes involved in formulating a problem and expressing its solution(s) in such a way that a computer—human or machine—can effectively carry out" (para. 5). Thus, computational thinking is an underlying process to computer programming. And as Grover and Pea (2013) state, computer programming "is not only a fundamental skill of [computer science] and a key tool for supporting the cognitive tasks involved in [computational thinking] but a demonstration of computational competencies as well" (p. 40). Wing (2008) explains that "the essence of computational thinking is abstraction" (p. 3717) and elaborates:

> Computational thinking is a kind of analytical thinking. It shares with mathematical thinking in the general ways in which we might approach solving a problem. It shares with engineering thinking in the general ways in which we might approach designing and evaluating a large, complex system that operates within the constraints of the real world. It shares with scientific thinking in the general ways in which we might approach understanding computability, intelligence, the mind and human behaviour. (p. 3717)

The relationship of computer programming and computational thinking with mathematical and scientific thinking and learning has been recognized since the development of the Logo programming language (cf., Papert, 1980a; Feurzeig & Lukas, 1972). This relationship is also highlighted in Brennan and Resnick's (2012) proposed three-dimensional framework characterizing "computational thinking" in terms of

> *computational concepts* (the concepts designers engage with as they program, such as iteration, parallelism, etc.), *computational practices* (the practices designers develop as they engage with the concepts, such as debugging projects or remixing others' work), and *computational perspectives* (the perspectives designers form about the world around them and about themselves). (p. 1)

In the following sections we discuss computational thinking in mathematics and computational thinking in mathematics education.

**Computational Thinking in Mathematics**

In terms of the development of mathematics itself, the European Mathematical Society (2011) recognized an emerging way of engaging in mathematical research: "Together with theory and experimentation, a third pillar of scientific inquiry of complex systems has emerged in the form of a combination of modeling, simulation, optimization and visualization" (p. 2). The notion of a third pillar had been raised previously in a 2005 report by the United States' President' Information Technology Advisory Committee (2005) highlighting the role of digital technology: "Together with theory and experimentation, computational science now constitutes the 'third pillar' of scientific inquiry, enabling researchers to build and test models of complex phenomena" (p. 1). In 2016, mathematicians who led a 6-month long thematic semester on *Computational Mathematics in Emerging Applications* at the Centre de recherches mathématiques (CRM) in Montreal (Canada) indicated that:

> A fundamental change is taking place in the role of applied and computational mathematics. The relationship between the modelling, analysis, and solution of mathematical problems in applications has changed. … In emerging applications, the choice of models goes hand in hand with the computational tools and the mathematical analysis. (CRM, 2016, para. 1)

These emerging practices in mathematics research, we argue, fall under the umbrella of computational thinking for mathematics and are grounded on programming technology. Indeed, Weintrop et al.'s (2016) taxonomy (see Figure 1) gives insights into the computational thinking engagement by mathematicians and scientists, which encompasses the activities described by the European Mathematical Society (2011) and by the organizers of the computational mathematics session at CRM. Weintrop et al.'s work was based on an extensive literature review, an analysis of mathematics and science learning activities, and interviews with "biochemists, physicists, material engineers, astrophysicists, computer scientists, and biomedical engineers" (p. 134); the authors also outline what they believe to be the integral computational thinking practices for mathematics and science. Broley, Buteau, and Muller (2017) exemplified, through concrete research of mathematicians' work, the different forms of integral computational thinking practices proposed by Weintrop et al.

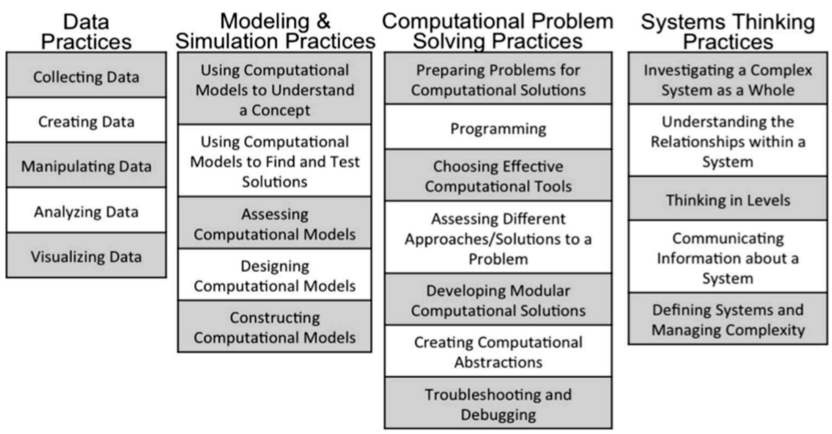

*Figure 1*. Taxonomy of computational thinking in mathematics and science (Weintrop et al., 2016, p. 135).

Adopting Brennan and Resnick's (2012) framework in the context of mathematics, the work of Weintrop et al. (2016) not only provides discipline-specific details for the computational practices dimension, but also foregrounds computational perspectives—that is, perspectives the mathematicians have come to recently develop about mathematics as a discipline "in line with the increasingly computational nature of modern science and mathematics" (Weintrop et al., 2016, p. 127).

**Computational Thinking in Mathematics Education**

Furthermore Weintrop et al. (2016) argue that "the varied and applied use of computational thinking by experts in the field provides a roadmap for what computational thinking instruction should include in the classroom" (p. 128). Their detailed taxonomy thus provides us with what it means, in the mathematics classroom, to engage in computational thinking for mathematics as mathematicians would do.

As mentioned earlier, computational thinking in mathematics education has a legacy of over 45 years in the Logo programming language and in the theory of constructionism (Papert & Harel, 1991). The fundamental premise of the constructionist paradigm is to create student-centered learning situations for students to consciously engage in constructing (e.g., program) shareable, tangible objects, through meaningful —usually computer-based– projects: “People construct new knowledge with particular effectiveness when they are engaged in constructing personally meaningful products ... [that is] something meaningful to themselves and to others around them” (Kafai & Resnick, 1996, p. 214).

Studies of constructionism at higher-level mathematics education show how programming supports students’ understanding of mathematical concepts (e.g., Leron & Dubinsky, 1995; Wilensky, 1995) and how it contributes to the development of critical thinking skills (e.g., Abrahamson, Berland, Shapiro, Unterman, & Wilensky, 2004; Marshall, 2012). In fact, Noss and Hoyles (1996) stress that a learner, when engaging in modifying a program, articulates relationships between concepts involved in a microworld “and it is in this process of articulation that a learner can create mathematics and simultaneously reveal this act of creation to an observer” (p. 54). In our work we concur with the constructionism approach for classroom implementation of programming and the computational thinking that it involves, and conceive mathematical learning by drawing from ideas found in situated learning theory, as described next.

**Learning Mathematics by Engaging in Computational Thinking**

Our view of learning draws from Lave and Wenger’s (1991) work on communities of practice. Hoadley (2012) points that two definitions of community of practice stem from Lave and Wenger’s work: (i) a feature based definition that derives from the words themselves meaning a community that shares practices and (ii) a process based definition which focuses on the process of learning whereby communities of practice are seen as groups in which a constant process of “legitimate peripheral participation” takes place. In our work, we rely on the process-based definition. Lave and Wenger use the concept of legitimate peripheral participation to describe how learners enter a community and gradually take up its practices. We use this idea of legitimate peripheral participation to understand how students learn mathematics through computational thinking. “Mathematics” is not seen as a body of knowledge to be acquired by the student, but rather as a process of participation through which the student gradually gains membership to a community (of mathematicians). Also, we do not see computational thinking from a cognitive point of view (e.g., seeing a computer as an interactive learning tool in illustrating concepts). Instead, we focus on how students create and use computer tools to engage in opportunities to participate peripherally in practices considered to be integral to the mathematical community as outlined by Weintrop et al. (2016). In other words, we focus on how students (newcomers) engage in computational thinking for mathematics as mathematicians (elders) would do.

This view on learning concords with the constructionism paradigm. Papert (1971) argued that “being a mathematician, … like being a poet, or a composer or an engineer, means *doing*, rather than knowing or understanding” (p.1), and that through programming mathematics, learners engage in “computational mathematics” (p.25) through which they mathematize. For Papert (1980b), the computer provides the learner a means for constructing “objects to think with” and “allow[s] a human learner to exercise particular powerful ideas or intellectual skills” (p.204) through exploration and discovery in a knowledge domain. This resonates with how many mathematicians and scientists use the computer in the 21$^{st}$ Century as described earlier.

The work by Broley et al. (2017), cited earlier, exemplifies how undergraduate students learned mathematics through the construction of interactive computational objects (i.e., ‘objects to think with’), and how these practices align with those of working mathematicians: for example, a first-year undergraduate’s engagement in computational problem-solving practices –where she had to design, program, and use an interactive environment to explore, graphically and numerically, the behavior of a dynamical system based on a two-parameter cubic– shared similarities with a mathematician’s engagement in his research on permutation of subsequences (see Figure 2).

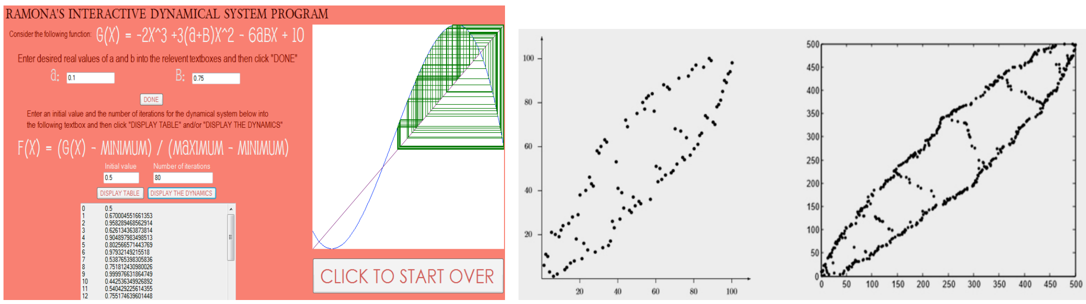

*Figure 2*. Examples of computational problem-solving practices. Left: screenshot of an undergraduate’s exploratory work of a dynamical system. Right: screenshot of a mathematician’s exploratory work on a permutation structure (Broley et al., 2017, pp. 4, 6).

When students become proficient at using programming to engage in computational thinking for mathematics “as mathematicians would do” (i.e., engaging in the computational practices as well as taking on the computational perspectives similar to how a mathematician would do), we consider that this technology has been integrated or that appropriation has occurred. We now turn to discussing this and how it can be assessed.

**Students’ Appropriation of Programming as a Computational Thinking Instrument**

Cook, Smagorinsky, Fry, Konopak, and Moore (2002) explain that appropriation is a developmental process involving socially formulated, goal-directed, and tool-mediated actions through which learners actively adopt (i.e., what we could call “make their own”) conceptual and practical tools, thus internalizing ways of thinking related to specific settings in which learning takes place. The instrumental approach (Rabardel, 1995/2002) is a useful framework for analyzing technological integration (Artigue, 2002; Guin & Trouche 1999) and gaining insights into how students appropriate a (technological) tool, and such an approach is used increasingly at the university level (cf., Gueude, Buteau, Mesa, & Misfeld, 2014).

The instrumental approach describes how artifacts (whether material or symbolic) are appropriated when they are transformed into instruments through schemes of usage and action by what is called *instrumental genesis* (Artigue, 2002). Trouche and Drijvers (2010) suggest that an instrument has been appropriated when a “meaningful relationship exists between the artifact and the user for a specific type of task” (p. 673). Thus, in order to assess the appropriation and technological integration, it is necessary to look at the instrumental genesis, by looking at both the artifact and its attached schemes. One way to do so is to look at the traces that students leave in their activity and what they do with an artifact (Trouche 2004). Parallel to this, it is also necessary to take into account the teacher’s activity: his/her conceptions, design, and orchestrations of the teaching resources (Trouche, 2004) and the *instrumental integration*, which is "how teachers organise the conditions for instrumental genesis of the technology proposed to the students and to what extent (s)he fosters mathematics learning through instrumental genesis" (Goos & Soury-Lavergne, 2010, p. 313). Instrumental integration describes four stages of growing technology use in the classroom (Assude, 2007): (a) instrumental initiation (stage 1)—students engage only in learning how to use the technology; (b) instrumental exploration (stage 2)—mathematics problems motivate students to further learn to use the technology; (c) instrumental reinforcement (stage 3)—students solve mathematics problems with the technology, but must extend their technology skills; and (d) instrumental symbiosis (stage 4)—students' fluency with technology scaffolds the mathematical task resulting in an improvement of both the students' technology skills and their mathematical understanding.

We associate these stages to a student's computational thinking development dimensions from Brennan and Resnick's (2012) framework: stages 1 and 2 to computational concepts, stages 2 to 4 to computational practices, and stages 3 and 4 to computational perspectives. And it is in stage 4 where we argue that the student has appropriated programming as an instrument for mathematics "as mathematicians would do" (both in terms of computational practices and perspectives) as mentioned in the previous section, which we term "programming as a computational thinking instrument for mathematics."

## Next Steps for the Research

In this paper, we presented the theoretical framework underlying our study focused on how undergraduate mathematics students come to appropriate programming as a computational thinking instrument for mathematics. Brennan and Resnick (2012) suggest ways of assessing computational thinking development, including project portfolio analysis and interviews. Accordingly, in our research we will collect student participants' programming-based mathematics projects (14 in total over the three courses) together with their corresponding reflective journals, and students' lab reflections. We will also conduct semi-structured individual interviews with each of the participants in order to gain insights into students' creation process (including decision-making) and traces of their ongoing work. This is planned for two cohorts of 10 students each, followed over 3 consecutive years. Final interviews and questionnaires will be used at the end of the participants' 4- or 5-year program studies, to examine the sustainability of their programming use. Aligned with Trouche's (2004) recommendation, semi-structured interviews with course instructors, field notes of computer lab session observations, as well as course material will provide insights into the instructors' didactical aims and participants' learning environment. The latter data will also shed light on the instructors' pedagogical decisions and to what extent these are in accordance with the constructionist paradigm.

# Scaling-Continuous Variation: A Productive Foundation for Calculus Reasoning

Robert Ely
University of Idaho

Amy Ellis
University of Georgia

*This paper introduces a new mode of variational and covariational reasoning, called scaling-continuous reasoning. Scaling-continuous reasoning builds on Leibniz' ideas of increments and infinitesimals and does not rely on images of motion. Instead, it entails (a) imagining a variable taking on all values on the continuum at any scale, (b) understanding that there is no scale at which the continuum becomes discrete, and (c) re-scaling to any arbitrarily small increment for x and coordinating that scaling with associated values for y. We present one clarifying example of this type of reasoning and argue that scaling-continuous reasoning can support a robust understanding of foundational ideas for calculus, including rates of change, differentiation, and the definite integral.*

*Keywords:* covariation, rate of change, infinitesimal

*A curved line may be regarded as being made up of infinitely small straight-line segments.*
– The Marquis de L'Hôpital, 1696

*When I think of a curve, I think of a bunch of really tiny lines.*
– Wesley, research participant

## Introduction

Researchers argue that continuous covariational reasoning is critical for students' development of a robust understanding of function, rates of change, and the foundational ideas of calculus (e.g., Carlson et al., 2003; Kaput, 1994; Thompson & Carlson, 2017). Further, students need opportunities to reason covariationally throughout their K-12 schooling in order to be positioned to make meaningful sense of introductory calculus courses at the undergraduate level. Thompson and Carlson (2017) emphasize, in particular, the importance of smooth continuous reasoning, while also acknowledging the challenges in supporting students' ideas of smoothness. In response to these challenges, we introduce a new mode of reasoning, *scaling-continuous variation / covariation*. Building on Leibniz' notion of infinitesimal increments, scaling-continuous reasoning entails an image of the continuum as infinitely zoomable, coupled with the understanding that one can re-scale to any arbitrarily small increment for *x* and coordinate that scaling with associated values for *y*. We argue that this mode of reasoning can support productive ways of thinking about key calculus ideas, including varying and instantaneous rates of change, limit and differentiation, and the definite integral.

## Background: Variation and Covariation as Foundational Ideas for Calculus

Developing a conception of quantities' values varying continuously – and consequently understanding functions as processes of covariation – is central to the emergence of calculus understanding (e.g., Carlson et al., 2003; Kaput, 1994; Rasmussen, 2000; Thompson & Carlson, 2017; Zandieh, 2000). Research suggests that students both enter and emerge from freshman calculus courses with a weak understanding of the function concept, struggling to conceptualize a function as a mapping, to use functions to model dynamic situations, and to develop robust understandings of varying and instantaneous rates of change (Breidenbach et al., 1992; Carlson, 1998; Carlson et al., 2002; Dubinsky & Harel, 1992; Monk & Nemirovsky, 1994; Thompson, 1994). One factor contributing to these difficulties is the lack of emphasis on variation in secondary mathematics; students typically do not have access to exploring functions as a way to measure variation before calculus (Cooney & Wilson, 1996; Ellis, 2011; Roschelle, Kaput, & Stroup, 2000; Thompson & Carlson, 2017; White & Mitchelmore, 1996). Thompson and Carlson (2017) argue that continuous covariational reasoning is epistemologically necessary for students to develop the foundational ideas of calculus, and moreover, students are unlikely to succeed in calculus without this foundation already in place. Students must therefore build ideas of continuous variation in secondary school in order to develop the ways of thinking necessary for meaningful calculus learning at the undergraduate level.

Researchers have addressed covariational reasoning in a variety of ways, but for the purposes of this paper we focus on work that considers the imagistic foundations that can support students' abilities to think covariationally (e.g., Castillo-Garsow, 2012; 2013; Saldanha & Thompson, 1998; Thompson, 1994; Thompson & Carlson, 2017; Thompson & Thompson, 1992). These researchers describe covariational thinking as the act of holding in mind a sustained image of two quantities' values varying simultaneously; students imagine how one quantity's value changes while imagining changes in the other. A person thinking covariationally can couple two quantities in order to form a multiplicative object (Thompson & Saldanha, 2003), subsequently tracking either quantity's value with the immediate understanding that the other quantity also has a value at every instance (Saldhanha & Thompson, 1998).

Castillo-Garsow (2012; 2013) distinguished between two types of continuous variation, which he termed chunky and smooth; Thompson and Carlson (2017) subsequently built on these distinctions to create a covariational reasoning framework. Chunky continuous variation is similar to thinking about values varying discretely, except that one has a tacit image of a continuum between successive values. This image entails intermediate values without imagining the quantity actually taking on those values (Thompson & Carlson, 2017). Instead, one imagines change occurring in completed chunks, without imagining that variation occurs within the chunk. In contrast, smooth continuous variation entails an image of a quantity changing in the present tense; one can imagine a value varying as its magnitude increases in bits while simultaneously anticipating smooth variation within each bit (Thompson & Carlson, 2017). An image of a quantity's value varying from $a_1$ to $a_2$, one will also include an image of that value passing through all intermediate measures between $a_1$ and $a_2$.

Thompson & Carlson (2017) emphasize Castillo-Garsow and colleagues' point that smooth variational thinking requires thinking about motion (Castillo-Garsow, 2012; Castillo-Garsow, Johnson, & Moore, 2013). They note that this argument "is reminiscent of Newton's description of fluents – the flowing quantities that were at the root of his calculus" (Thompson & Carlson, 2017, p. 430). Further, they point to the importance of motion to smooth covariational reasoning as well, explaining that this is akin to defining a function parametrically in terms of an underlying time variable, in which a parameter is used in the sense of a variable that is not assigned to an axis in a coordinate system. They describe the act of coordinating quantities' values as similar to forming the pair $[x(t), y(t)]$, in which the parameter "$t$" represents conceptual time, which is distinguished from experiential time in that it is an image of measured duration: "We are speaking of someone imagining a quantity as having different values at different moments, and envisioning that those moments happen continuously and rhythmically" (p. 445).

Smooth-continuous reasoning, which relies on this underlying image of time-parametrization, reflects one mode of robust variational and covariational reasoning. We propose an additional mode of reasoning, which we call scaling-continuous reasoning, and suggest that scaling-continuous reasoning may be both distinct from and equally robust to smooth continuous reasoning.

## Scaling: An Alternative to Motion

Motion is an essential image for Newton's reasoning with variation and covariation. For Newton, a variable quantity was a "fluent," which depended on and changed with time. A "fluxion" was an instantaneous speed of this fluent's motion, and what we call a derivative is a ratio of two fluxions (Edwards, 1979). In contrast with Newton, G. W. Leibniz, the other inventor of calculus, seldom described variation, functions, and ideas of calculus in terms of motion. Instead, Leibniz attended to *differences* (differentiae) or *increments* between two values of a quantity, and he distinguished among types of these differences based on their relative *scales* or orders. For instance, Leibniz began with the notion of a "function[1]," an algebraic relationship between the values of a variable quantity such as $x$ and the values of another variable quantity, $y$ (Bos, 1974). Leibniz's differential calculus was then a way to derive from such a function a new equation describing the relationship between infinitesimal increments of the two quantities, $\mathrm{d}x$ and $\mathrm{d}y$. Integral calculus simply went the other way, enabling the determination of a function from a given differential equation.

Here is a brief characteristic example of Leibniz' discourse about the product rule:

> $d(xy)$ is the same as the difference between two adjacent $xy$, of which let one be $xy$, the other $(x+dx)(y+dy)$. Then $d(xy) = (x+dx)(y+dy) - xy$, or $xdy + ydx + dxdy$, and this will be equal to $xdy + ydx$ if the quantity $dxdy$ is omitted, which is infinitely small with respect to the remaining quantities, because $dx$ and $dy$ are supposedly infinitely small. (From Leibniz' *Elementa*, quoted in Bos, 1974, p. 16.)

There are several things to notice about Leibniz' ideas. Firstly, he began by creating a new variable quantity, $xy$, and then sought to derive an equation describing the *correspondence* between an infinitesimal increment of this quantity, $d(xy)$, in terms of infinitesimal increments ($dx$ and $dy$) of the other two quantities $x$ and $y$. These increments were static entities, although they were variable because their values depend upon where on the curve they are taken. Although Leibniz did not appeal to motion, he relied on an underlying image of every increment of one quantity, no matter how small, corresponding to an increment of an associated quantity. This is one of the crucial ideas entailed in continuous covariation (Thompson & Carlson, 2017).

Secondly, Leibniz dismissed the quantity $dxdy$ because it is infinitely small even in comparison to other infinitely small quantities such as $dx$ and $xdy$. Leibniz developed a scheme of orders of the infinitesimal and the infinite in order to systematize an idea of *scaling*. For instance, at the finite scale, infinitesimals such as $dy$ are negligible, but at the first-order infinitesimal scale they become significant, with second-order differences still negligible. The idea of imagining covariation and correspondence different scales was crucial to a coherent system of calculus for Leibniz. It is also part of successful formalizations of this system, such as nonstandard analysis (Keisler, 1986). The manner in which infinitesimal differences in the continuum become significant at different scales is illustrated by Keisler's image of a

[1] It appears that Leibniz actually coined this term. His usage differs from our modern idea in that this relationship need not be uni-valued, but must be represented algebraically.

microscope with an infinite scale factor (Figure 1).

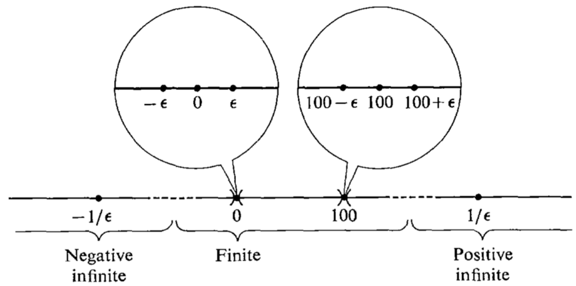

*Figure 1: Infinite microscope on the continuum reveals infinitesimal increments (Keisler, 1986)*

It is also notable that Leibniz' sense of variation, although not explicitly illustrated in the quote above, contained *no atomic level* of scaling. One may imagine zooming in on the continuum to smaller and smaller increments. Regardless of how far one scales, even zooming in by higher orders of infinity, at no level will the continuum ever reveal itself to be discrete points.

Finally, Leibniz emphasized "that a curvilinear figure must be considered to be the same as a polygon with infinitely many sides" (1684, p. 126). It is not that the curve *is* such a polygon, but that it can be *treated* as one. According to Bos (1974), this idea reflects the close relationship between Leibniz' idea of variation and of the infinitesimal, in which successive terms of sequences have infinitely small differences. Thus, "the conception of a variable and the conception of a sequence of infinitely close values of that variable, come to coincide" (p. 16).

## Scaling-Continuous Variation and Covariation

With Leibniz' reasoning in mind, we propose a new category for variational and covariational reasoning that is distinct from the smooth-continuous category, but yet plausibly just as robust for supporting coherent and powerful reasoning with continuous quantities, functions, and rates of change. We call this category *scaling-continuous* for variational and covariational reasoning. Scaling-continuous reasoning entails the following:

1) *Variation*: Imagining that at any scale, the continuum is still a continuum and a variable takes on all values on the continuum. There is no scale at which the continuum is discrete or one reaches a point. One can conceive of the continuum as infinitely "zoomable", in which the process of zooming will never reveal any holes or atoms.
2) *Covariation*: Conceiving of a re-scale or "zoom" into any arbitrarily small increment for $x$ and coordinating that scaling with associated values for $y$. One can imagine a window of $x$-values growing or shrinking, and the window of $y$-values simultaneously growing/shrinking, as a correspondence between increments of $x$ and $y$.
3) This way of thinking does not fundamentally rely on an image of motion or an underlying time parameter.

Scaling-continuous reasoning reflects only one aspect of Leibniz' way of thinking about calculus. We do not treat it as necessarily entailing Leibniz' other ideas; for instance, it does not explicitly entail any particular conception about the infinite or the infinitesimal. It is possible to appeal to the image of scaling or zooming to discern or to describe covariation at different levels, without also having encapsulated an image of an infinite scale factor revealing infinitesimal increments. This latter image would require another cognitive act beyond just employing scaling-continuous reasoning. Although Bos (1974) points out that for Leibniz the idea of infinitesimal and variable are closely wed, we do not wish to presume them wed, a priori, for students who are in the process of developing covariational reasoning.

## An Example: Wesley's Scaling-Continuous Reasoning

Here we introduce an episode from a teaching experiment in which the second author worked with two students who reasoned about constant and varying rates of change. One of the students, Wesley[2], communicated ideas consistent with scaling-continuous reasoning. Because this is a theoretical report, we present the following only as a motivating and clarifying example. We use as a guideline that new theoretical work should emerge through encounters with research episodes, and it was through a few key examples from students at both the secondary and undergraduate levels that we developed the theoretical category of scaling-continuous reasoning. We chose this excerpt with Wesley, a secondary student, because his descriptions of scaling-continuous ideas were both spontaneous and clearly articulated.

One aim of the teaching experiment was to introduce contexts in which students could explore situations that, to us, entailed two continuously covarying quantities. The students investigated linear, quadratic, cubic, and higher-order polynomial functions in settings emphasizing rates of change. The following episode was the result of a task in which a triangle dynamically swept out from left to right (Figure 2); students observed a movie of the sweeping action and then produced a sketch of the total accumulated area compared to the length swept.

It is important to note that placing students in situations that we as researchers conceive of as continuous does not guarantee that students will reason with those situations continuously. In fact, on the day prior, both students drew piecewise linear graphs. During this episode, however, the students produced graphs that they described as "smooth curves" (Figure 3). Wesley (W) explained why the graph should be curved, stating that on the prior day, his graph had looked piecewise linear because he had used big increments, but "if you add the tiny increments, like in between, then it curves out," indicating that straight segments were a vestige of a rough graphing process.

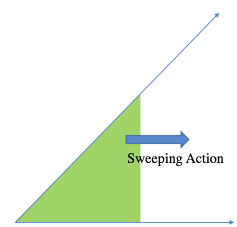

*Figure 2: A static image of the triangle's area swept from left to right*

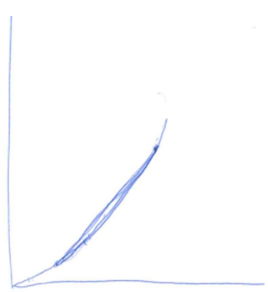

*Figure 3a*

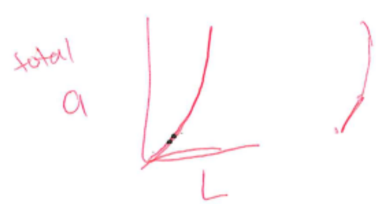

*Figure 3b*

*Figure 3: Wesley (3a) and Olivia's (3b) sketches comparing accumulated area with length swept*

To clarify, the teacher-researcher (TR) asked what the graph would look like between two points that were "super close together," marking two small black dots on Olivia's graph in Figure 3b.

[2] Gender-preserving pseudonyms were used for all participants.

Would it be curved or straight? The following dialogue ensued:

W: I think it would, like, like these two points here (his points on Figure 3) and if you add them, do them exactly it's kind of like that and it kind of goes not straight to the curve and I think it would be more of a, a little bit more of a curve.

TR: You think it'd be a curve?

W: Yeah.

TR: And how come?

W: Because, like, there's tiny points *in between* those tiny points.

TR: Ah. There's tiny points in between those tiny points. (To Olivia): Does that make sense?

O: Yeah.

TR: What if I picked two points that were so close together that I couldn't, you couldn't even like see the difference? They were just so close together there's like an infinitesimal difference in between them. Would the connection between them be a straight line or a curve still?

O: Like the tiniest ones? [TR: Mm-hm.] Then it would be a straight line.

TR: Hmm. (Turns to Wesley). What do you think?

W: I think it'd be more of a curve because I think like it goes on infinitely kind of the points. So if you zoomed in really close on those it would like look like that and then *in between those there's still more points and it goes on forever*.

TR: Hmm. (Turns to Olivia). What do you think?

O: I still think it'd be a straight line because to me it's just a whole bunch of little straight lines and so like to me it would eventually stop because you're graphing the triangle's, like, placing, and so if you like had to choose a place to graph it from each time, then you would connect the points straight like, just straight but a whole bunch of those makes a curve, you know? (She sketches the graph on the right in Figure 3a). And so, I think this or even smaller would be the straight line. The smallest one.

TR: Hmm. What do you say to that? (Turns to Wesley).

W: I think, like, because like if they're two really tiny points right here and you zoomed in a ton it would kind of look something like these two points (in Figure 3) and then *there's still like really little points in between those points*.

The above episode reveals a contrast between Wesley and Olivia's reasoning. For Olivia, the graph is composed of straight segments. The size of those segments does not seem to be absolute, but rather to depend on a choice that is made during the graphing process. The rest of the graph is made by connecting the endpoints, but she does not treat the graph locations on the straight segments as representing quantities in the same way that the endpoints do. Here, and elsewhere in the teaching experiment, Olivia does not conceptualize variation within the straight bits of her graphs. Thus, she seems to be reasoning with, at best, chunky-continuous covariation.

In contrast, Wesley's reasoning is characterized by scaling-continuous variation and covariation. He describes variation happening within bits on his graph, and on each interval he treats the quantities' values as varying continuously, taking on all possible values within the interval. Thus, he imagines the graph to be curved on every interval, no matter how small, appealing to the idea that there are points in between the "tiny points". Wesley does not appear to rely on chunky continuous reasoning, because he fluidly rescales and imagines points in between the points, at any scale, even zooming in infinitely, explaining that this can go on forever.

However, Wesley's reasoning is not smooth-continuous variation either, because he never speaks of, nor does his imagery appear to rely on, a variable moving and tracing out values as it moves. In fact, consistent throughout the teaching experiment is Wesley's lack of reference to movement. Instead his imagery entails zooming and scaling. He explains that if you take any small increment "and you zoomed in a ton" you would see variation, "and then there's still like really little points in between those points." Furthermore, Wesley is explicit that this ability to zoom in, to rescale, "goes on forever," "goes on infinitely," and never grounds out at some atomic level. This is a crucial element of scaling-continuous reasoning, that there is continuous variation at every scale and it never becomes discrete. This entails the *recursion* Thompson and Carlson describe with smooth-continuous variation: "…the person, while reasoning variationally, is alert to the *potential need* to think about smaller intervals in precisely the same way as they are thinking about the interval that is currently in their reasoning" (2017, p. 440). This recursion extends to covariational reasoning for Wesley also; the fact that he sees the graph as curved at each new level of scaling indicates that there is covariation between the two quantities even at the new scale, and that this covariation is non-constant.

## Supporting Calculus

We propose that scaling-continuous covariational reasoning may provide a robust foundation for student thinking in calculus; after all, it was instrumental in Leibniz' invention of calculus. Scaling-continuous reasoning can support an understanding of the ideas of rate of change, limit and derivative, and definite integrals, among others. For instance, Thompson & Carlson (2017) note that the idea of a function's rate of change being non-constant occurs by thinking of a function having constant rates of change over infinitesimal intervals of its argument, "but different constant rates of change over different infinitesimal intervals of the argument" (p. 452). As evidenced by Wesley's explanations, this image is a direct outcome of scaling-continuous covariation, through which one imagines zooming to an infinitesimal scale to imagine a tiny interval on which the function's rate of change is constant. Further, it can provide a foundation for developing an image of instantaneous rate of change, in which the rate of change at a point can be imagined as an average rate of change over an infinitesimal interval. This offers a natural motivation for the limit definition of the derivative.

Scaling-continuous reasoning can also support the concept of definite integral. In an undergraduate calculus course taught by the first author (Ely, 2017), students developed the idea of a definite integral as an accumulation of infinitely many infinitesimal bits of a quantity, each bit corresponding to an infinitesimal increment of the independent variable. This interpretation of definite integral, in turn, provided a robust support for meaningful modeling with integrals.

We do not suggest that smooth-continuous reasoning is unimportant for the development of key ideas about function and calculus. Indeed, we agree that it is a critical aspect of understanding the mathematics of change, including the ideas of calculus, and we support instructional efforts at all grade levels to develop conceptions of continuous covariation. Instead, we suggest that an additional form of reasoning, scaling-continuous variation / covariation, may also plausibly foster productive understandings to support learning in calculus. Given the potential for this form of reasoning to support key calculus ideas, we advocate for additional research to better understand the nature of scaling-continuous variation and covariation and its affordances for productive mathematical thinking.

*We describe the creation of a learning progression about partial derivatives that extends from lower-division multivariable calculus through upper-division physics courses for majors. This work necessitated three modifications to the definition of a learning progression as described in the literature. The first modification is the need to replace the concept of an upper anchor with concept images specific to different (sub)disciplines. The second modification is that rich interconnections between ideas is the hallmark of an expert-like concept image. The final modification is using representations in several ways to support the development of translational fluency in emerging experts. These theoretical changes are supported by examples of research and curriculum in the use of differentials in thermodynamics.*

*Keywords:* Learning progression/trajectory, partial derivatives, multiple representations, representational fluency, thermodynamics.

## Learning Progressions

Science education has recently focused on describing learning progressions (LPs) for content that spans multiple years of instruction (Duschl, Schweingruber, & Shouse, 2007; Lemke & Gonzales, 2006); a similar idea, known as a learning trajectory, has been used in mathematics education (Clements & Sarama, 2004, p. 83). Though many of the LPs described in the literature have focused on K-12 instruction, there are science topics at the university level for which a similar model may prove valuable for educators. LPs are typically characterized by a sequence of qualitatively different levels of knowledge and skills. One goal in the development of LPs is to refocus instruction from concepts that are less consequential to those that are more central to mathematics and science (Plummer, 2012). In particular, LPs are not based solely on a logical analysis of mathematics and science ideas—they are sequences that are supported by research on learners' ideas and skills.

Although the research literature includes various definitions for what constitutes a learning progression (Lemke & Gonzales, 2006; Sikorski & Hammer, 2010; Sikorski, Winters, & Hammer, 2009), the National Research Council defines a learning progression to be "the successively more sophisticated ways of thinking about a topic" (Duschl et al., 2007). The range of content addressed by an LP is defined by a lower anchor, which is grounded in the prior ideas that students bring to the classroom, and by an upper anchor, which is grounded in the knowledge and practices of experts. These anchors are identified by research on the thinking of both novices and experts. An LP hypothesizes pathways that students may follow through content, pathways that are then tested empirically (Corcoran, Mosher, & Rogat, 2009). Individual students might follow one of many such pathways, which may be influenced by a variety of factors, including the educational environment.

Some have noted limitations with learning progressions. LPs tend to place students in definite levels of sophistication, when students might in fact give different answers to different questions, making it difficult to place students on a single level. LPs also tend to identify only one scientifically correct upper anchor. We agree with the assessment of Sikorski and Hammer (2010, p.1037) that "rather than describe students as 'having' or 'not having' a particular level of knowledge" recent learning research "conceptualizes students' knowledge as manifold, context-sensitive, and coupled to and embedded in the social and physical environment." In this paper, we describe a perspective on learning progressions that embraces this manifold view of knowledge by incorporating the idea that it is a learner's *concept image* (Tall & Vinner, 1981) that progresses in a way that broadens or enriches a learner's understanding of a topic.

In the next section, we describe three implications of thinking about LPs in terms of concept images: (1) upper anchors must be generalized in a way that allows experts from different content areas to be different from each other, (2) the strength of the interconnections within an individual's concept image are indicative of expertise, and (3) the role that representations and representational fluency play in illuminating the LP must be elaborated. Then, we illustrate our suggested theoretical changes with an example from an LP we are developing on student understanding of partial derivatives, spanning the collegiate curriculum from lower-division multivariable calculus courses through upper-division physics courses in thermodynamics.

## Theoretical Additions to Learning Progressions

### Experts' Concept Images as "the" Upper Anchor

Interviews with faculty experts (Kustusch, Roundy, Dray, & Manogue, 2012, 2014; Roundy, Weber, et al., 2015) have demonstrated, for example, that physicists and engineers have several ways of reasoning about small quantities that are not shared by mathematicians. These studies, along with our own internal group discussions, have shown that the ways in which experts approach complex problems vary from person to person and from field to field—mathematics experts and physics experts are not the same! We identify the rich and varied understandings of experts with the *concept image* of Tall and Vinner (1981, p.152), *i.e.,* "the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes." Thus, we see the goal of an LP not as a definite, idealized upper anchor, but rather as a richer understanding more akin to the concept images of experts from varied fields.

### Connections as Indicative of Expertise

Hiebert and Carpenter (1992, p.67) suggest that understanding a mathematical idea requires it to be part of an internal network and that "the degree of understanding is determined by the number and strength of the internal connections." From a concept image perspective, we view a learning progression as describing the enrichment and the increased interconnectivity of a learner's concept image. As developing professionals, middle-division students need to develop such connections rapidly. Yet Browne (2002) found that middle-division students tend not to go back and forth between elements of a concept image spontaneously. To help students increase the strength of their connections, our LP emphasizes opportunities for students to translate between such elements.

Students' ability to transfer knowledge in these ways offers an important means for the empirical validation of our LP. Some of our data (Bajracharya, Emigh, & Manogue, 2017) shows that, while students readily develop a broad concept image, the separate pieces within such a concept image are not necessarily well connected. In contrast, the research discussed above indicates that experts have a rich set of tools that they can use fluently. This representational fluency is itself a key attribute of the upper anchor; achieving such fluency is one of the primary goals of our curricular materials. We regard a learning progression as leading to the enrichment of students' concept images.

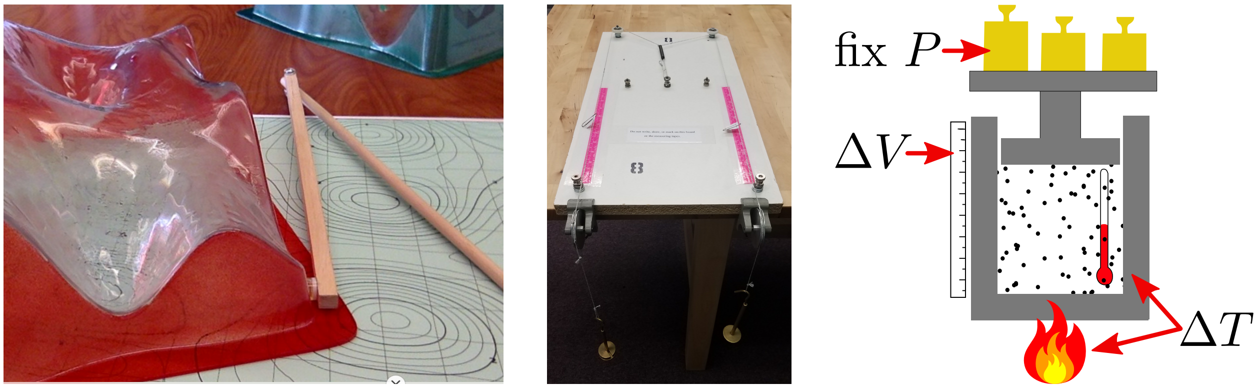
**Representations and Representational Fluency**

In addition to conceptual knowledge, an important aspect of a learner's concept image of a topic is knowledge of (external) representations, such as graphs, equations, experimental configurations, *etc*. Representations are tools that communicate information between learners and instructors, and that also aid learners with thinking and learning (Hutchins, 1995; Kirsh, 2010). Therefore, representations are centrally featured in our learning progression, both in our instruction and in our research about expert and student reasoning.

In our curriculum, we think about external representations in three ways: as languages for doing mathematics/physics, as disciplinary artifacts, and as pedagogical tools. First, we consider different types of representations to be different languages for doing mathematics and physics. For example, one might calculate a partial derivative at a given point in the domain from an equation, a table of data, or a contour plot. These three different ways of expressing a multivariable function have different features and therefore require different procedures for making the calculation. Starting with an equation requires acting on the equation with a differential operator, thereby transforming one algebraic expression into another, and then the evaluation of the new expression at the desired value in the domain. Starting with a table of discrete data requires reading off values, taking differences, and finding a ratio. In this case, it is necessary to include checks to insure that the differences come from a sufficiently linear regime, with the definition of "sufficiently" depending upon the experimental context (Dray, Gire, Manogue, & Roundy, 2017). We want students to be fluent with each of these representations, and also to be able to coordinate or move between representations. The language metaphor suggests that it should be possible for students to achieve some fluency with representations, which would be consistent with an interconnected concept image.

Second, we think of some external representations as disciplinary artifacts. We use the term artifact to emphasize that they are tools of cultural interest within the discipline. Continuing the metaphor of representations as language, these particular representations play the role of technical vocabulary. This distinction is particularly productive when a representation is commonly used in the professional community but is pedagogically problematic. We want students to be able to communicate with the broader community of mathematicians or physicists, so we make a point of introducing these representations in our instruction. For example, a physicist describing a thermal system might plot, on a single graph, data from two (or more) distinct processes. In cases where the resulting curves intersect, an expert interprets this plot as two smooth functions that describe two different experiments, but some students interpret such plots as a single function with a "cusp," and therefore a discontinuous first derivative (Emigh & Manogue, 2017). Plotting multiple experiments (functions) on a single set of axes is common in physics and physics courses but atypical in mathematics courses.

Third, we use representations as pedagogical tools. In particular, we introduce some representations for their pedagogical affordances even if they are not normative (*i.e.,* used by professionals



*(a) Surfaces* *(b) PDM* *(c) Name the experiment*

*Figure 1: Three representations with pedagogical affordances. (a) A plastic surface and matching contour map. (b) The Partial Derivative Machine (PDM), a mechanical analogue of thermodynamic systems. (c) An experiment to measure $\left(\frac{\partial V}{\partial T}\right)_p$ in which the temperature of a gas in a piston is changed using a burner, and the change in volume is measured with a ruler while the pressure is held fixed by weights on the piston.*

while doing their work). For example, professionals do not make plastic surfaces (Wangberg & Johnson, 2013) to represent functions of two variables. However, these surfaces (see Figure 1a) are useful tools for helping students understand many multivariable calculus concepts, including partial derivatives, level curves, the gradient, and line/surface/volume integrals. Similarly, the Partial Derivative Machine (Figure 1b) is a mechanical system that was invented to help students understand thermal systems because the two systems have the same underlying mathematical structure (Sherer, Kustusch, Manogue, & Roundy, 2013). However, those who study thermal systems do not use Partial Derivative Machines in their research.

## Example from a Partial Derivatives Learning Progression

In this section, we describe selected elements from a learning progression for partial derivatives that spans advanced undergraduate courses in mathematics and physics. We focus on partial derivatives because, to physicists, partial derivatives are physically meaningful quantities. We begin by describing an instructional activity that is part of our overall LP and that focuses on key elements of the concept image for partial derivatives. Then, we highlight several results from a research project that has informed our LP and has suggested new curricular changes.

### The "Name the Experiment" Instructional Activity

A typical example of a thermodynamic system is a gas in a piston (Figure 1c). Such a system has a number of physical properties that may be measured and controlled, such as temperature $T$, pressure $p$, volume $V$, and entropy $S$. These properties are not independent, as the *state* of the system (when in equilibrium) is defined by just *two* of these quantities. Each of these four quantities—as well as any other measurable property of a gas—is referred to as a *function of state*, meaning that its value is fully determined by the *state* of the system, which itself may be determined by (*i.e.,* may be a function of) any pair of state variables. Physicists denote such dependencies by algebraic statements such as $T = T(S, V)$ which is to be interpreted as "we are currently thinking of the physical temperature $T$ as depending on the physical quantities entropy $S$ and volume $V$."

We note that this notation is not identical to the function notation commonly taught and used in mathematics.

When encountering partial derivatives in thermodynamics, students have difficulty understanding the significance of the quantity that is being held fixed—a quantity physicists denote using a subscript, as in $\left(\frac{\partial V}{\partial T}\right)_p$ to hold the pressure fixed. The quantity to be held fixed needs to be specified because it is not physically possible to "hold everything else fixed," and there is no unique pair of independent variables describing the system. Roundy, Kustusch, and Manogue (2014) introduced an instructional activity aimed at improving students' overall understanding of thermodynamic variables and what is meant by holding a variable fixed. In the activity, students are prompted to design an experiment that could be done to measure a given partial derivative. One goal of the "Name the Experiment" activity is for students to recognize an experiment as a representation of a particular partial derivative. Linking the experiment—a type of conceptual story—to the algebraic symbols goes beyond simply assigning a physics meaning to each symbol. The experimental story includes a relationship among these physical quantities over time. Figure 1c shows an example of how one could measure $\left(\frac{\partial V}{\partial T}\right)_p$ by heating a gas in a piston, while holding the pressure fixed using unchanging weights on the piston. Determining this derivative requires measuring the small changes $\Delta V$ and $\Delta T$ and then computing their ratio. This procedure reflects the ratio layer of Zandieh's (2000) framework for concept image for the derivative, as embodied in the experimental representation introduced by Roundy, Dray, Manogue, Wagner, and Weber (2015). This framework for *ordinary derivatives* is the starting point for our concept image for *partial derivatives*.

**Research on Representational Fluency with Partial Derivatives**

In this section, we present some of our research and describe how it has influenced our LP. This research focused on how students coordinate information from different types of representations. We gave a problem-solving task (see Figure 2a) involving the calculation of a partial derivative from a table of data and a contour graph, neither of which is sufficient on its own to solve the problem. Each of these representation types is commonly used by professional scientists; therefore this task is an appropriate probe of the students' representational fluency. This task was given as a think-aloud interview to students (N=8) who had completed an upper-division thermodynamics course (Bajracharya et al., 2017).

The interview task is a challenging problem with a solution requiring the coordination of many different aspects of the concept image. The analysis suggested that, in order to identify where students are having trouble, it is necessary to examine the individual steps in a solution method at a high level of detail. To facilitate our analysis, we developed a visual means of displaying these steps, which we call a transformation diagram. An example is shown in Figure 2b for one idealized solution to the interview prompt using the method of differential substitution. (Other solution methods, such as sketching a constant-pressure path on the contour map, are also valid and were attempted by students.) In the diagram, boxed items refer to individual representations, arrows refer to transformations between representations, and the transformation steps are numbered for convenience. The transformation diagram is a research tool; we do not (yet) use it as a pedagogical tool. Below, we briefly discuss the interview results pertaining to the solution shown in the diagram, and describe what these results tell us about our curriculum.

The top row of the diagram shows the three different representations of given information: a symbolic expression, a table, and a graph. Each representation gives information about a relationship between three different variables, and this information can be translated (step 1) into a purely

**Evaluate $\left(\frac{\partial U}{\partial T}\right)_P$ at $P$ = 10 atm., $T$ = 410K using the information below.**

*Figure 2: An interview task (a) focused on coordinating representations, and a diagram (b) showing the transformations between representations in one idealized solution.*

symbolic form, such as $U(T, V)$, that explicitly identifies the dependent and independent variables associated with that information. It is then possible to determine the total differential for each representation (step 2). This pair of steps proved surprisingly challenging for some students. We believe this is partly due to the fact that jumping directly from the given information to the total differentials is too big a jump for many students to make. Experts often go through the symbolic representation mentally, but students are rarely taught to use it as an intermediate step. We aim to design instructional sequences that can leverage this result to help students identify and use such stepping stones while solving complicated problems.

Once the total differentials have been found, they can be combined using substitution to eliminate $dV$, which does not appear in the desired partial derivative (step 3). This expression is compared to the differential form of the multivariable chain rule, $dU = \left(\frac{\partial U}{\partial T}\right)_p dT + \left(\frac{\partial U}{\partial p}\right)_T dp$, to identify the desired partial derivative as the coefficient of $dT$ (step 4). This pair of steps was particularly difficult for the interviewees—they were consistently unable to consolidate information from three separate representations into a single expression. This finding has suggested a new curricular goal for our LP, to help students learn when, how, and why it is necessary to consolidate information in this fashion.

Once a multivariable chain rule has been determined, each of the three new partial derivatives can be approximated (step 5) as a ratio of small changes and then read from the graph or the table (step 6). In practice, we found that few students struggled with either of these steps, once they had a symbolic expression for partial derivatives that were individually calculable from only a single representation of information. This result validates this piece of our learning progression and suggests that elements of our curriculum that focus on finding derivatives from data have been successful and should continue to feature prominently in future instruction.

## Conclusion

We have described an expansion of the theory for learning progressions in undergraduate courses, illustrated by the specific example of partial derivatives in mathematics and physics. Our learning progression focuses on students' development of a rich, expert-like concept image involving multiple layers and representations, informed by extensive research on both students and experts. This perspective has led us to develop curriculum that fosters students' ability to go back and forth between many fine-grained representations fluidly and spontaneously.

# Revisiting Reducing Abstraction in Abstract Algebra

| Kathleen Melhuish | Anna Marie Bergman | Jennifer Czocher |
|---|---|---|
| Texas State University | Portland State University | Texas State University |

*In this paper, we revisit Hazzan's (1999) fundamental work on reducing abstraction in abstract algebra tasks. As we analyzed hundreds of students' activity related to abstract algebra tasks, we identified many ways students reduced abstraction that did not align with the original framework. We leverage additional theories of abstraction to expand and refine Hazzan's framework to reflect new aspects of familiarity, contextualization, complexity and connectedness, and formality. For each of the new categorizations, we provide illustrations of students engaged in the relevant reduction of abstraction. We conclude with consideration to how the expanded framework may highlight productive types of abstraction reduction.*

*Keywords:* Abstraction, Abstract Algebra, Student Activity

It is well-documented that abstract algebra is a challenging course for students (Dubinsky, Dautermann, Leron, & Zazkis, 1994; Leron, Hazzan, & Zazkis, 1995; Weber & Larsen, 2008). For many students, this is the first time they engage with mathematical objects that are brought into existence via formal definitions. These stipulated concepts are general, complex, and often unfamiliar to students. Hazzan (1999) created the *reducing abstraction* framework to document how students engaged with the generality, complexity, and unfamiliarity of concepts in abstract algebra tasks. She leveraged a number of theories of abstraction to categorize various ways students reduced abstraction when engaging these tasks. This work is foundational and remains one of the more nuanced treatments of student activity in abstract algebra.

In our recent work exploring hundreds of students responses to abstract algebra tasks (Melhuish, 2015), we similarly observed students reducing abstraction. However, we identified a number of ways students reduced abstraction beyond the classifications in Hazzan's (1999) work. In this paper, we synthesize additional theories of abstraction to expand Hazzan's framework in order to better reflect the nuances and variety of approaches found in our students' activity. We share our expansions and provide illustrations of students engaged in reducing abstraction in both productive and unprodctive ways.

## Theories of Abstraction in Mathematics Education

In the field of mathematics education, we have many treatments of the abstraction construct stemming from Piaget's comprehensive work to von Glasersfeld's constructivism and Freudenthal's *Realistic Mathematics Education*. As Piaget noted (1980), "All new knowledge presupposes an abstraction..." (p. 89). However, what scholars mean by an abstract concept, and what we mean by abstraction varies according to a given theory of learning. Hazzan (1999) originally identified three treatments of abstraction: relationship between the object of thought and the thinking person, process-object duality, and complexity of concept of thought. We see these three categorizations as essential, but not exhaustive for exploring student task engagement in the setting of abstract algebra. We discuss several theories of abstraction that ultimately inform our expanded framework.

Before we begin the discussion, we acknowledge an important dimension along which theories of abstraction differ: activity-based versus cognitive. In our overview, we condense features of the theories with little attention to whether the theory was meant to describe cognition or activity. Rather, our purpose is to identify the means through which abstraction is posited to occur.

**Abstracting via Apprehending Properties**

A number of abstraction theories focus on students apprehending properties from a set of known objects. Piaget's (2013) theory of empirical abstraction provides the foundation of much of this work. For empirical abstraction, properties are observed through empirical investigation. If you view a set of white objects, you can abstract the idea of whiteness. Skemp (1986) further expanded this theory explaining, "Abstracting is an activity by which we become aware of similarities ... among our experiences. Classifying means collecting together our experiences on the basis of these similarities" (p. 21) Skemp presented a two-part process of recognizing similarity and then creating a class of object based on similarities. Scheiner (2016) built on this idea further by introducing structural abstraction. Rather than purely empirical (abstracting from empirical objects), abstraction can occur through exploration of mental objects. This exploration may be focused on similarity, but may also occur through focusing on complementary aspects. In each of these theories, a concept is abstracted through collecting a relevant set of properties.

**Abstracting via Building Connections and Complexity**

An alternative lens for abstraction focuses on building connections between or within concepts. Connections play a fundamental role in a number of abstraction theories such as within Dubinksy and McDonald's (2001) schemas or Hoyles, Noss, and Kent's (2004) webbing. Abstraction occurs through the correct coordination of various concepts. This may be internal such as in Dayvdov's (1990) theory where understanding a concept involves unity amongst its connected parts. Alternately, an assembly metaphor (e.g. Ohlsson and Lehtinen, 1997) may underlie a connection focused abstraction theory. Ohlsson and Lehtinen explained that new knowledge structures are developed via assembling "previously acquired ideas" (p. 42). In this sense, a concept is abstracted via coordination of various properties and/or concepts that compose the finalized object.

**Abstracting via Decontextualization**

Decontextualization theories tend to focus on moving from a familiar context to building something abstract that is independent of the context. This type of abstracting can be found in the school of Realistic Mathematics Education and Hershkowitz, Schwarz, and Dreyfus' (2001) *abstraction in context.* These theories distinguish horizontal mathematizing, "the process of describing a context problem in mathematical terms – to be able to solve it with mathematical means" (Gravemeijer & Doorman, 1999, p.117), from vertical mathematizing, where this activity is mathematized through abstracting, generalizing and formalizing (Rasmussen et al., 2005). This type of abstraction occurs when *model of* a specific context or problem (one which is mathematically real to a student) transition to a *model for* additional mathematics that does not rely on the underlying context. These task-based theories align themselves with two views of abstraction related to familiarity. First, a concept can be thought of as abstract if it has moved from a model of a familiar situation to a model for other contexts. Alternately, a concept within a context is more or less abstract depending on how mathematical real it is to an individual. This is roughly equivalent to a student's familiarity with it (cf. Wilensky, 1991).

## Abstracting via Delineation and Refinement

While many theories posit that concepts move from concrete to abstract, Dayvdov (1990) introduced an alternative view where the abstraction process concretizes an abstract kernel of an idea. His theory posits that an object begins as an undeveloped (potentially inconsistent) basic form. This form can be analyzed, and refined until a coherent model is developed. This theory of abstraction can be thought of as moving from a vague idea of concept to a concretely delineated defined concept. The delineation may be more fundamental in advanced mathematics where stipulated definitions form the basis of mathematical structures. Zandieh and Rasmussen (2010) provide insight into this sort of refinement through illustration of students' concept images and definitions of triangle developing. In some senses, this type of abstraction connects to pseudo-empirical abstraction (Piaget, 2013) where abstraction can occur via interacting with an object. In Dayvdov's sense, an object may be a mathematical model rather than a purely empirical "real-world" object. Tall and Pinto (2002) provide such an example where a student moves from a generic visual representation of limit to build to the formal definition. From this theoretical lens, a concept is abstracted when a stipulated definition is abstracted from imprecise models.

## Abstracting via Encapsulating Processes

The final treatment of abstraction is that of process-object duality. This type of abstraction has been explicated through a number of theories including Dubinsky and McDonald's (2001) Action-Process-Object-Schema theory, Sfard's (1991) object reification, and Gray and Tall's (1994) procept theory. Each of these theories operationalizes Piaget's work in the context of various mathematics settings. The underlying feature is the encapsulation of or reification of some particular process into an object. These theories break into three stages: a process that requires individual steps, a holistic view of the process, and a view of the process as an object itself to be used in other processes. For example, Asiala et al. (1997) illustrated this duality in abstract algebra where students may rely on the canonical procedure for creating a coset rather than or in conjunction with treating a coset as an object itself. In this sense, a concept is abstracted when it is no longer treated exclusively as a process, but rather can be used as an object for other processes.
